All species were collected from a limestone substratum, either in repose or crawling upon it. *C. muricatus*, however, also occurred on a small maritime shrub, *Rhachicallis americana*. Individuals from this substratum were also collected and treated separately during the laboratory phase of this study. Collected individuals of all species were preserved in 70% ethyl alcohol within seconds of collection to minimize the loss of fecal pellets by natural defecation.

Fecal pellets were removed from 740 individuals (i.e., 80–130 individuals per species) (Table 1). Prior to dissection, shell measurements (shell height, shell width, aperture height, and aperture width) of each individual were determined by means of digital calipers. Each shell was then broken, the soft body was removed, and the rectum and its contained fecal pellets were excised from each body. Fecal pellets removed from the rectum were placed on a pre-weighed drying boat, their wet weight was determined, and the number extracted from each individual was counted.

The height and width of 250 fecal pellets (i.e., five from each of the first 50 individuals dissected) were determined for each species by means of a microscopic monocular micrometer. Because there was no reliable, accurate way to measure depth, pellet size was expressed as area, not volume. Means and standard deviations of fecal pellet area were calculated for all species, and a Kruskal-Wallis single factor analysis of variance (ANOVA) by ranks was performed to determine species-specific differences, if any. Linear regressions were performed to assess the within-species relationship between fecal pellet number and body size, as indicated by shell height. If these analyses indicated a significant relationship, the slopes of the regression lines could be compared by an analysis of covariance (Zar 1984) to determine if there were significant differences between species.

Fecal pellets were placed in a 55°C drying oven until a constant dry weight was attained. The means and standard deviations for fecal pellet dry weight were calculated on a per-pellet basis for all species, and these values were compared between species by means of a Kruskal-Wallis single factor ANOVA by ranks. The pellets from each individual were then assessed for meeting a critical dry weight (i.e., a minimum quantity of fecal material

TABLE 1.

Summary statistics for number of individuals dissected, total number of fecal pellet samples, number of samples containing only one individual, number of samples containing more than one individual (i.e., a pooled sample), and the mean, standard deviation, and range for the number of individuals contained in the pooled samples.

	Number of individuals dissected	Total number of samples	Number of samples with only one individual	Number of pooled samples	Number of individuals in a pooled sample		
					Mean	Standard deviation	Range
P. nucleus	113	37	0	37	3.05	0.88	2–5
N. riisei	80	3	0	3	26.7	12.2	16–40
N. ziczac	122	38	1	37	3.27	2.77	2–13
N. angustior	80	6	0	6	13.3	2.16	11–17
N. dilatata	81	20	0	20	4.15	1.18	2–6
T. antonii	130	56	4	52	2.42	0.67	2–5
C. muricatus on plants	54	45	42	3	2.67	0.58	2–3
C. muricatus on rocks	62	35	12	23	2.17	0.49	2–4

necessary to assure a sufficient, measurable sample size after acid treatment). The critical dry weight was determined to be about 4.5 mg. If the fecal pellets from an individual weighed less, they were combined with others from individuals of the same species (i.e., pooled) until the critical weight was reached or exceeded. It was necessary to pool fecal pellets for all species (Table 1), but many individuals of *C. muricatus* and *T. antonii* had sufficiently large and/or numerous fecal pellets that attained or exceeded critical weight.

Each dried fecal sample attaining critical weight (i.e., either the rectal contents of one individual or a pooled sample of pellets from several individuals within a species) was washed with de-ionized water onto a 25-mm nitrocellulose filter attached to a Millipore microfiltration apparatus. The water was drained from the apparatus with a vacuum pump, leaving the fecal pellets on the filter. Then, 1 M nitric acid was added to the apparatus and allowed to react with the calcium carbonate in the fecal sample until all effervescence ceased, indicating conversion of calcium carbonate to carbon dioxide according to the following reaction:

$$CaCO_{3\,(S)} + 2\,HNO_{3\,(Aq)} \rightarrow Ca(NO_3)_{2\,(Aq)} + CO_{2\,(G)} + H_2O_{\,(Aq)}$$

After effervescence ceased, another dose of nitric acid was added to ensure that the reaction was complete. The filter paper containing the fecal sample was thoroughly washed with de-ionized water, removed to a pre-weighed drying boat, and dried in an oven to a constant weight. The difference between the dry weights prior to and after the acid treatment is considered to be the amount of calcium carbonate removed by the acid treatment plus an assumed negligible amount of other acid-volatile or acid-soluble organic materials. This difference will be referred to subsequently as the fecal carbonate fraction or, simply, ingested carbonate.

The fecal carbonate fraction was compared between each species and between the two subsets of *C. muricatus* (i.e., those collected from limestone and those collected from plants). Means and standard deviations, expressed as proportions, were calculated for all species and were compared by a Kruskal-Wallis single factor ANOVA by ranks. Two species, *N. riisei* and *N. angustior*, required extensive pooling to produce a sample that reached the critical mass needed for analysis (Table 1). Thus, they were represented by a small number of pooled samples ($n = 3$ and $n = 6$, respectively). Accordingly, all species except these two were again compared by a Kruskal-Wallis single-factor ANOVA by ranks to assess the impact caused by extensive pooling and to eliminate any bias caused by it.

C. muricatus and *T. antonii* included both unpooled and pooled samples. Such data were compared within each species (and within each species according to habitat for *C. muricatus*) by means of a *t* test to assess the impact of pooling. The parametric *t* test was selected for comparison of within-species proportions because both normality and equality of variance tests were within required limits. All statistical tests were performed using the Sigma Stat statistical package.

On the basis of fecal carbonate estimates determined in this study, we also estimated the annual bioerosive impact of these species on the shore (1) per individual on the basis of an estimated 48-h defecation cycle (the duration from ingestion to defecation); (2) per individual per year, also on the basis of an estimated 48-h defecation cycle; and (3) total carbonate removed from this shore per species per year on the basis of density estimates by Metz (1997). Because the densities of each species varied with respect to both species and location on the shore, bioerosive impacts were calculated on the basis of mean densities within the occupied range of each species, not for the entire platform. The 48-h duration of the littorinid defecation cycle was never tested empirically. Laboratory behavior of these animals suggested, however, that the defecation cycle, although influenced by numerous extrinsic factors including duration of repose, is probably no longer than a mean 48 h and is likely much shorter. Thus, the carbonate removal calculated for each species using the 48-h estimate is probably a conservative assessment of the bioerosive impact of the littorinids. No attempt was made to estimate carbonate removal by *P. nucleus* and *C. muricatus* from plants because there were no estimates available concerning their density on shore.

RESULTS

Fecal pellets were removed from between 80 and 130 individuals of each species (Table 1). Between 20 and 56 samples, consisting of fecal pellets from one to several individuals, were processed for all species except *N. riisei* and *N. angustior*. Because the latter produced such small pellets, it was necessary to combine those from several individuals to obtain a sample sufficient for analysis. Thus, 80 *N. riisei* yielded only three pooled samples for analysis, and 80 *N. angustior* yielded only six.

Mean fecal pellet size, expressed as area (Table 2), and mean fecal pellet weight (Table 3) were calculated for each species. *N. angustior* produced the smallest fecal pellet in terms of both mean size and mean weight per pellet. *C. muricatus* produced the largest pellets with respect to mean size, but *T. antonii* had the largest pellets with respect to mean weight. The pellets produced by both of these species were significantly larger than those produced by the other species with respect to size (Table 2) and weight (Table 3). *C. muricatus* pellets also differed significantly in size from those of *T. antonii*, but not significantly, with respect to weight. Intraspecific variation in pellet size was relatively great for all species, as reflected by high standard deviations (Table 2). Dunn's pairwise comparisons following a Kruskal-Wallis single-factor ANOVA by ranks also indicated fecal pellet size to be significantly different between most species (Table 2). Variation in pellet weight within each species was slight to moderate, as indicated by standard deviation values (Table 3), and there were no significant

differences in pellet weight between *N. angustior*, *N. dilatata*, *N. riisei*, *N. ziczac*, and *P. nucleus*.

Among the species of Littorinidae, the mean number of fecal pellets per individual generally increased as mean shell size increased (Table 4; Fig. 1). The smallest littorinid (*N. riisei*) produced the fewest number of pellets, and the largest species (*C. muricatus*) produced the most pellets among the littorinids. *P. nucleus* produced significantly more fecal pellets than any of the littorinids, but each pellet was significantly smaller than that produced by any littorinid of comparable size. Linear regressions were performed to compare the number of pellets as a function of size (shell height) for each species (Table 5). Despite the general trend of increasing numbers of pellets with increasing body size for all species except *N. dilatata*, the predictive value for all regressions was poor, as reflected by very low adjusted r^2 values, ranging from a low −0.002 for *C. muricatus* to a high of 0.37 for *N. ziczac*. Accordingly, the slopes of the regression lines were not compared between species.

Samples of *T. antonii*, *C. muricatus* collected from plants, and *C. muricatus* collected from rock included both single-individual and pooled (several individuals) pellet samples. We performed *t* tests performed between the individual and pooled subsets of each group, which detected no statistically significant differences between any of them.

The proportion of carbonate (strictly speaking, acid-volatile or acid-soluble material, represented mostly by calcium carbonate) in the fecal pellets varied greatly (Table 6). *C. muricatus* fecal pellets collected from plants contained the smallest carbonate fraction (18.6%), whereas *T. antonii* and *P. nucleus* contained the largest (93.1 and 92.8%, respectively). There were also three other distinct groupings: (1) *N. riisei* and *N. dilatata* (88.7 and 88.3%, respectively), (2) *N. ziczac* and *C. muricatus* from rocks (74.9 and 74.8%, respectively), and (3) *N. angustior* (67.0%). Dunn's pairwise comparisons following a Kruskal-Wallis single-factor ANOVA by ranks also indicated that the fecal carbonate content was not significantly different between those species with the highest amount (*T. antonii*, *P. nucleus*, *N. riisei*, and *N. dilatata*) and not significantly different between those with low to middle amounts (*N. ziczac*, *C. muricatus* from rocks, *N. riisei*, *N. dilatata*, and *N. angustior*) (Table 6). The carbonate content of fecal pellets from *C. muricatus* found on plants (18.6%) differed significantly from that of conspecific individuals taken from rock as well as from that of all other species except *N. angustior* (67.0%).

When *N. riisei* and *N. angustior* were removed from the data set and the Kruskal-Wallis single factor ANOVA by ranks was performed again without them (Table 6), two new significant differences appeared between *N. dilatata* and *C. muricatus* from rocks and between *N. dilatata* and *N. ziczac*.

Two large, upper-shore species, *C. muricatus* (from rock) and *T. antonii*, processed the greatest mean amounts of carbonate per defecation cycle (3.07 and 2.44 mg, respectively) and per year (0.546 and 0.435 g, respectively) (Table 7; Fig. 2). The two smallest species, *N. riisei* and *N. angustior*, processed the smallest mean amount of carbonate per defecation cycle (0.21 and 0.23 mg, respectively) and per year (0.037 and 0.040 g, respectively). Expressed on an individual basis, *N. dilatata* also seems to have only a modest impact, processing only 1.12 mg per defecation cycle or 0.199 g per year.

These relationships are much different when population densities are considered. Population densities of the Littorinidae on this shore ranged from 80 individuals/m^2 for *N. ziczac* to 736 individuals/m^2 for *N. dilatata* (Table 7). *C. muricatus*, *T. antonii*, *N. riisei*, and *N. angustior* had densities of 128, 208, 272, and 480 individuals per m^2, respectively, within occupied ranges. On the basis of these densities, *N. dilatata* removes the largest amount of carbonate from the platform annually, 146.5 g/m^2 (Table 7; Fig. 3). *T. antonii* and *C. muricatus* from rocks had the second and third highest values, removing 90.5 g/m^2/y and 69.9 g/m^2/y, respectively. All other species had much lower values for annual carbonate removed: *N. angustior* with 19.2 g/m^2/y, *N. ziczac* with 16.9 g/m^2/y, *C. muricatus* on plants with 15.6 g/m^2/y, and *N. riisei* with 10.1 g/m^2/y.

DISCUSSION

Although the Littorinidae and Planaxidae are primarily herbivores, the focus of their feeding varies widely, often according to habitat. Species that occupy the algal gardens of the lower eulittoral may ingest the algae upon which they live. For example, *Littorina littorea* is attracted to and feeds upon *Ulva lactuca*, and *L. obtusata* is attracted to this species plus *Fucus serratus* and *Ascophyllum* spp. (Watson & Norton 1985, Watson & Norton 1987). Other littorinids browse on the surfaces of seaweeds or seagrasses, consuming epiphytic algae, fungi, or microorganisms such as diatoms, protozoa, cyanobacteria, and bacteria (Norton et al. 1990). Several littorinids, especially members of the genus *Littoraria*, browse on the surfaces of mangroves (Reid 1986, Christensen 1998). Others, such as *Bembicium auratum*, feed on

the microflora in the mud beneath the mangroves (Branch & Branch 1981a). Perhaps the majority of littorinids that occupy rocky shores browse directly on rock surfaces and ingest detritus, small live animals, egg capsules, sand grains and fragments of rock, lichens, and epilithic and endolithic algae (Norton et al. 1990). Species occupying the eulittoral on rocky shores probably focus on epilithic and/or epiphytic algae with those inhabiting similar habitats sometimes seeking different foods. For example, the stomach contents of *L. planaxis*, a eulittoral snail of granitic shores in California, include microphytes such as green algae, blue-green algae, and abundant quantities of diatoms, the latter probably the primary food source (Foster 1964). On the same shore, *L. scutulata* often occurs on and grazes macrophytic algae such as *Cladophora*, *Pelvetia*, and *Rhodoglossum* (Dahl 1964).

Higher upon the shore where drier conditions are more common, epilithic and epiphytic algae usually disappear, often to be replaced by a surface film of encrusting black lichens, which are grazed upon by several species of littorinids including *N. unifasciata* in Australia (Branch & Branch 1981b). On the highest zones of tropical limestone shores, however, endolithic algae, especially cyanobacteria, are present (Peckol & Guarnagia 1989) and provide high-zoned littorinids a food source in an otherwise nearly barren habitat (North 1954, Hodgkin et al. 1959, Underwood 1984a, Underwood 1984b, Underwood 1984c). A few rocky-shore littorinids, such as *C. muricatus*, range to the fringe of maritime vegetation and derive additional nutrition by grazing upon their stems and leaves.

Planaxidae occupy bedrock or cobble shores and, like the Littorinidae, employ a radula to scrape the hard surfaces upon which they live. *P. nucleus* lives in a high-energy, mid-intertidal habitat among boulders or large rocks usually surrounded by loose, mobile stones. Planaxids generally have a large, powerful foot that grips the substrate tenaciously, preventing dislodgement by the waves or rolling stones (Houbrick 1987).

Most previous studies of intertidal gastropod fecal content have emphasized the nutritious organic fraction, not the inorganic component. Accordingly, most of these studies employed either ashing or isotope analysis to estimate the organic fraction (Black et al. 1988, Norton et al. 1990, Newell & Bärlocher 1993, Christensen 1998). For example, Black et al. (1988) examined the fecal content of six species of western Australian intertidal herbivorous gastropods and one chiton by an ashing technique. That portion of the feces not removed by ashing represented the non-organic feces fraction, composed primarily of calcium carbonate, the rock type upon which these molluscs lived. Expressed as percentages, the feces of the pulmonate limpet *Siphonaria kurracheenis* contained 69% carbonate, the feces of the acmaeid limpet *Callisella onychitis* contained 77% carbonate, the feces of *L. unifasciata* contained 73% carbonate, the feces of *N. australis* contained 80% carbonate, the feces of the nerite *Nerita atramentosa* contained 83% carbonate, the feces of the acmaeid limpet *Patelloida alticostata* contained 84% carbonate, and the feces of the chiton *Clavarizona hirtosa* contained 89% carbonate. Some of these species also possessed distinctly different radulae. For example, the cusp size of the *S. kurracheenis* radula was much smaller and that for *N. atramentosa* and much larger than other species with a similar body size. Black et al. (1988) concluded that such differences might influence competitive interactions of species occupying the same shore level, although they recognized that either specific behaviors or the nature of the rock surface might further mediate such interactions.

The vertical ranges of several of the Littorinidae of the Jamaican limestone platform overlap to a greater degree than some of the Australian species studied by Black et al. (1988), a situation that should only enhance the possibility of competitive interactions. There is little evidence, however, of such interactions among the Jamaican littorinids (Britton 1992, Lang et al. 1998, and this study). Furthermore, the nature of the radulae of the Jamaican species, although displaying some species-specific differences, are much more similar (Bandel & Kadolsky 1982) than those of the species studied by Black et al. (1988). The proportions of carbonate contained in the feces of both Australian and Jamaican intertidal molluscs, however, were very similar, an indication that both groups rely to a considerable degree on food attached to or within the substratum. It also possibly implies that such a food source is not especially limiting for the molluscs feeding upon it.

P. nucleus was found to have a very high fecal carbonate fraction (92.8%), consistent with expectations for individuals living in a high-energy, limestone boulder environment devoid of epilithic macrophytes or epiphytes. The mobile stones that dominate this beach are poorly suited for either algal attachment or growth. Likely food sources for *P. nucleus* include either diatoms washed up on the rocks by waves or endolithic algae, the latter necessitating ingestion of considerable rock carbonate while grazing for

this food source. Our data support the latter as a primary food source for *P. nucleus*. The only other planaxid for which diet has been studied is the Indo-Pacific *P. sulcatus*, which grazes upon epilithic algae but lives in a different habitat (i.e., bedrock shores where such algae are frequently abundant) (Rohde 1981).

The low-carbonate fraction in the fecal pellets of *C. muricatus* collected from plants (18.6%; Table 6) is likely the result of their most immediate diet prior to collection. If these individuals were grazing upon the plants or, more likely, on the epiphytic flora upon them, then the fecal carbonate fraction should be lower than that of conspecifics feeding exclusively upon the rocky substratum. The longer the duration of grazing upon plants, the greater the expected reduction of carbonate in the fecal pellets. In fact, *C. muricatus* from plants had the second highest standard deviation of all species tested (Table 6), indicating considerable variation among individuals, as should be expected. It has also been observed that *C. muricatus* moves readily to and from *R. americana* branches and the rocky platform (JCB, unpublished data). Thus, the carbonate present in the fecal pellets of specimens collected from plants is interpreted as carbonate ingested when the individual grazed upon limestone. Conversely, some *C. muricatus* individuals collected from rock could have a disproportionately low fecal carbonate content due to having recently grazed on the plants.

N. ziczac and *N. riisei* occupy approximately the same low shore habitat, characterized by frequent wave splash, occasional tidal inundation, and some epilithic and much endolithic algae on which to graze. The former is largest foreshore littorinid and produced the largest fecal pellets of those studied from this habitat (Tables 2 and 3). The latter, on the other hand, is the smallest species studied, but its fecal pellets were slightly larger and heavier than those of *N. angustior*, facilitated perhaps by a larger storage space within more globose shell. The feces of both species contained considerable carbonate, *N. ziczac* with a mean of 74.9% and *N. riisei* with a mean of 88.7%. The differences, although slight, might indicate a tendency toward resource partitioning, with *N. ziczac* perhaps taking more epilithic algae than *N. riisei*. On the other hand, these differences are not significant, perhaps due to the small number of pooled samples of *N. riisei*. The three pooled samples of *N. riisei* (Table 1) exhibited approximately the same variation as that for 38 samples for *N. ziczac* (SD of mean proportions = 0.058 and 0.049, respectively; Table 6).

The greatest variation among samples occurred with *N. angustior*, which also produced the smallest fecal pellets in terms of size (Table 2) and weight (Table 3), likely the result of a slender shell providing a small internal volume. This species was represented by only six pooled samples. Its feces contained a mean carbonate

TABLE 7.

Means and standard deviations of quantities of carbonate processed per individual based on an estimated 48-h defecation cycle and derived estimates of mean quantities of carbonate processed annually per individual and the total amount removed annually per species per m^2 on the Jamaican shore based on density estimates cited in Metz (1997).

fraction of 67.0%, with a standard deviation, expressed as a proportion, of 0.142 (Table 6). The range of *N. angustior* on the platform overlaps the frequently wetted upper distribution of both *N. ziczac* and *N. riisei* but also extends several meters landward into the lower range of *N. dilatata* where the rocks can remain unwetted by seawater for many days (Lang et al. 1998). One should expect the diet of *N. angustior*, of necessity, to include a considerable quantity of either endolithic algae or lichens, the former, at least, accompanied by a considerable quantity of carbonate. These samples, however, show that *N. angustior* fecal pellets possess the smallest proportion of carbonate of all species tested except for *C. muricatus* from plants. Because *N. angustior* is not known to graze upon maritime vegetation along this platform (JCB, personal observation), such behavior is not a potential cause for the lower carbonate content of the feces. If *N. angustior* focused upon the epilithic lichens, which are abundant within its range, fecal carbonate might be somewhat diminished. Such a diet might also suggest possible specialization in the radular structure, but Bandel and Kadolsky (1982) found the radulae of *N. ziczac*, *N. angustior*, *N. dilatata*, and *N. riisei* to be very similar. It seems unlikely, therefore, that *N. angustior* has such a specialized diet, but whether it does or does not is simply conjecture and requires further testing.

When all species were compared, the Kruskal-Wallis single factor ANOVA by ranks showed no significant differences among the four species with the highest fecal carbonate fraction (93.1–88.3%; *T. antonii*, *P. nucleus*, *N. riisei*, and *N. dilatata*; Table 6). There were no significant differences found among *N. riisei*, *N. dilatata*, *N. ziczac*, *N. angustior*, and *C. muricatus* on rocks (88.7–74.8%), but there were significant differences between *C. muricatus* on plants (18.6%) and all other species except *N. angustior* (67.0%). There were also significant differences within *C. muricatus* on plants (18.6%), those on rocks (74.8%), and *P. nucleus* (92.8%); and between *C. muricatus* from plants, those from rocks, and *T. antonii* (93.1%).

When *N. riisei* and *N. angustior* data were removed and the ANOVA was performed again without them, all of the significant differences previously detected remained unchanged, and two new significant differences appeared: one between *N. dilatata* and *C. muricatus* from rocks and the other between *N. dilatata* and *N. ziczac* (Table 6). Apparently, the large variation within the *N. angustior* samples obscured these differences when all eight groups were compared. In contrast, the large variation within the *C. muricatus* samples from plants did not alter the ANOVA results, probably because the mean proportion of carbonate was so much lower than the others that the high variation did not obscure any other significant differences.

Our original hypothesis, that fecal carbonate should vary with position on shore and increase toward the landward portion of the platform, was poorly supported by the data. Another pattern emerged, albeit unexpected and subtle, which might also be indicative of resource partitioning (Fig. 4). Depending upon shore position three pairs of littorinid associates are present, one of each pair having a relatively high fecal carbonate content and the other having somewhat to significantly less. On the high shore, *T. antonii* had the greatest amount of fecal carbonate, whereas rock-dwelling *C. muricatus* had the sixth highest amount and significantly less than that of *T. antonii* (Table 6). It is apparent from this study that *C. muricatus*, unlike *T. antonii*, feeds both upon endolithic algae and the epiphytic biota clinging to certain maritime plants, hence mediating the carbonate fraction of its feces. On the midshore, *N. dilatata* had the fourth greatest fecal carbonate fraction, and *N. angustior* had the seventh, a nonsignificant but distinctive difference. On the low shore, *N. riisei* had the third greatest fecal carbonate fraction, and *N. ziczac* had the fifth greatest, again a nonsignificant but distinctive difference. Perhaps the species pairs at the lower shore levels focus on somewhat different food sources, as does the high-shore pair. Alternately, and perhaps more parsimonious with these data, either food may be nonlimiting throughout the platform habitat, such that neither competition nor

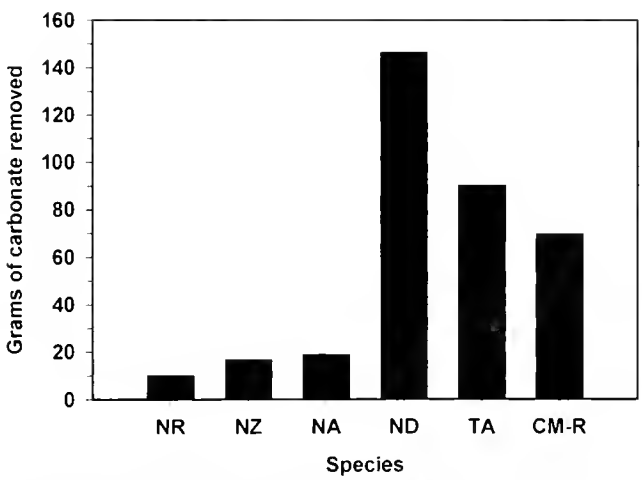

Figure 3. Estimated annual carbonate removed per m^2 from the Jamaican limestone platform shore by littorinid species, based on density estimates from Metz (1997). resource partitioning is an issue or each species is broadly opportunistic with respect to food selection, grazing on epilithic primary production when available and on endolithic primary production when epiphytes are reduced in abundance.

The platform littorinids have a significant bioerosive impact on this tropical limestone shore. The combined grazing of *C. muricatus* and *T. antonii* strips considerable carbonate (160.4 g/m^2/y) from the upper shore. This translates to the removal of about 1,472 kg annually along the approximately 500-m-long platform and across an upper shore band about 24 m wide. Although *N. dilatata* is a moderate-sized species with each individual having only a modest bioerosive impact, it also has the highest population density (a mean of 736 individuals/m^2). Thus, it significantly impacts the central platform, removing limestone at the rate of 146.5 g/m^2/y (Table 7; Fig. 3), and, because its range covers a band about 17 m wide, it removes a little more than 1,245 kg annually from this shore. The lower shore, although having more littorinid species, experiences the least amount of littorinid bioerosion, both per species and in total (Table 7). Several factors contribute to this diminished impact. The lower shore is horizontally limited, being 7 m wide at best and hardly more than 5 m wide if the range of *N. angustior* is excluded. Population densities of *N. ziczac* are very low, minimizing its impact. Although both *N. angustior* and *N. riisei* can be very abundant locally, dense populations are patchy and often separated by areas of sparse density. Their small size also reduces the bioerosive impact of each individual. Finally, the presence of epilithic algae on some parts of the lower shore may provide an almost carbonate-free alternate food source. Thus, the total annual carbonate removal rate, combining the grazing impact of *N. riisei*, *N. ziczac*, and *N. angustior*, is 46.2 g/m^2/y, or almost 140 kg annually. It should be noted, however, that other, much larger, grazing gastropods, especially *Nerita tesselata*, *N. peloronta*, and *N. versicolor*, and one common chiton, *Acanthopleura granulata*, occupy the lower shore (Minton & Gochfeld 2001) and have the potential to remove considerably greater quantities of carbonate than the low shore littorinids. For the entire platform, all littorinid species account for the removal of a little more than 2,850 kg of limestone annually.

In conclusion, all species studied ingested considerable quantities of carbonate, probably indicating that all rely to some degree upon endolithic algae for food. *C. muricatus* was the only species clearly identified as also having an alternate food source, probably epiphytes on the branches, stems, and leaves of the maritime shrub *R. americana*. Although the rock-dwelling Littorinidae ingested different quantities of carbonate, ranging from 67–93%, there was no clear relationship between the amount of carbonate ingested and the position each species occupied on shore. However, species pairs that cohabitate on particular shore levels possessed noticeably different mean fecal carbonate fractions, leaving open the possibility that some form of resource partitioning might be involved. There was no indication, however, what it might be. The quantity of carbonate in *P. nucleus* fecal pellets was similar to that found in the several littorinid species studied, but the size and morphology of *P. nucleus* fecal pellets (spindle shaped) were significantly different from those found among the Jamaican Littorinidae (ovoid shaped). The Littorinidae occupying the rocky intertidal platform remove significant quantities of carbonate from the shore each year and should be considered important bioerosive species.

ACKNOWLEDGMENTS

We sincerely appreciate the help provided in Jamaica by the Resident Directors of the Hofstra University Marine Laboratory, Deborah Gochfeld and Dwayne Minton (1998), and Patricia Hankenson and Mike Lewis (1999). Jens Tang Christensen kindly contributed additional *N. angustior* and *N. riisei* specimens from the limestone platform. Robert McMahon and David Hicks provided numerous useful comments and suggestions, many of which we have incorporated in the final draft. We are especially indebted to Eugene Kaplan and the late Edgar Ross, who, together, had the vision and foresight to transform a small, minor, resort property into a teaching and research laboratory readily accessible to a broad spectrum of the academic community. The Texas Christian University Department of Biology provided some financial assistance for this project. Portions of this study first appeared as a TCU Department of Biology Master's Thesis by the senior author, which also includes additional data not presented here.

ELLOBIIDAE—LOST BETWEEN LAND AND SEA

ANTÓNIO M. DE FRIAS MARTINS
Department of Biology, University of the Açores, Apartado 1422 9501-801, Ponta Delgada São Miguel, Açores, Portugal

ABSTRACT The Ellobiidae are a diverse group of archaeopulmonate snails living mostly near the sea. Their shell length ranges from barely 2 mm to over 100 mm. Six structural types of reproductive system set the boundaries for the subfamilial division: Pythiinae, Ellobiinae, Carychiinae, Cassidulinae, Pedipedinae, and Melampodinae. This division is in general supported by four structural types of nervous system and by the internal morphology of the penial complex. The halophile ellobiids are commonly associated with the supratidal fringe of mangroves and salt marshes; they are also important components of the supratidal biota of the mobile rocky shore. The various species occupy different portions of the shore. In rocky habitats, in addition to horizontal zonation, the ellobiids also partition their vertical distribution. The purpose of this study is to describe the zonation patterns of the halophile ellobiids of the cobble shores of the Açores and, in less detail, of the associated malacofauna.

KEY WORDS: Ellobiidae, systematics, morphology, anatomy, ecology, cobble shores, Açores

INTRODUCTION

The Ellobiidae have long been recognized as a cohesive taxonomic unit (Lamarck 1809) and were illustrated in the most important iconographic works of the nineteenth century (Reeve 1841, Reeve 1877, Küster 1844, Kobelt 1897–1901). Classification was based exclusively or primarily on shell morphology. Pfeiffer (1856, 1876), elaborating on shell descriptions of all species known at the time and adding many of his own, provided an important monographic treatment for the group. Zilch's (1959) subfamilial arrangement was also based on shell characteristics. Radular (Odhner 1925) and anatomical features have since been included in taxonomic research and have contributed greatly to the clarification of the relationships of the various taxa (Morton 1955, Martins 1996a, Martins 1996b, Martins 1998).

Ellobiids are important members of the supratidal communities of marshes and mangroves, and their contribution to the ecological balance of those environments has been somewhat recognized in studies dealing with their general biota (Berry 1963, Brown 1971, Sasekumar 1974, Murty & Balaparameswara Rao 1977, Li & Gao 1985). More specific studies have been done on *Melampus bidentatus* and *M. coffeus* (Hausman 1932, Holle & Dineen 1957, Morrison 1958, Morrison 1959, Golley 1960, Grandy 1972, Russell-Hunter et al. 1972, Orton 1976).

The various species of halophile ellobiids occupy different portions of the shore, their distribution being loosely related to their

taxonomic affiliation. The Pythiinae (*Pythia* and, to a lesser extent, *Myosotella*) venture farther inland and may live in an almost terrestrial environment, whereas the Pedipedinae prefer the upper intertidal. Within the Melampodinae, some species of *Melampus* are found usually in mangroves and marshes, whereas others and *Tralia* prefer cobble shores.

The ellobiids abound also on cobble shores, and attempts have been made to quantify their horizontal and vertical distributions on such environments (Martins 1980, Martins & Cunha 1992). Morton et al. (1998) summarized the ecology of ellobiids on the cobble shores of the Açores.

This paper will briefly introduce the Ellobiidae as a morphologically and anatomically highly diverse family and, reinterpreting data from Martins (1980), present a model for their distribution along the cobble shores of the Açores.

MATERIALS AND METHODS

Morphology and Anatomy

The ellobiids range in shell size from barely 2 mm (*Leuconopsis*) to 100 mm (*Ellobium*); most species, however, do not exceed 25 mm. The smallest taxa inhabit moderately exposed rocky shores, whereas the largest species prefer the still backwaters of mangrove swamps.

Currently, six subfamilies of the Ellobiidae are recognized: Pythiinae, Ellobiinae, Carychiinae, Cassidulinae, Pedipedinae, and Melampodinae. Although shell morphology and internal anatomy have been considered in delimiting the subfamilies, these are based primarily on characteristics of the reproductive and nervous systems (Morton 1955, Martins 1996a, Martins 1996b, Martins 1998).

The dentate appearance of the shell aperture establishes a generalized ellobiid profile. However, the elaboration of the apertural teeth is far from uniform and, although relatively constant at the genus level, shows variability within and similarities across the subfamilies, which is not consistent with the corresponding internal anatomy. For example, a tridentate inner lip with the middle tooth strongest is seen in *Myosotella* (Pythiinae), *Ellobium* (Ellobiinae), and *Tralia* (Melampodinae); a narrow, elongated aperture, typical of *Melampus*, is also found in *Microtralia* (Cassidulinae) and *Pseudomelampus* (Pedipedinae); a double columellar tooth, typical of *Pedipes*, is also found in some *Auriculastra* (Ellobiinae) as well as in *Creedonia* (Cassidulinae).

The anatomy of the reproductive and nervous systems shows a series of patterns that lead to more consistent assemblages (Fig. 1) (see also Martins 1996a, Martins 1998). The subfamilies can then be characterized as follows: (1) Pythiinae: monaulic, entirely glandular pallial gonoducts and long visceral nerve ring (pleural, parietal and visceral ganglia and respective connectives) with both parieto-visceral connectives of about the same length; (2) Ellobiinae: diaulic, entirely glandular pallial gonoducts and long visceral nerve ring with the right parieto-visceral connective much shorter than its left counterpart; (3) Carychiinae: monaulic, entirely glandular pallial gonoducts, the prostate gland anterior to the mucous gland, whereas in all other subfamilies both glands are located side-by-side; nervous system as in the Ellobiinae; (4) Cassidulinae: monaulic, entirely glandular pallial gonoducts, the distal portion of the bursa duct transformed into a nonglandular, well-developed vaginal atrium where the oviduct empties; nervous system with visceral and esophageal (cerebral and pedal ganglia, cerebro-pedal

High tide level at 0; remaining numbers are meters away from 0, with negative numbers being seaward. See text for transect identification and Table 1 for species abbreviations (data from Martins 1980).

connectives and pedal commissure) rings moderately wide, approximately of equal size; (5) Pedipedinae: monaulic to incipient semidiaulic, pallial gonoducts with glandular coverage only on the proximal (posterior) half; visceral nerve ring extremely concentrated, right connectives of the esophageal nerve ring shorter than their left counterparts; and (6) Melampodinae: advanced semidiaulic pallial gonoducts, the residual glandular portion concentrated proximally (posteriorly); visceral nerve ring extremely concentrated, connectives of the esophageal nerve ring of approximately equal length.

Additional diagnostic features have been sought in the internal morphology of the penis, which have in many cases corroborated the assemblages just presented (Martins 1996a, Martins 1998).

Ellobiids on Cobble Shores

The ellobiids are common inhabitants of the supratidal of certain rocky habitats. Cobble beaches are a common feature of the Açorean rocky shore (Morton et al. 1998) and are the habitat of five species of halophile ellobiids (Fig. 2). The distribution of these species along the cobble shores has previously been recorded (Martins 1980). Following is an elaboration on those data to present a model for their distribution. The distribution of the associated malacofauna will also be presented (Table 1).

Five of the original 11 transects of 1-m^2 quadrats (Martins 1980) were selected on the basis of their relatively similar length to provide a more or less homogeneous set of data (Table 2). The locations of the transects and the sampling dates are as follows:

Transect A: West of Ponta do Alcaide, Silveira, Terceira, Açores. February, 1976.

Transect B: Calhau da Pata, Caminho de Baixo, São Mateus, Terceira, Açores. March, 1976.

Transect C: Pópulo, São Miguel, Açores. January, 1976.

Transect D: Ponta de São Pedro, Vila Franca do Campo, São Miguel, Açores. February, 1976.

Transect E: Atalhada, Lagoa, São Miguel, Açores. March, 1976.

Cobble shores are, in principle, exposed to at least moderate wave action. All but transect C have moderate to high exposure to wave action, with transect C being more protected.

Kite diagrams were constructed to illustrate the distributions of the species. For ellobiids, data (as percentages) from the five transects were combined, and the percentages present at each height above or below high tide level were used to construct the kite diagrams. For other species, presence/absence was simply totaled for all five quadrats at a particular height, for a maximum of five.

RESULTS

The distribution of the ellobiids and associated malacofauna along the cobble shores of the Açores is summarized in Figure 3.

DISCUSSION

The five species of ellobiids exhibit a definite pattern of distribution along the cobble shore. *Myosotella myosotis* lives highest up, almost assuming a terrestrial habitat, indicated by the presence of terrestrial pulmonates at these levels. It is followed by *Ovatella vulcani* and *Pseudomelampus exiguus*, which closely overlap. Additional information (Martins 1980) showed that, although overlapping along the transect, both species are somewhat separated vertically in the cobble accumulation. The former prefers the upper levels, whereas the latter is more abundant toward the bottom, frequently found under half-buried porous rocks. *Pedipes pedipes*, although overlapping with the latter two species, aggregates closer to a level just above the high tide level, a distribution more narrowly exhibited by *Auriculinella bidentata*. Here, too, there appears to exist vertical zonation, with *P. pedipes* preferring the upper levels, whereas *A. bidentata* lives underneath the rocks (Martins 1980). The single specimen of *P. pedipes* recorded from D9 (quadrat 9 of transect D) could be interpreted as accidental presence because the next closest recording is another single specimen in A6. However, transect D is in a highly exposed area, and

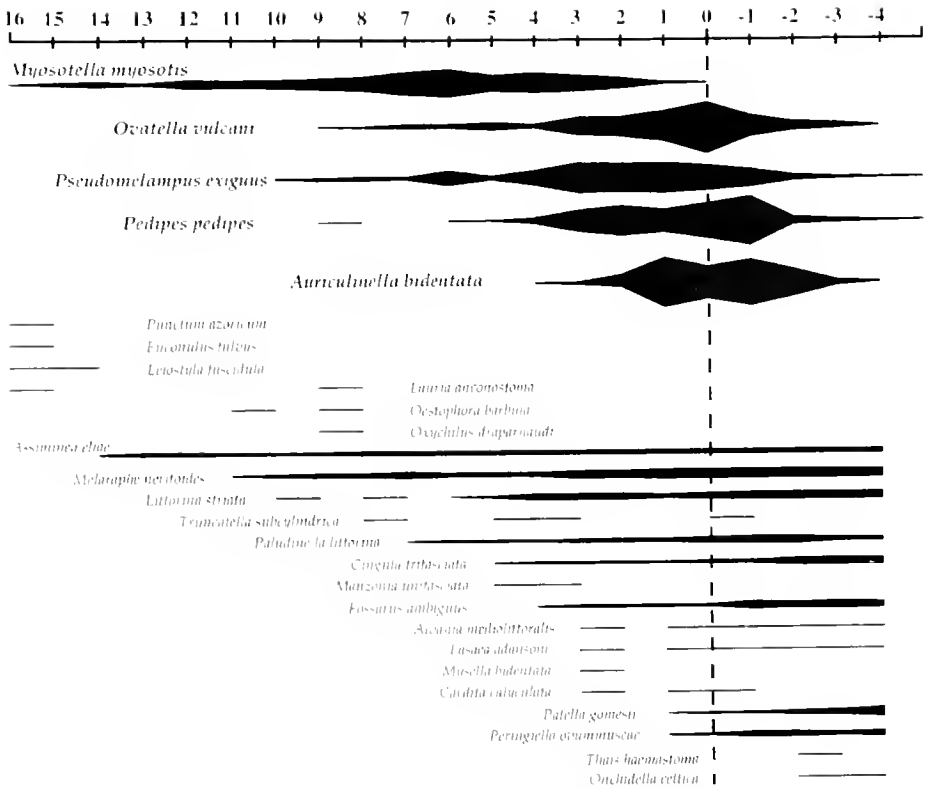

Figure 3. Distribution of ellobiids and associated malacofauna along the cobble shores in the Açores. Combined percentage (ellobiids) and cumulative presence (associated malacofauna) on five transects of different lengths. Dotted line (0) marks the high tide limit, located at the landward end of quadrat 0. Associated malacofauna not recorded in quadrat −4. (Adapted from Martins 1980.)

strong hydrodynamism could explain this apparently unusual presence, an interpretation supported by the equally more landward distribution of *Pseudomelampus exiguus* in transect D.

The ellobiids of a boulder shore of Hong Kong, although a different species assemblage, exhibited similar distribution patterns (Martins & Cunha 1992). Their horizontal distribution was more clearly understood when their vertical distribution in each quadrat along the transect was examined: In general, the horizontally widely distributed species maintained some preference for an upper vertical level as they approached the sea. The data for the Açores, presented here, lack transect profiles and vertical quantification, not allowing for inferences of this kind. However, as already referred to by Martins (1980), in many instances similar behavior occurs in the Açorean species.

Worth mentioning, within the associated malacofauna, is the wide horizontal range of *Assiminea eliae*, restricted to Terceira Island, contrasting with the more marine preference of another assimineid, *Paludinella littorina*, which is present on both islands.

The two littorinids present in the studied areas exhibit their commonly observed relative distribution pattern, with *Melaraphe neritoides* extending farther inland than *Littorina striata* (Morton et al. 1998).

ACKNOWLEDGMENTS

I thank Joseph C. Britton and Robert McMahon for welcoming a study on ellobiids at a littorinid symposium. The comments of an anonymous reviewer were most appreciated. Support for the presentation of this paper was provided by Fundação Calouste Gulbenkian and Fundação para a Ciência e a Tecnologia (Portugal).

WHEN TO MOVE AND WHERE TO GO: MOVEMENT BEHAVIOR OF THE TROPICAL LITTORINID *CENCHRITIS MURICATUS* (LINNAEUS, 1758)

DEBORAH J. GOCHFELD[1,2] AND DWAYNE T. MINTON[1,3,*]

[1]*Hofstra University Marine Laboratory, Priory, St. Ann, Jamaica, West Indies;* [2]*Department of Pharmacognosy, University of Mississippi, Mississippi 38677;* [3]*Department of Zoology, University of Hawaii, Honolulu, Hawaii 96822*

ABSTRACT Movement behavior in intertidal molluscs is related to the intensity of physical and biological stress. Tropical littorinids are exposed to extreme environmental conditions, and movement at night or on a tidal cycle may alleviate desiccation and heat stress, as would returning to a sheltered location following foraging. We examined the movement behavior of individually marked *Cenchritis muricatus* on a Jamaican shore for 30 days. On 6 days, selected from different parts of the lunar cycle, snail locations were monitored at 3-h intervals. Movement did not occur on a diurnal, tidal, or lunar cycle. Although *C. muricatus* preferentially rested in crevices, there was no evidence of homing behavior. Snails resting on exposed rock surfaces were four times more likely to move than snails resting in more sheltered microhabitats. In general, movement in *C. muricatus* appears to occur in direct response to wetting: >89% of movements occurred within 12 h after rainfall or heavy dew. We believe this behavior is primarily a response to desiccation stress, but it may also facilitate foraging.

KEY WORDS: movement behavior, movement periodicity, microhabitat, tropical littorinid

INTRODUCTION

Rocky shore intertidal gastropods display a variety of movement behaviors, ranging from homing to a specific location on the rock to periodic migrations up and down the shoreline. Homing to a particular scar on the rock following foraging excursions is well known in limpets (Underwood 1979, Branch 1981, Chelazzi et al. 1988, Della Santini et al. 1995) and chitons (Chelazzi et al. 1988, Little 1989). Vertical migrations or periodicity in foraging activity occurring on a diurnal or tidal cycle have been demonstrated in neritids (Underwood 1979, Little 1989), limpets (Hartnoll & Wright 1977, Branch 1981, Little 1989, Gray & Naylor 1996), and littorinids (Little 1989, Ohgaki 1989, Norton et al. 1990). In addition, seasonal migrations, often associated with reproductive events, have been observed in some limpets (Underwood 1979, Chelazzi et al. 1988, Della Santini et al. 1995) and littorinids (Chelazzi et al. 1988, Takada 1992).

Most studies of movement behavior in littoral gastropods assume that desiccation stress is a primary influence on the evolution of the timing of movement (Little 1989). For gastropods occupying tropical rocky shores, which are exposed to direct sunlight and extremely high temperatures, individuals should move when the risk of desiccation and heat stress is lowest, such as during rain or high tides or during the night when temperatures are cooler. Tropical high-shore gastropods may avoid potentially lethal daytime conditions by use of a limited cyclic activity period and by selective use of microhabitat (Garrity & Levings 1984) as well as by withdrawing into their shells and cementing the shell to the rock with a mucus holdfast (McMahon & Britton 1991). Supralittoral gastropods also display a variety of morphological and physiological adaptations, which enable them to persist under extreme conditions of heat and desiccation (McMahon 1991, Britton 1992).

The Caribbean littorinid *Cenchritis muricatus* (Linnaeus, 1758) occupies the highest position in the supralittoral fringe of rocky shorelines (Fraenkel 1968, Lang et al. 1998, Minton & Gochfeld, 2001). The zone occupied by *C. muricatus* is subjected to extreme environmental conditions of heat and desiccation and is rarely inundated by seawater. Few studies have examined the ecology of *C. muricatus* (Lang et al. 1998), and little is known about its behavior patterns, although Lang et al. (1998) noted that this species spends most of its time in repose, and Kaplan (1988) suggested that *C. muricatus* must migrate downshore to forage at night when it is cooler. The objectives of this study were to investigate the movement behavior of *C. muricatus* over a range of temporal scales. Unlike many earlier studies, the present study spans an entire lunar cycle to discriminate between movement patterns based on diurnal, tidal, or lunar cues.

MATERIALS AND METHODS

This study was carried out on an uplifted Holocene limestone reef on the north coast of Jamaica near the Hofstra University Marine Laboratory at Priory, St. Ann. This north-facing platform rises up to 3 m above sea level and ranges from 10–25 m wide in the study area. The substrate is predominantly unvegetated and heavily microkarstified. Snails were selected from ten sites within an area 100 m long.

On 23 July 1998, five adult individuals of *C. muricatus* (length: 17.1 ± 0.6 mm; width: 13.2 ± 0.7 mm) were selected from each of ten sites, marked, and returned to their original locations. Snails were marked using colored nail polish or enamel paint, followed by an application of clear enamel to prevent the color from wearing off. Snails from the same site were painted different colors so that we could identify individuals.

After 3 days we found as many of the marked snails as we could and placed a numbered coin on the rock beside them to denote their present location. For each snail, we measured the nearest distance and compass heading to the ocean and the microhabitat in which it was located. Distance measurements were determined using a fiberglass measuring tape. Distances recorded in this study represent the shortest distance measured between the snail's previous and present locations. Because it is unlikely that snails travel in straight lines, these values represent the minimum distances traveled and are therefore underestimates of the rate of movement. We used four microhabitat classifications: surface (on the exposed rock surface), pit (depression in the rock of sufficient size to house only a single adult individual), crevice (depression in

*Corresponding author.

the rock of sufficient size to house more than one adult individual), and vegetation (either on or under vegetation). In addition, a dab of paint corresponding to the color of the snail was placed on the rock at the snail's initial location to determine whether the snail showed evidence of homing to this site.

During subsequent observations, the following data were collected: distance moved from the previous location (denoted by the coin), compass direction moved, and microhabitat of the new location. The coin was then moved to the snail's new location.

Observations were made daily, generally between 8 AM and 12 PM, from 26 July to 24 August 1998, corresponding roughly to a lunar cycle. In addition, during 6 days randomly selected from within this period (27 July, 29 July, 4 August, 8 August, 19 August, and 22 August), observations were made at approximately 3-h intervals for 24 h. To test the hypothesis that movement in *C. muricatus* was restricted to nocturnal periods, a chi-square test was performed on a 2 × 2 contingency table that compared the number of nocturnal vs. diurnal observation periods during which movement vs. no movement was recorded. Tidal periodicity in movement behavior was analyzed by correlating the relative tide height, measured with an automated data logger based at the Hofstra University Marine Laboratory, with movement patterns for the dates on which 24-h observations were conducted. The tide data for 27–28 July were omitted from this analysis due to a malfunction of the data logger. Lunar periodicity in snail movement behavior was examined by converting the lunar phase into a relative value between +1 (full) and −1 (new) and correlating this value with the percentage of snails moving on each day over the lunar cycle. For this analysis, snails that were observed to move multiple times during the 24-h observation periods were included only once. Rainfall was monitored using a plastic rain gauge.

Microhabitat Availability

At each site, microhabitat availability was determined by haphazardly placing 0.0625-m^2 quadrats on unvegetated substrate in the zone in which *C. muricatus* occurred (n = 3–12 quadrats per site, depending on the width of this zone). The type of microhabitat (crevice, pit, or surface) present at each of 16 points within the quadrat was identified. All replicates (n = 63) were pooled to determine mean proportions of each microhabitat available to *C. muricatus*. The overall preference of *C. muricatus* for each microhabitat was determined by comparing the number of snails occupying each microhabitat with the availability of that microhabitat using a chi-square test. Additionally, for each snail, its occurrence in the three microhabitats was compared with the availability of each microhabitat by a chi-square test to investigate its apparent microhabitat preference. Although the number of individual snails associated with vegetation are reported, percent cover of vegetation was not quantified, and therefore the preference of snails for vegetation was not analyzed.

Wetting Experiment

To determine whether the quantity or salinity of wetting influenced the movement of *C. muricatus*, snails were exposed to different quantities of fresh water or to seawater. On a hot sunny day, 16 1-m^2 quadrats were haphazardly laid on a relatively flat area of shoreline in the general vicinity of, but not actually in, our study sites. Quadrats were randomly assigned to four treatments: no water (control), 250 ml fresh water, 500 ml fresh water, or 250 ml sea water. These volumes of water were equivalent to 0.25 mm and 0.5 mm of rainfall or wave splash. All *C. muricatus* within each quadrat were counted initially. Water was applied to the treatment quadrats using a plastic bottle with a piece of plastic wrap attached to the top with a rubber band. Several small holes were punched in the plastic wrap, which allowed the water to be sprinkled evenly over the substrate. Once the quadrats were wetted, we determined the percentage of snails that had moved after 10 min. Control quadrats were not wetted but were monitored in the same way. A one-way analysis of variance (ANOVA) was used to examine the effect of wetting on snail movement. Significant results were then analyzed using Tukey's pairwise comparisons with an overall $\alpha = 0.05$.

RESULTS

Altogether, 64 periods were sampled, and 37–46 marked snails (42.6 ± 2.47) were located during each observation period. We made 2,726 total observations on 48 different snails (56.7 ± 13.6 observations per snail).

Rates and Direction of Movement

The majority of our observations (91%) were of snails that did not move. When *C. muricatus* did move, they were able to move relatively rapidly. The maximum rate of movement recorded was 38 cm/h, with a mean overall rate of movement of 5.0 ± 5.5 cm/h (n = 175). Individuals of *C. muricatus* did not display any consistent preferred direction of movement (Bonferroni-corrected Rayleigh's test for random angular dispersion, $\alpha = 0.001$; maximum $R = 5.9$; $n = 48$ snails; minimum $P = 0.005$). When the movements of all snails were pooled and the direction of the ocean was standardized, there was no evidence of directional movement (Rayleigh's test, $R = 29.5$; $n = 366$ observations; $P > 0.05$) (Fig. 1).

We found no evidence of homing in *C. muricatus*, either to the initial marked "homes" or to any subsequent resting sites. On the

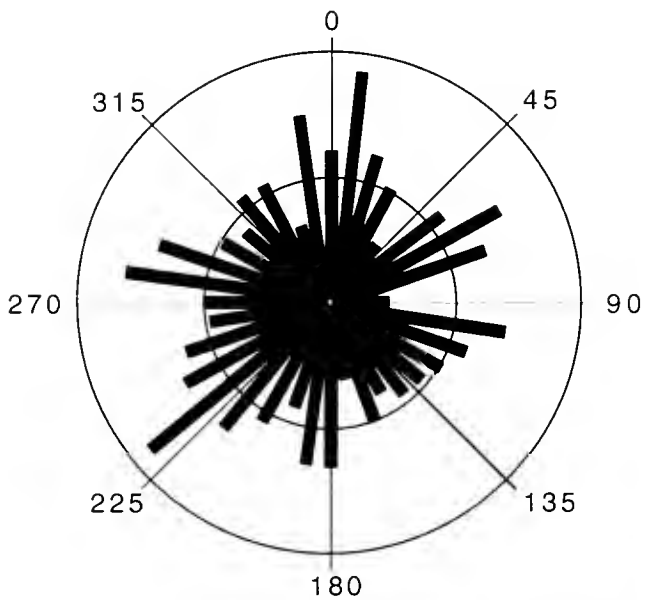

Figure 1. Frequency distribution of directions of all movements made by *Cerithidea muricatus* during all observation periods (n = 366 observations). Radial lines represent 10 and 20 snails, respectively. Directions of movement at each site have been standardized so that the direction of the ocean is zero.

other hand, all snails remained within 1–2 m of the sites from which they were originally released. In fact, 1 y later (24 July 1999), 14 (28%) of our marked snails were found within 3 m of the areas from which they were first collected.

Movement Periodicity

Individuals of *C. muricatus* were equally likely to move during the day as at night during our 24-h observation periods ($\chi^2 < 0.001$; df = 1; $P = 0.99$) (Fig. 2). There were some periods of high snail movement on three dates, and in each case the period of high snail movement occurred during the hours following a rainfall or, in the case of the night of 22–23 August, a period of unusually heavy dew. We observed no correlation between the percentage of snails moving and the level of the tide (Pearson correlation, $r = -0.249$; $t = -1.5426$; $n = 38$; $P > 0.1$) (Fig. 2). There was also no correlation between the percentage of snails moving and the phase of the moon ($r = -0.229$; $t = -1.245$; $n = 30$; $P > 0.2$) (Fig. 3). Again, there were several dates on which a high percentage of snail movement was recorded, and each of these corresponded with a preceding rainfall (Fig. 3).

There was a relationship between movement and rainfall. Overall, 89.1% of snail movements occurred within 12 h following a rainfall. The percentage of snails moving during observation periods within 12 h following rainfall (50.5 ± 23.0%; $n = 15$ periods) was significantly greater than during observation periods that were not preceded by a rainfall within 12 h (1.7 ± 4.11%; $n = 45$ periods; unpaired two-sample t test, $t = 8.12$; df = 14; $P < 0.0001$). To determine whether snail movement decreased with increasing time since rainfall, all observations within 12 h following rainfall for the 24-h observation periods were examined. The percentage of snails moving was greatest shortly following a rainfall and showed a significant linear decrease over time (regression, $y = 76.3 - 4.54x$; $r^2 = 0.35$; $P = 0.044$). Although the percentage of snails that was active decreased following rainfall, there was no change in the rate of movement as the time from rainfall increased (regression, $y = 26.6 - 1.18x$; $r^2 = 0.16$; $P = 0.19$). Snail movement appears to cease more rapidly during daytime than at night; however, our low sample sizes did not permit us to test this statistically.

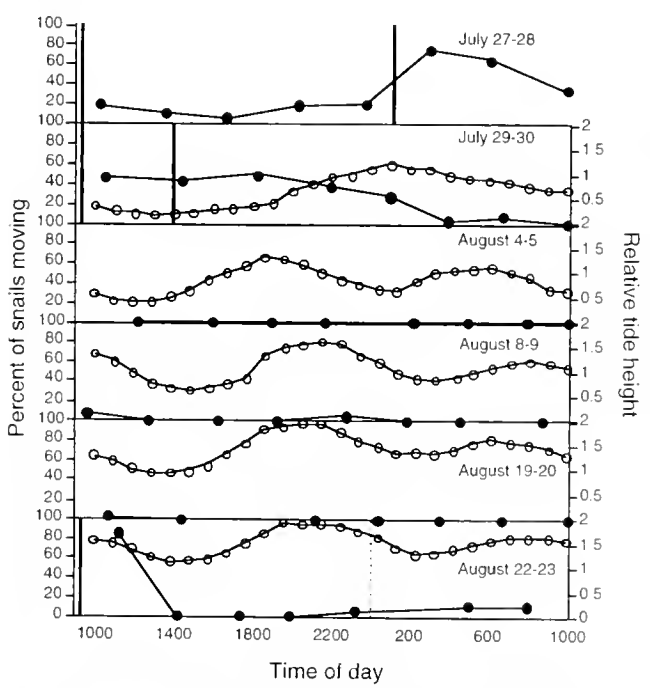

Figure 2. Movement of *Cenchritis muricatus* during the six 24-h observation periods. The percentage of snails moving (solid circles) and relative tide height (open circles) are shown. Tide data from 27–28 July were omitted due to equipment malfunction. Solid vertical lines indicate times of rainfall; dashed vertical line indicates an unusually heavy dew.

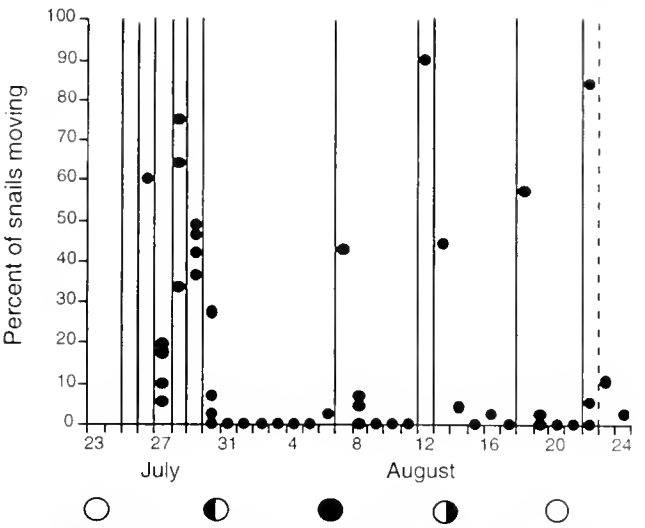

Figure 3. Movement of *Cenchritis muricatus* over the lunar cycle from 26 July to 24 August 1998. For dates on which there were multiple observation periods, the percentage of snails moving during each observation period is indicated. Solid vertical lines indicate dates on which rainfall occurred; dashed vertical line indicates an unusually heavy dew.

Effect of Microhabitat on Location and Movement

When all observations from all snails were pooled, *C. muricatus* exhibited a strong preference for crevices and pits over exposed surface ($\chi^2 = 5324.21$; df = 2; $P < 0.001$). Observations during which snails were found on or under vegetation ($n = 426$) were excluded from this analysis. Of the remaining 2,296 observations, 54.2% were in crevices, 28.0% were in pits, and 17.8% were on the surface, in spite of the fact that only 14.9% of the area consisted of crevices, 8.5% was pitted, and 77.1% was exposed surface. When chi-square tests were performed on microhabitat preferences for each snail independently, 45 of 46 snails showed significant preferences for crevices and pits over exposed surface (all at $P < 0.001$). In 31 cases, crevices was the major contributor to these significant chi-square values, and in 14 cases, pits was the major contributor.

In the absence of rainfall, snails were equally likely to move from all microhabitats (2.5, 1.1, 0.96, and 1.4% from exposed surface, pits, crevices and vegetation, respectively; $\chi^2 = 2.74$; df = 3; $P > 0.1$). Following a rainfall, snails were more likely to move from a resting position on the surface (24.3%) than from pits (9.2%), crevices (9.8%), or vegetation (9.9%; $\chi^2 = 60.7$; df = 3; $P < 0.001$).

Wetting Experiment

There was a significant effect of wetting on the percentage of snails moving (one-way ANOVA: $F = 9.88$; df = 3; $P = 0.001$). However, a Tukey's multiple comparisons test indicated that the

type of wetting treatment (250 ml vs. 500 ml fresh water vs. 250 ml sea water) had no effect on the percentage of snails moving. The percentage of snails moving in all treatment quadrats combined was 63.9 ± 23.0%, as compared with 0 in the control quadrats.

DISCUSSION

This study demonstrated that individuals of *C. muricatus* do not exhibit diurnal, tidal, or lunar periodicity in their movement patterns. Movement in *C. muricatus* appears to occur in response to wetting of the substrate by rain or dew. Individuals of *C. muricatus* occurred preferentially in pits and crevices, and this selection for sheltered microhabitats and a propensity to move only under moist conditions suggest that these behaviors may have evolved as means to reduce desiccation potential in this tropical high-shore species.

Lang et al. (1998) observed that *C. muricatus* spends most of its time in repose, and this study supports that observation. When *C. muricatus* did move, it did not show evidence of directional movements, and it did not move long distances. During our study, we were able to locate all but two of our marked snails, and all were found within 2 m of their original locations. One year later, we were able to find 14 (28%) of our marked snails, all of which were within 3 m of their initial locations. This pattern of short, nondirected movements—a random walk, in effect—appears to maintain the distribution of *C. muricatus* along the shore, both over the short and long term, as suggested by Chelazzi et al. (1988). Underwood (1977) also found that three species of intertidal gastropods moved in random directions, at least over a 1- to 3-day period, and Petraitis (1982) observed that *Littorina littorea* moved randomly except following dislodgment, when movement was aimed at returning the individual to its initial zone on the shore.

We did not observe any evidence of diurnal, tidal, or lunar migration in *C. muricatus* during this 4-wk study. Nocturnal foraging has been implicated in littorinids (Voltolina & Sacchi 1990), and Kaplan (1988) suggested that *C. muricatus* might migrate downshore to forage on algae in the intertidal zone at night, when temperatures are cooler and the potential for desiccation is reduced. However, this was not the case in our study. One possible explanation for the absence of nocturnal migrations in *C. muricatus* may be that its food source, which most likely consists of endolithic and/or epilithic algae (Norton et al. 1990, McQuaid 1996), is adequate in the supralittoral fringe.

The absence of tidal rhythmicity to movement in *C. muricatus* is not unexpected. The supralittoral fringe zone occupied by *C. muricatus* is highest on the shore and is never inundated by tides except during severe storms, none of which occurred during our study. Therefore, *C. muricatus* does not receive an exogenous cue from the tide itself, which might initiate movement, and there does not appear to be an endogenous cue for tidal periodicity in movement behavior. Zann (1973) also noted the absence of tidal periodicity to movement in supralittoral gastropods that were not subjected to regular tidal action.

Although clearly not ubiquitous, patterns of diurnal or tidal periodicity of movement are known from littorinids. Ohgaki (1989) noted that *Nodilittorina exigua* in Japan exhibits upward migrations with the high tide, and foraging activity in *L. littorea* is also associated with the tide (Newell et al. 1971). *L. scutulata* exhibits diurnal periodicity in foraging activity (Voltolina & Sacchi 1990). On the other hand, Little (1989) reviews foraging activity in a variety of littoral molluscs and lists only three species that exhibit foraging activity with no regular pattern relating to tides or time of day; all three of these species are littorinids.

Unlike many earlier studies on movement in intertidal molluscs, our observations on *C. muricatus* spanned an entire lunar cycle. Nevertheless, we did not see any evidence of movement periodicity associated with the lunar cycle during our study. In some species of littorinids, reproductive behavior has been linked to lunar cues (Hughes & Roberts 1980, Berry 1986). In at least one species of high-shore littorinid, there is evidence of a seasonal downshore migration associated with spawning (Ohgaki 1988). *C. muricatus* may display a similar seasonal reproductive migration, which would not necessarily have been observed during our study. In fact, in June–July 1998 and 1999, large aggregations of *C. muricatus* were observed low on the shore at the water's edge, well below this species' typical supralittoral fringe habitat (unpublished data). Upshore migrations were subsequently observed in mid-July. It is suspected that this migration is associated with reproduction; however, this has not yet been confirmed.

There was no evidence of homing to specific sites on the rock in *C. muricatus*. However, the fact that snails were found at or near their initial locations a year later, following a massive downshore migration, suggests that there may be a mechanism by which individuals are able to return to the same general location on the shore. Other littoral molluscs that migrate vertically with the tide are able to return to the same approximate locations following downshore foraging movements, and this is probably regulated by a complex of stimuli (Underwood 1979, Chelazzi et al. 1988).

Movement in *C. muricatus*, as in several other species of supralittoral gastropods, appears to occur exclusively when the rock is wet. The results of the wetting experiment indicate that the volume and salinity of the water was unimportant in eliciting movement behavior. Because *C. muricatus* occupies the highest zone on the rocky shore in Jamaica, this area is rarely reached by wave splash and is never inundated by tides. On the other hand, rainfall and dew can wet this zone on a reasonably regular, if unpredictable, basis. If rainfall occurs in midday, the rock can dry quite rapidly, but at night the rock may remain damp for several hours. Although we did not measure relative humidity, *C. muricatus* may also move when relative humidity of the air is very high (R. McMahon, pers. comm.).

Individuals of *C. muricatus* appear to take advantage of the wet rock for their foraging excursions. Foraging when the rock is wet may be an adaptive mechanism to reduce desiccation potential, which is normally severe in this zone. In addition, rainfall may facilitate foraging by softening the epilithic biofilm, the probable food source of *C. muricatus*. Chapman (1994a) reported that *Nodilittorina pyramidalis*, a high-shore species from Australia, also feeds opportunistically when the rock is wet, either by rain or tide, and becomes inactive when the rock dries. The limpet *Siphonaria pectinata* forages when the substrate is very damp or wet, and when the relative humidity drops below 75% during foraging, the limpet stops moving and attaches to the rock even if it has not returned to its home scar (Ocana & Emson 1999). This is presumably an adaptive mechanism for limiting water loss until the limpet can return to its home scar (Ocana & Emson 1999).

Individuals of *C. muricatus* preferentially occupied pits and crevices as opposed to exposed surfaces on the rock. Gastropods occupying the supralittoral fringe zone on tropical shores are exposed to direct sunlight and extreme temperatures during their prolonged periods of emersion. The preferential use of pits and

crevices by *C. muricatus* may be an adaptation to mediate extreme environmental conditions. Individuals of *C. muricatus* occupying crevices tend to have lower ambient temperatures than those on exposed rock surfaces (Lang et al. 1998). Crevices and pits may also provide some degree of shade in a habitat otherwise fully exposed to direct sunlight, and snails occurring in these microhabitats may be able to trap more moisture. Snails found on or under vegetation may also experience reduced desiccation potential as a result of shading and reduced contact with the hot rock, although they may also be farther from their food source.

Preferential use of certain microhabitats, particularly crevices, has been reported in several other littorinids (Garrity 1984, Underwood & Chapman 1992), although explanations for such preferences vary. Our data are consistent with other studies of tropical littorinids, which found that pits and crevices provided protection from heat stress and desiccation (Garrity 1984, Peckol et al. 1989). To the contrary, studies of temperate littorinids suggest that the use of pits and crevices do not protect against heating or desiccation (Chapman 1994b) but may provide a more abundant food source (Voltolina & Sacchi 1990) or protection from wave action (Raffaelli & Hughes 1978). Except during severe storms, *C. muricatus* at our study site in Jamaica is not at risk from wave action, but desiccation potential on this tropical shoreline is high and may pose a serious risk to individuals of this species (Lang et al. 1998). Littorinids occurring in crevices may also be protected from predation pressure (Catesby & McKillup 1998); however, predation on *C. muricatus* is probably a relatively minor selection pressure at our study site.

Individuals of *C. muricatus* on exposed rock surfaces were more likely to move when the substrate was wet, whereas individuals in more sheltered microhabitats (pits, crevices, or vegetation) were more likely to remain stationary. This difference in behavior as a function of microhabitat may reflect the more extreme desiccation potential on exposed rock surfaces, and moving from an exposed surface to a sheltered habitat may be advantageous. Alternatively, snails on exposed surfaces may be more energetically stressed due to increased heat and desiccation potential and may be more inclined to resume foraging when the rock is wet than are snails in more sheltered microhabitats. When the rock was dry, very few snails moved, regardless of their resting microhabitat.

Foraging activity in *C. muricatus* appears to be an opportunistic strategy in which snails are able to take advantage of favorable conditions during which desiccation potential is reduced. For molluscs found in the supralittoral fringe on tropical shorelines, desiccation potential may be an important selective pressure, although other abiotic factors may be equally or more important because most highshore gastropods are able to tolerate greater levels of desiccation than they ever experience in their natural habitats (R. McMahon, pers. comm.). Substratum temperatures of the exposed rock surface in the supralittoral fringe at our study site in July reached a high of 45°C (Minton & Gochfeld in press), whereas the heat coma temperature of *C. muricatus* is 42.1°C (Britton 1992). Therefore, *C. muricatus* is exposed to potentially lethal temperatures for extended periods of time and has evolved behavioral mechanisms that minimize its potential for desiccation and heat stress, including preferential use of sheltered microhabitats and movement only when the rock surface is damp or wet.

ACKNOWLEDGMENTS

We thank Dr. Eugene Kaplan, Sandy Walters, Sandy Ross, and the staff of the Hofstra University Marine Laboratory/Columbus Beach Cottages for providing lodging and facilities during the course of this study. Dirk served as a dutiful field assistant during our nocturnal observation periods. This project was supported by a grant to D.M. from Conchologists of America, Inc.

A MOLECULAR ASSAY IDENTIFIES MORPHOLOGICAL CHARACTERS USEFUL FOR DISTINGUISHING THE SIBLING SPECIES *LITTORINA SCUTULATA* AND *L. PLENA*

PAUL A. HOHENLOHE[1]* AND ELIZABETH G. BOULDING[2]

[1]*Friday Harbor Laboratories, University of Washington, 620 University Rd, Friday Harbor, Washington 98250;* [2]*Department of Zoology, University of Guelph, Guelph, Ontario N1G 2W1, Canada*

ABSTRACT Sibling species *Littorina scutulata* and *L. plena* are difficult to distinguish in the field. Here we present a new molecular tool and use it to evaluate the discrete and quantitative morphological characters that have been proposed as diagnostic. We collected 385 snails of both species from 11 sites in Washington state and used restriction enzyme digestion of a PCR-amplified, 480 bp fragment of the mitochondrial cytochrome b gene to distinguish the species. This new molecular assay produces species-specific restriction fragment patterns that correspond with identification of males by penis morphology. To evaluate the usefulness of morphological characters, we scored three discrete shell characters (presence of basal band, presence of basal ridge, and size of checker pattern) as well as tentacle coloration. The four discrete characters differ significantly between the two species, though none is completely diagnostic. Tentacle coloration is the most reliable character and may be combined with the shell characters for successful identification. The two species also differ significantly in overall size and in three out of five size-independent shell shape measurements, with *L. scutulata* having larger, taller-spired shells with narrower apertures. However, shell shape does not separate the species well because of intraspecific variation, and it is unlikely to be useful for species identification. Further analysis suggests that at least some of this intraspecific variation is genetic rather than environmental. The distributions of the two species overlap broadly in Washington, though only *L. plena* was found in exposed outer coast habitats, contrary to previous work.

KEY WORDS: *Littorina scutulata*, *L. plena*, species identification, sibling species, molecular systematics

INTRODUCTION

The taxonomic history of the *Littorina scutulata* species complex, a group of sympatric intertidal prosobranch gastropods in the Northeastern Pacific, has been complicated by morphological similarity across species and variation within species. Currently two sibling species are recognized, *L. scutulata* (*sensu stricto*) Gould 1849 and *L. plena* Gould 1849, which are distinguished on the basis of reproductive characters, including penis, pallial oviduct, and egg capsule morphology (Murray 1979, Mastro et al. 1982, Reid 1996). These characters, however, are difficult to use for the non-destructive field identification that is necessary for many ecological studies. Reproductive characters cannot be used for juveniles, and we have found the dissection necessary for examining pallial oviduct morphology to be difficult, especially in small specimens.

Other diagnostic morphological characters have been proposed. Three discrete shell characters have been described: a pale basal band (Murray 1982, Reid 1996, Chow 1987, Rugh 1997) and a narrow basal ridge (Rugh 1997), both found more often in *L. plena*, and the pattern of checkers on many shells, which tend to be smaller in *L. plena* than in *L. scutulata* (Reid 1996, Rugh 1997). Rugh (1997) was able to use these three shell characters alone to correctly identify 17 male specimens of both species from southern California. Reid (1996) described differences in tentacle coloration: *L. scutulata* individuals tend to have "transverse black bands and flecks," while *L. plena* tend to have a "broad, unbroken black stripe with transverse flecks, or all black." Murray (1982) described a set of discriminant functions of four quantitative shell measurements that correctly classified 96% of specimens. Further principal component analysis by Murray (1982) showed *L. scutulata* shells to be generally taller with narrower spire angles and shorter aperture openings relative to shell height. Chow (1987) combined three quantitative shell measurements with number of whorls, presence of a basal band, and presence of tesselation in another discriminant function analysis. This analysis correctly classified 92% of specimens, but only when using snails from one habitat; combining specimens from different habitats introduced too much intraspecific variation to allow correct classification. Chow (1987) also found *L. scutulata* shells to be larger, narrower, and less likely to have a basal band, which agreed with past work. Other characters used with varying success to distinguish these species include spiral sculpture on the shell and radular characters (Reid 1996, Mastro et al. 1982).

Mastro et al. (1982) found eight polymorphic allozyme loci at which the two species differ in their allele frequencies. However, none of these loci was diagnostic. No other molecular studies to date have identified a reliable molecular character at a polymorphic locus that distinguishes the two species.

The previous studies of morphological differences used specimens that were positively identified using reproductive characters, thus excluding pre-reproductive animals. Here we present a molecular technique for identifying individuals of all ages using mitochondrial DNA. We use this tool to evaluate the reliability of characters that can be observed on intact animals: the three discrete shell characters described above, tentacle coloration, and quantitative shell shape differences.

MATERIALS AND METHODS

We collected 385 snails of both species from 11 areas around Puget Sound and the outer coast of Washington state in January 1998 (see Fig. 1) and kept them alive until DNA extraction. Animals of all sizes, including juveniles, from within a randomly chosen, small (~1 m^2) area of rocky shore habitat were collected. Individuals anesthetized in 7% $MgCl_2$ seawater solution were

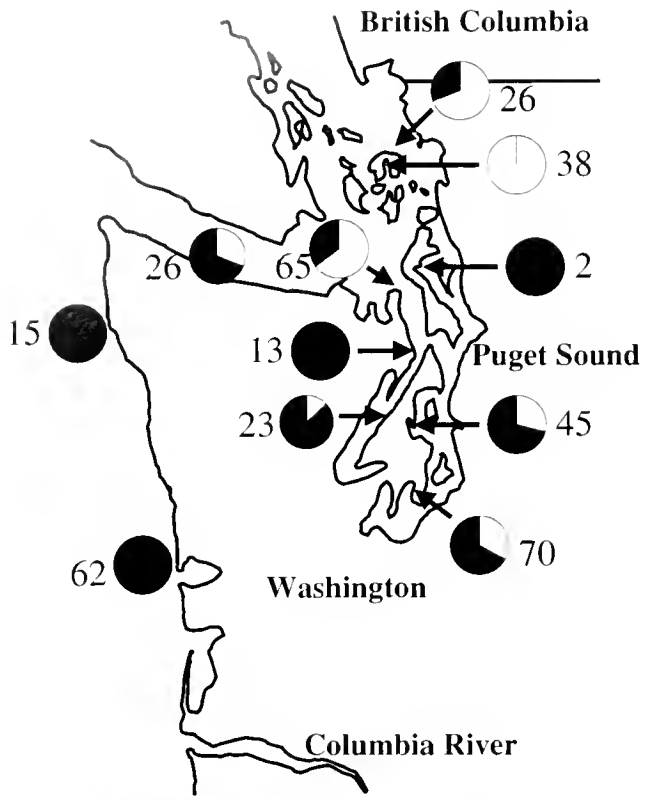

Figure 1. Map of western Washington state showing collection sites in Puget Sound and on the outer coast. Pie diagrams show relative abundance of *L. plena* (dark) and *L. scutulata* (light) with the total sample size for each site.

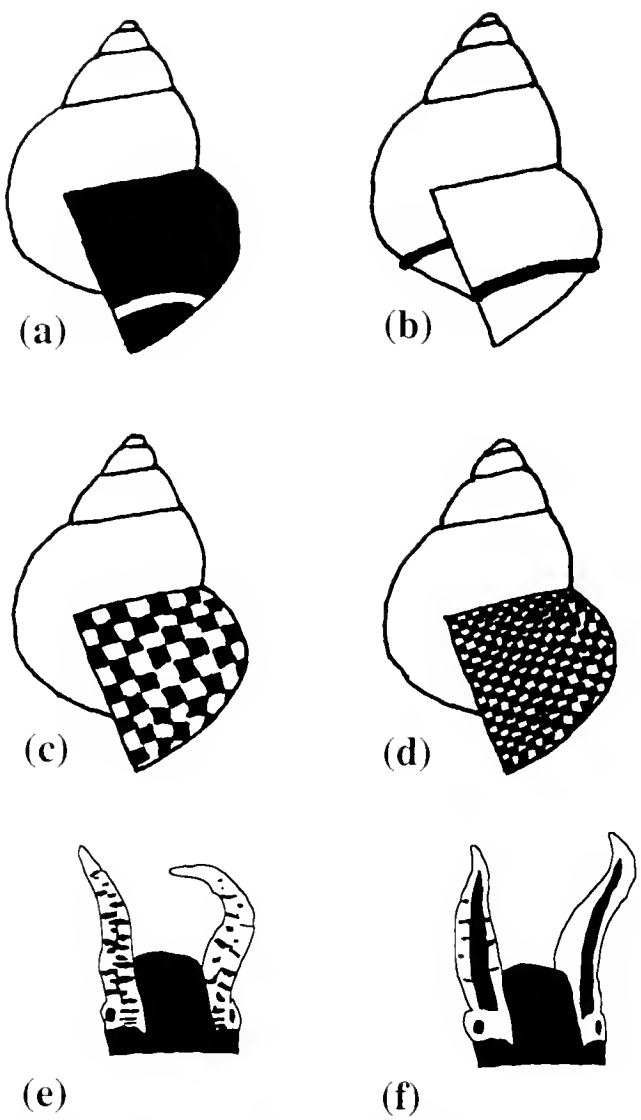

Figure 2. Discrete characters. (a) A pale basal band and (b) basal ridge are found more often in *L. plena*. (c) A pattern of large checkers typifies *L. scutulata*, while (d) small checkers are found more often in *L. plena*. (e) Two tentacle coloration patterns found in *L. scutulata*: transverse bands (left) and bands and spots (right). (f) Two tentacle patterns found in *L. plena*: a broad central stripe with bands (left) and without bands (right).

scored for three discrete shell characters (Fig. 2a–d): basal band present or absent, basal ridge present or absent, and checkers large, small, or absent. Large checkers lie in five to 12 spiral rows, depending on shell size, while small checkers number more than 10 spiral rows. Tentacle coloration was scored in one of seven categories: dark transverse bands, spots and bands, spots, dark central stripe, central stripe with bands, no color, or all dark (Fig. 2e–f; see also Reid 1996). In all further analyses, the first three categories were grouped as "transverse bands," and the last four were grouped as "central stripe." Individuals' sex was also recorded and males scored as *L. plena* or *L. scutulata* penis type. *L. scutulata* penes are relatively short with a terminal bifurcation, while *L. plena* penes are longer, often coiled, with a bifurcation near the base (Reid 1996).

Animals were then sacrificed for molecular analysis. Using the extraction protocol and PCR primers described in Kyle and Boulding (1998), a 480 bp fragment of the mitochondrial cytochrome-b gene was amplified for each individual. These were then digested for two hours using the restriction enzyme *Alu* I and the digests run on a 2% agarose gel. To predict restriction sites for the two species, we examined 36 *L. plena* and 18 *L. scutulata* haplotype sequences from Kyle and Boulding (2000) (Genbank accession nos. AF077238–AF077291). Identification of these sequences by Kyle and Boulding (2000), however, depended on a single *L. plena* sequence from Reid et al. (1996) (Genbank accession no. U46815), so our analysis also functioned to confirm the identification of those sequences. We expected fragments of 161, 233, and 86 bp for *L. scutulata* and 109, 15, and 356 bp for *L. plena*.

Eight quantitative shell measurements were taken from each individual using a dissecting microscope connected to computer imaging software (Fig. 3). Since six of these measurements are lengths, they were combined into three non-dimensional ratios to remove the effect of overall shell size as follows: Relative aperture height = Aperture height / Shell height; Whorl ratio = Whorl n–2 / Whorl n–1; and Aperture shape = Short axis / Long axis. Statistical tests and discriminant function analysis used these three ratios as well as spire angle and aperture angle (Fig. 3).

In an attempt to improve differentiation of the two species based on shell morphology, further discriminant function analyses were done using different sets of variables. In the first, size was included specifically by adding shell height to the three ratios and two angles, providing six variables for discriminant analysis. In the second revision, the original six linear measurements were not combined into ratios as above, but rather normalized by the

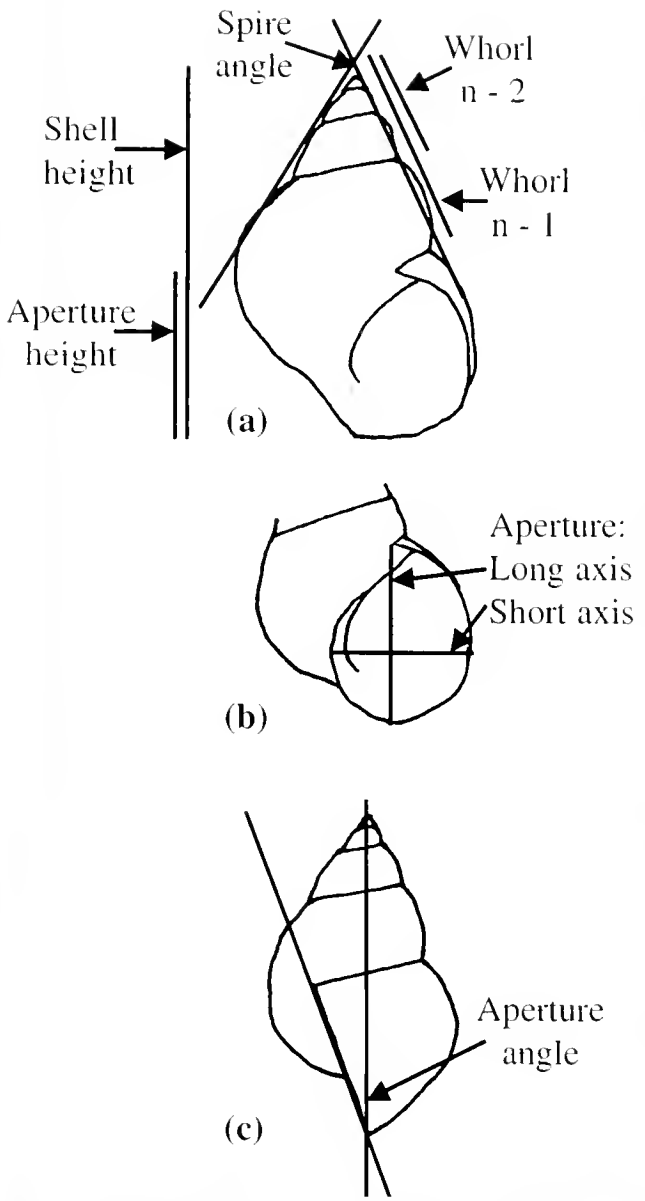

Figure 3. Quantitative shell measurements. Shells were viewed through a dissecting scope and video camera connected to a computer and measurements were taken using imaging software. The two angles were measured in degrees and the six lengths in mm.

method of Clarke et al. (1999). The effects of size were removed from each linear measurement by dividing the geometric mean of each specimen's measurements:

$$\text{geometric mean} = 10\text{^}[(\log_{10}(x_1) + \log_{10}(x_2) + \ldots + \log_{10}(x_6))/6]$$

where x_1 through x_6 are the original linear measurements. This provided two angles and six normalized linear measurements for discriminant analysis.

The third attempt to improve the discrimination used only the specimens from six sites at which both species were found (see Fig. 1) and analyzed the three ratios and two angles as above. Finally, another analysis was performed on data limited to three sites of similar habitat following Chow (1987). These three sites are the three southern Puget Sound sites shown in Figure 1. All are protected shores at which both species were found.

RESULTS

Restriction enzyme digestion with *Alu* I produced two discrete fragment length patterns as expected: one pattern with three closely spaced bands (*L. scutulata*) and another with two widely spaced bands (*L. plena*; the 15 bp fragments typically migrated off the gel). These corresponded precisely with identification of males by penis morphology (n = 48 *L. scutulata* and 71 *L. plena*). This supports the identification of sequences in Kyle and Boulding (2000) and suggests that these restriction sites are consistent across haplotypes within each species. The following analyses are based on these 119 males as well as females identified using only restriction digest and males identified by penis morphology alone. Sample sizes vary because of damage to some shells during DNA extraction.

The frequency of each of the four discrete characters differs significantly between the species (Table 1) consistent with Rugh (1997) and Reid (1996). The differences remain significant following Bonferroni correction of the original p-values from four separate contingency table analyses (Rice 1989). However, no single character completely separates the two species. The shell characters were often not visible because of shell erosion from wave action or fungal or other epiphytic growth, creating a potential bias toward identification as *L. scutulata* from the first two characters. Many undamaged shells also lack any checker pattern. Tentacle coloration, because it was always scorable in live animals, was the most reliable discrete character.

Following Bonferroni correction of the original p-values from six separate two-tailed *t*-tests (Rice 1989), the species differ significantly in four shell measures (Table 2). *L. scutulata* shells are significantly larger than *L. plena* shells. Of the five size-independent shell measures, the two species differed significantly in spire angle, whorl ratio, and aperture shape. These results are consistent with those of Murray (1982) and Chow (1987), confirming that *L. scutulata* shells are larger, narrower, and taller-spired with narrower apertures. Relative aperture height, though not significantly different, also follows the trend found by Murray (1982). Three of these shell measures, shell height, whorl ratio, and aperture shape, remain significant when considering only the six sites at which both species were found (Table 2). The difference is lost for spire angle. However, the difference in relative aperture height reverses and becomes statistically significant when only these sites are considered.

Combining specimens from all the collection sites, these five

TABLE 1.

Species differences for four discrete characters. Species were identified by restriction enzyme digest and penis morphology. Data given are number of specimens (percentage) in each category. The p-values are Bonferroni corrections (Rice 1989) of separate χ^2-tests.

Character	State	*L. scutulata*	*L. plena*	p-value
Basal band	present	18 (12.4)	124 (51.7)	<0.001
	absent	127 (87.6)	116 (48.3)	
Basal ridge	present	23 (15.9)	149 (62.1)	<0.001
	absent	122 (84.1)	91 (37.9)	
Checker pattern	large	122 (84.1)	25 (10.4)	<0.001
	small	5 (12.4)	93 (38.8)	
	absent	18 (12.4)	122 (50.8)	
Tentacle color	transverse bands	130 (89.7)	10 (4.2)	<0.001
	central stripe	15 (10.3)	230 (95.8)	

TABLE 2.

Quantitative shell measurements. Numbers given are mean (standard deviation), and the p-values are Bonferroni corrections (Rice 1989) of separate two-tailed *t*-tests. For each measure, the first row includes specimens from all sites, and the second row includes only specimens from the 6 sites at which both species were found.

Measurement all sites: 6 sites:	*L. scutulata* n = 142 n = 104	*L. plena* n = 210 n = 146	p-value
Shell height (mm)	8.1 (1.6)	6.3 (1.3)	<0.001
6 sites	7.4 (1.2)	6.3 (1.2)	<0.001
Spire angle (deg.)	54.2 (4.0)	55.5 (5.8)	0.045
6 sites	54.4 (4.1)	54.5 (5.5)	>0.5
Aperture angle (deg.)	24.0 (2.4)	23.8 (2.1)	>0.5
6 sites	23.9 (2.4)	23.9 (2.2)	>0.5
Relative ap. Height	0.516 (0.038)	0.519 (0.039)	>0.5
6 sites	0.528 (0.034)	0.513 (0.039)	0.01
Whorl ratio	0.595 (0.163)	0.555 (0.045)	<0.001
6 sites	0.607 (0.188)	0.568 (0.002)	0.045
Aperture shape	0.703 (0.038)	0.726 (0.037)	<0.001
6 sites	0.697 (0.040)	0.721 (0.037)	<0.001

shell measures were used in a discriminant function analysis without much success: the function correctly classified only 69% of *L. scutulata* and 66% of *L. plena* specimens. This seems to be the result of overlapping intraspecific variation for all of the characters.

Attempts to improve the discriminant function analysis were marginally successful. Because *L. scutulata* shells were significantly larger, including shell height improved posterior classification to 76% for *L. scutulata* and 81% for *L. plena*. Normalizing the linear measurements by the geometric mean (Clarke et al. 1999) improved classification of *L. scutulata* to 82%, but reduced successful classification of *L. plena* to 62%. Limiting the analysis to the six sites where both species were found made no improvement over the original dataset: 69% for *L. scutulata* and 68% for *L. plena*. Finally, restricting the analysis to the three protected Puget Sound sites only slightly improved classification: 66% for *L. scutulata* and 74% for *L. plena*. These results are summarized in Table 3.

The geographic ranges of these two species overlap significantly in Washington, although *L. scutulata* is found only in moderately exposed to sheltered areas of Puget Sound while *L. plena* is found from sheltered sites in Puget Sound to the exposed headlands of the outer coast (Fig. 1). This conflicts with Reid (1996), who found only *L. scutulata* in exposed habitats.

TABLE 3.

Varying success of discriminant function analyses of quantitative shell measurements. Correct posterior classification percentages are given along with total sample size of specimens for each species.

Variable combination	L. scutulata	L. plena
2 angles, 3 ratios	69 (n = 142)	66 (n = 210)
2 angles, 3 ratios, shell height	76 (n = 142)	81 (n = 210)
2 angles, 6 linear measurements normalized by geometric mean	82 (n = 142)	62 (n = 210)
2 angles, 3 ratios from sites with both species	69 (n = 104)	68 (n = 146)
2 angles, 3 ratios from protected habitats only	66 (n = 38)	74 (n = 99)

DISCUSSION

L. plena individuals tend to have a pale basal band, basal ridge, and small checker pattern on their shells and a broad central stripe on their tentacles, while *L. scutulata* individuals lack the basal band and ridge, have a larger checker pattern, and have transverse bands and spots on their tentacles (see Fig. 2). In addition, *L. scutulata* shells are larger and taller-spired with narrower apertures. However, we do not believe the discrete shell characters alone to be sufficient, as did Rugh (1997), nor do we believe shell shape differences to be diagnostic, as did Murray (1982). Though the species differ significantly in these characters, intraspecific variation and shell damage may confound identification.

No combination of quantitative shell measurements in a discriminant function analysis provided reliable identification. The most successful analysis used shell size explicitly, which could potentially bias the identification of different ages of snails, so its utility in ecological studies would be limited. Neither method of removing the effects of size matched the discrimination ability of Murray (1982) or Chow (1987), suggesting that interspecific differences are truly confounded by intraspecific variation. One attempt to eliminate some intraspecific variation by examining only sites at which both species were found did not improve the results, so this dataset does not show any evidence for character displacement in shell shape. Limiting the analysis to a single habitat type was not successful either. Since this analysis attempted to reduce environmental phenotypic variation, the result suggests that at least some of the intraspecific variation observed is genetically based.

One likely explanation for our different results is that these previous studies used only reproductive, hence larger, animals. Species differences may become more apparent as the snails grow (Reid 1996; Hohenlohe pers. obs.), and ecological applications typically require identification of animals of all ages. Murray (1982), Chow (1987), and Rugh (1997) primarily used specimens from California, and geographic differences may also play a role. Chow (1987) also combined discrete and quantitative characters in a single analysis, which was not done here.

We found *L. plena* occupying a wider range of habitats in Washington, from sheltered Puget Sound sites to the exposed outer coast. In contrast, *L. scutulata* was found only on sheltered to moderately exposed shores. This result conflicts with some previous work (Reid 1996) but is consistent with other data on species distributions (Hohenlohe 2000). This discrepancy is investigated further in Hohenlohe (2000).

These species can be distinguished non-destructively by combining the characters discussed here. Male penis morphology can be easily examined by holding the snail upside down, underwater, under a dissecting microscope. For females and non-reproductive males, tentacle coloration is the most reliable character and can be combined with shell characters on undamaged specimens. For positive identification of all ages and both sexes, restriction enzyme digestion of cytochrome b with *Alu* I is straightforward and reliable and provides a diagnostic character independent of morphology.

ACUTE THERMAL TOLERANCE IN INTERTIDAL GASTROPODS RELATIVE TO LATITUDE, SUPERFAMILY, ZONATION AND HABITAT WITH SPECIAL EMPHASIS ON THE LITTORINOIDEA

ROBERT F. McMAHON
Department of Biology, The University of Texas at Arlington, Box 19498, Arlington, Texas 76019

ABSTRACT Acute thermal tolerance was determined as mean heat coma temperature (HCT) for samples of 30 to 36 individuals each (range = 17–71) of 60 species of intertidal snails from rocky shores (40 species), mangroves (17 species) and salt marshes (3 species) at 10 collecting sites across a latitudinal range of 12.5°– 54.6° (54.61° N – 35.00° S). HCT was quadratically correlated to latitude, increasing with decreasing latitude above 25°, but remaining constant in tropical latitudes below 25°, indicating that thermal tolerance of tropical species is not as latitudinally influenced as in subtropical and temperate species, or, alternately, that tropical species have attained physiologically near maximal levels of thermal tolerance. Mean HCT was greater in the Littorinoidea than in the other six superfamilies tested, perhaps accounting its dominance of high-shore habitats where increased thermal tolerance reduces water loss due to evaporative cooling. Similarly, the high-shore superfamilies, Cerithoidea and Neritoidea, also had high mean HCT values. Increasing thermal selection with shore height was reflected in increasing HCT among low-, mid- and high-shore species. HCT did not differ among littorinoidean and nonlittorinoidean snails on low- or high-shores, but was elevated in mid-shore littorinoideans, suggesting retention of the elevated thermal tolerance of this latter group's high-shore ancestors. In contrast, progressive HCT increase with shore height among mid- and high-shore nonlittorinoideans suggests that they evolved from low-shore ancestors. Among all taxa, thermal tolerance increased progressively across rocky shores, mangroves and salt marshes. Littorinoidean snails had greater HCT than nonlittorinoidean snails among all three habitats, suggesting that mangrove and salt-marsh littorinoideans retain the elevated thermal tolerance of their high rocky shore ancestors. In contrast, HCT of nonlittorinoidean snails increased across rocky shore, mangrove and salt marsh habitats suggesting that they pose different thermal selection pressures on species evolving into them from the low-shore.

KEY WORDS: Gastropoda, heat coma temperature, intertidal gastropods, Littorinoidea, thermal adaptation, thermal tolerance, zonation

INTRODUCTION

A plethora of studies describe the thermal tolerance of intertidal invertebrates relative to vertical zonation. Sessile species, such as barnacles, present a fairly clear pattern of increased thermal tolerance with increasing zonation level, elevated thermal tolerance of higher zoned species considered an adaptation to the elevated ambient temperatures associated with insolation during prolonged tidal emersion (reviewed by Newell 1979). The situation for mobile intertidal gastropods is more problematic because they seek temperature microrefugia (McMahon & Yipp 1992, Chapman & Underwood 1996) and are active only during periods of reduced thermal stress (Ruwa & Jaccarini 1988). Thus, their acute upper thermal tolerance limits may not consistently correlate with their vertical distributions (for a review see McMahon 1990). Further, intertidal gastropod mobility results in species having broad, sympatric vertical distributions with extensive species overlap (Broekhuysen 1940, McMahon 1990, Lang et al. 1998) and species vertical distributions changing with season (Vaughn & Fisher 1992). Thus, assignment of gastropods to narrowly defined vertical zones is difficult at best and often impossible.

In a review of their resistance and capacity adaptations, McMahon (1990) hypothesized that intertidal gastropods can be divided into three major zonational groups characterized by unique suites of physiological adaptions. Sublittoral to lower eulittoral species (referred to hereafter as low-shore species) are primarily aquatic, generally not ranging above the mean low tide mark, where they are submerged most of the time (>86%). Thus, low-shore species appear to be adapted to an aquatic existence and usually unable to sustain aerial gas exchange when emerged. Their low shore habitat is more temperature-stable than periodically emersed eulittoral and eulittoral fringe-maritime zone habitats (McMahon 1988, 1990).

Eulittoral gastropod species (referred to hereafter as mid-shore species) are restricted to areas between high and low tide marks where they experience only short-term tidal emersion (<12 h), spending 14–86% of the time in air depending on shore height. Thus, mid-shore species lead an amphibious existence, their adaptations hypothesized to center on remaining active during emersion and immersion. Thus, their aerial and aquatic O_2 uptake rates are generally equivalent even though aerial gas exchange results in extensive evaporative water loss (McMahon, 1990). When emersed in direct sunlight, mid-shore gastropods may evaporatively cool to prevent lethal tissue warming, rapidly rehydrating during subsequent tidal inundation (McMahon 1990, McMahon & Yipp 1992, Lang et al. 1998).

Upper eulittoral fringe-maritime zone species (referred to hereafter as high-shore species) are restricted to regions above the high tide mark where they experience prolonged emersion (8–10 days) between successive spring tides (emersed for 86–98% of the time). Adaptations in this group are hypothesized to center on tolerance of prolonged emersion including elevated temperature tolerance and reduction in O_2 uptake rates during emersion which conserve organic energy stores and minimize evaporative water loss. Thus, some studies indicate that high-shore gastropods have higher acute upper thermal limits than mid-shore species (Broekhuysen 1940, Cleland & McMahon 1990, McMahon 1990, Britton 1992), hy-

E-mail: r.mcmahon@uta.edu

pothesized to allow avoidance of water loss due to evaporative cooling during prolonged emergence (McMahon 1990).

There is little sympatry among gastropod species occupying low-, mid- and high-shore habitats, but much sympatry within them (McMahon 1990), suggesting that adaptation to the physical conditions of any one zone restricts species from occupying others. Thus, it is hypothesized that low temperature tolerance in low-shore species prevents them from surviving the elevated temperatures experienced on mid- or high shores during isolation. Conversely, modification of the respiratory system for aerial as well as aquatic gas exchange is hypothesized to be a liability to mid- and high-shore species in the almost purely aquatic low-shore habitat. Mid-shore snails greatly increase foraging time by remaining active when tidally emersed and appear to have evolved mechanisms, including evaporative cooling and large body size, that allow regulation of body temperature at metabolically efficient levels during insolation. While their acute upper thermal limits are generally greater than those of low-shore species, mid-shore gastropods' capacity for evaporative cooling is hypothesized to have prevented their evolution of the extremely elevated temperature tolerances characteristic of high-shore species (McMahon 1990).

All of the above hypotheses regarding physiological correlates with species zonation patterns hinge on the assumption that thermal tolerance increases with height of occupation on the shore. This assumption is based on a series of studies on the relationship between vertical zonation and thermal tolerance in intertidal gastropods limited to a single shore. On a single shore, the number of species available for comparison is limited, being maximally 6 to 14 species (Broekhuysen 1940, Evans 1948, Fraenkel 1966, 1968, McMahon & Britton 1985, Cleland & McMahon 1990, McMahon 1990, Britton, 1992). Low species numbers on any one shore leads to difficulties in data interpretation as anomalously high or low thermal tolerance values for one or two species make zonational thermal tolerance patterns difficult to discern (for examples see Broekhuysen, 1940, Evans 1948, Fraenkel 1966, 1968, McMahon & Britton 1985, Britton 1992, reviewed by McMahon 1990).

Analysis of data for a restricted number of species from a single or just a few shores also prevents elucidation of latitudinal influences on thermal tolerance and empirical comparisons among taxonomic groups. Only two investigations of intertidal gastropod thermal tolerance have involved two or more geographically separated shores. Fraenkel (1968) studied gastropod thermal tolerance on shores in Bimini, Bahamas, Ocean Springs, Mississippi, and Woods Hole, Massachusetts and Stirling (1982), on shores in Hong Kong and Dar es Salaam, Tanzania. In both studies, differences in the thermal tolerance of the gastropod fauna were recorded between shores, but too few shores were investigated to reveal latitudinal trends. Further, cross-comparison of gastropod thermal tolerance data from studies by different authors on geographically separate shores is also problematic because of incompatible methodologies (Fraenkel 1968, Stirling 1982).

In order to empirically assess the effects of zonation level, latitude, habitat, and taxonomic position on the thermal tolerance of intertidal snails, I investigated acute upper thermal limits in 60 gastropod species from ten geographically separate shores over a latitude range of 12.5 – 54.61°, encompassing three different intertidal habitats (i.e., rocky shore, mangrove and salt marsh) and seven different superfamilies. These data were statistically evaluated for differences in upper thermal limit among tested species relative to latitude, and, with latitude as a covariant, among zonation levels, habitat types and taxa on the superfamilial level.

MATERIAL AND METHODS

Species Collection

Thermal tolerance determinations were carried out on samples of 60 intertidal gastropod species (Table 1) collected at 10 geographically separate sites ranging from 54.61° N to 35.00° S latitude including: Robin Hoods Bay, England (54.61°N, number of species (n) = 6); Filey Head, England (54.21°N, n = 2); Porth Towyn, Wales (53.04°C, n = 1); Woods Hole, Massachusetts (41.54°N, n = 1); Gulf Shores, Alabama (30.35°N, n = 1); Port Aransas, Texas (28.84°N, n = 2); Hong Kong (22.37°N, n = 16); Jamaica (18.46°N, n = 13); Darwin, Australia (12.50°S, n = 12); and Albany, Australia (35.00°S, n = 6). Forty species were from rocky shores, 17 from mangroves and three from salt marshes. Of rocky shore species, 18 occurred on the high shore, 13 on the mid-shore and nine on the low shore. Of 17 tested mangrove species, six were high-shore, nine were mid-shore and two were low-shore species. Of three tested salt marsh species, one was a high-shore and two were low-shore species (Table 1). The tested species included seven superfamilies: 25 species of Littorinoidea, 13 species of Cerithoidea, nine species of Neritoidea; four species of Trochacea; four species of Muricoidea; four species of Ellobioidea; and one species of Onchidoidea (Table 1).

Determination of Heat Coma Temperature

Upper thermal tolerance limit was determined as "heat coma temperature" (HCT) using a method (Cleland & McMahon 1990, McMahon & Britton 1985, McMahon & Russell-Hunter 1981, McMahon 1990) modified from that previously used for intertidal gastropods (Gowanloch & Hayes 1926, Broekhuysen 1940, Evans 1948, Southward 1958). At heat coma temperature, gastropods lose normal nervous function leading to muscle paralysis manifested by cessation of locomotion, loss of substratum attachment, ventral-medial lateral curling of the foot; and cessation of movement including tentacles and radular activity (Cleland & McMahon 1990, McMahon 1976, 1990, McMahon & Payne 1980, McMahon & Britton 1985, McMahon & Cleland 1990, McMahon & Russell-Hunter 1981).

Adult specimens of each species for which HCT was determined were collected at low tide and returned immediately to the laboratory. A randomly chosen subsample was randomly divided into five to six subsamples of five to six individuals each which were placed into separate, 50 ml test tubes with 40 ml of water from the collection site. Thus, total sample size was 30–36 individuals for most species. Sample size ranged from 17 (*Nerita chamaelon*) to 71 (*Littorina littorea*) (Table 1). Sample sizes greater than 36 individuals resulted when HCT determinations were repeated and their results combined (Table 1: *Batillaria sordida*, *Bembicium vittatum*, *Littorina littorea*, *Littorina saxatilis*, *Monodonta labio*, *Morula musiva*). Porous foam plugs blocked tube openings at the tube water surface, keeping individuals immersed. Subsample shell length range was representative of natural adult populations. Subsamples of larger gastropod species were placed in larger test containers (up to 500 ml), allowing freedom of movement, avoiding over-crowding and preventing severe O_2 depletion during determinations, otherwise all other procedures were identical. These larger containers were glass jars with plastic screw caps. After receiving snails, the plastic caps of larger volume jars were screwed on while the jar was submerged in water

TABLE I.

Mean heat coma temperatures (±standard deviation of the mean) for 60 species of intertidal gastropod collected from different rocky shore, mangrove and salt marsh localities at different latitudes and from different shore heights i.e., zonation levels.

Superfamily	Species	Site	Latitude	Habitat	Zonation level	n	Heat coma temp.
Cerithioidea	*Batillaria minima*	Jamaica	18.46° N	Rocky Shore (TP)	Eulittoral Fringe	30	43.5° C ± 0.97
Cerithioidea	*Batillaria multiformis*	Hong Kong	22.37° N	Mangrove	Lower Eulittoral	30	41.3° C ± 0.79
Cerithioidea	*Batillaria sordida*	Hong Kong	22.37° N	Rocky Shore	Lower Eulittoral	42	40.5° C ± 1.63
Cerithioidea	*Cerithidea ornata*	Hong Kong	22.37° N	Mangrove	Eulittoral Fringe	30	43.3° C ± 2.17
Cerithioidea	*Cerithidea rhizophorarum*	Hong Kong	22.37° N	Mangrove	Eulittoral	38	45.5° C ± 1.11
Cerithioidea	*Cerithideopsilla djadjariensis*	Hong Kong	22.37° N	Mangrove	Lower Eulittoral	38	40.9° C ± 1.26
Cerithioidea	*Cerithium antiquata*	Darwin, Australia	12.50° S	Mangrove	Eulittoral Fringe	28	44.1° C ± 0.31
Cerithioidea	*Clypeomorus* sp.	Darwin, Australia	12.50° S	Rocky Shore	Lower Eulittoral	20	40.1° C ± 1.07
Cerithioidea	*Planaxis nucleus*	Jamaica	18.46° N	Rocky Shore	Lower Eulittoral	25	38.1° C ± 0.71
Cerithioidea	*Planaxis sulcatus*	Hong Kong	22.37° N	Rocky Shore	Eulittoral	36	40.8° C ± 1.13
Cerithioidea	*Telescopium telescopium*	Darwin, Australia	12.50° S	Mangrove	Eulittoral	27	44.4° C ± 1.97
Cerithioidea	*Terebralia palustris*	Darwin, Australia	12.50° S	Mangrove	Eulittoral	30	44.7° C ± 0.84
Cerithioidea	*Terebralia semistriata*	Darwin, Australia	12.50° S	Mangrove	Eulittoral	25	43.0° C ± 2.22
Cerithioidea	*Terebralia sulcata*	Hong Kong	22.37° N	Mangrove	Eulittoral	30	43.6° C ± 1.59
Ellobioidea	*Cassidula angulifera*	Darwin, Australia	12.50° S	Mangrove	Eulittoral	20	37.9° C ± 3.39
Ellobioidea	*Cassidula rugata*	Darwin, Australia	12.50° S	Mangrove	Eulittoral	21	39.3° C ± 1.52
Ellobioidea	*Ellobium auriskadae*	Darwin, Australia	12.50° S	Mangrove	Eulittoral	30	39.2° C ± 0.86
Ellobioidea	*Melampus bidentatus*	Woods Hole, Mass	41.54° N	Salt Marsh	Eulittoral Fringe	25	38.8° C ± 1.12
Littorinoidea	*Bembicium vittatum*	Albany, Australia	35.00° S	Rocky Shore	Eulittoral Fringe	42	40.0° C ± 1.64
Littorinoidea	*Cenchritis muricatus*	Jamaica	18.46° N	Rocky Shore	Eulittoral Fringe	28	42.1° C ± 2.13
Littorinoidea	*Littoraria* sp.	Darwin, Australia	12.50° S	Mangrove	Eulittoral Fringe	23	43.9° C ± 0.87
Littorinoidea	*Littoraria filosa*	Darwin, Australia	12.50° S	Mangrove	Eulittoral Fringe	30	42.9° C ± 1.24
Littorinoidea	*Littoraria irrorata*	Port Aransas, Texas	28.84° N	Salt Marsh	Eulittoral Fringe	33	43.7° C ± 1.38
Littorinoidea	*Littoraria melanostoma*	Hong Kong	22.37° N	Mangrove	Eulittoral Fringe	27	44.3° C ± 1.20
Littorinoidea	*Littoraria scabra*	Hong Kong	22.37° N	Mangrove	Eulittoral Fringe	30	43.3° C ± 1.88
Littorinoidea	*Littorina arcana*	Robin Hoods Bay, Eng.	54.61° N	Rocky Shore	Eulittoral Fringe	35	32.8° C ± 0.94
Littorinoidea	*Littorina brevicula*	Hong Kong	22.37° N	Rocky Shore	Eulittoral Fringe	30	40.1° C ± 1.03
Littorinoidea	*Littorina compressa*	Porth Towyn, Wales	53.04° N	Rocky Shore	Eulittoral Fringe	36	27.6° C ± 0.76
Littorinoidea	*Littorina littorea*	Robin Hoods Bay, Eng.	54.61° N	Rocky Shore	Eulittoral	71	32.0° C ± 0.76
Littorinoidea	*Littorina neglecta*	Robin Hoods Bay, Eng	54.61° N	Rocky Shore	Eulittoral	35	31.8° C ± 1.32
Littorinoidea	*Littorina obtusata*	Robin Hoods Bay, Eng.	54.61° N	Rocky Shore	Lower Eulittoral	26	28.3° C ± 2.78
Littorinoidea	*Littorina mariae*	Robin Hoods Bay, Eng.	54.61° N	Rocky Shore	Lower Eulittoral	21	26.4° C ± 2.60
Littorinoidea	*Littorina saxatilis*	Robin Hoods Bay, Eng	54.61° N	Rocky Shore	Eulittoral Fringe	70	32.8° C ± 0.82
Littorinoidea	*Melaraphe neritoides*	Filey Head, Eng.	54.21° N	Rocky Shore	Eulittoral Fringe	21	34.8° ± 1.40
Littorinoidea	*Nodilittorina dilatata*	Jamaica	18.46° N	Rocky Shore	Eulittoral Fringe	30	45.4° C ± 1.59
Littorinoidea	*Nodilittorina exigua*	Hong Kong	22.37° N	Rocky Shore	Eulittoral Fringe	36	44.8° C ± 1.46
Littorinoidea	*Nodilittorina interrupta*	Port Aransas, Texas	28.84° N	Rocky Shore	Eulittoral Fringe	30	44.4° C ± 1.36
Littorinoidea	*Nodilittorina mespillum*	Jamaica	18.46° N	Rocky Shore (TP)	Eulittoral Fringe	30	45.6° C ± 2.19
Littorinoidea	*Nodilittorina pyramidalis*	Hong Kong	22.37° N	Rocky Shore	Eulittoral Fringe	35	46.3° C ± 0.71
Littorinoidea	*Nodilittorina rusca*	Jamaica	18.46° N	Rocky Shore	Eulittoral	30	45.3° C ± 1.68
Littorinoidea	*Nodilittorina unifasciata*	Albany, Australia	35.00° S	Rocky Shore	Eulittoral Fringe	30	41.1° C ± 1.24
Littorinoidea	*Nodilittorina ziczac*	Jamaica	18.46° N	Rocky Shore	Eulittoral Fringe	30	46.9° C ± 2.68
Littorinoidea	*Tectarius antoni*	Jamaica	18.46° N	Rocky Shore	Eulittoral Fringe	27	43.4° C ± 1.65
Muricoidea	*Lepsiella vinosa*	Albany, Australia	35.00° S	Rocky Shore	Eulittoral	30	39.2° C ± 0.96
Muricoidea	*Morula musiva*	Hong Kong	22.37° N	Rocky Shore	Lower Eulittoral	60	39.6° C ± 0.64
Muricoidea	*Nucella lapillus*	Filey Head, Eng.	54.21° N	Rocky Shore	Lower Eulittoral	36	29.6° ± 1.38
Neritoidea	*Nerita atramentosa*	Albany, Australia	35.00° S	Rocky Shore	Eulittoral	30	38.8° C ± 2.14
Neritoidea	*Nerita balteata*	Darwin, Australia	12.50° S	Mangrove	Eulittoral	28	41.1° C ± 1.08
Neritoidea	*Nerita chamaeleon*	Hong Kong	22.37° N	Rocky Shore	Eulittoral Fringe	17	43.3° C ± 0.69
Neritoidea	*Nerita peloronta*	Jamaica	18.46° N	Rocky Shore	Eulittoral	29	40.8° C ± 1.90
Neritoidea	*Nerita tessellata*	Jamaica	18.46° N	Rocky Shore	Eulittoral	30	40.9° C ± 1.20
Neritoidea	*Nerita versicolor*	Jamaica	18.46° N	Rocky Shore	Eulittoral	60	42.3° C ± 1.39
Neritoidea	*Neritina reclivata*	Gulf Shores, AL	30.35° N	Salt Marsh	Lower Eulittoral	30	41.3° ± 0.70
Neritoidea	*Neritina virginea*	Jamaica	18.46° N	Rocky Shore	Eulittoral	30	45.4° C ± 1.16
Neritoidea	*Puperita pupa*	Jamaica	18.46° N	Rocky Shore (TP)	Eulittoral Fringe	30	44.6° C ± 1.81
Onchidioidea	*Onchidium* sp.	Darwin, Australia	12.50° S	Rocky Shore	Lower Eulittoral	30	37.0° C ± 1.20
Trochacea	*Austrocochlea constricta*	Albany, Australia	35.00° S	Rocky Shore	Eulittoral	30	37.5° C ± 1.17
Trochacea	*Austrocochlea concamerata*	Albany, Australia	35.00° S	Rocky Shore	Eulittoral	30	35.6° C ± 0.82
Trochacea	*Lunella coronata*	Hong Kong	22.37° N	Rocky Shore	Lower Eulittoral	30	38.8° C ± 1.02
Trochacea	*Monodonta labio*	Hong Kong	22.37° N	Rocky Shore	Eulittoral	60	37.4° C ± 1.92

TP = Rocky shore species restricted to tide pool habitats

from the collection site in order to exclude all air bubbles and keep individuals immersed.

Containers holding snail subsamples were placed in a water bath to a depth at which bath water level exceeded test tube water level or was equivalent to that in the glass jars. Uniform bath water temperature was maintained by vigorous aeration or a circulating pump. The bath heater switch was manually controlled to raise bath water temperature and, therefore, container water temperature, at a rate of approximately 1°C 5 min^{-1}. This rate of increase makes lag between container water and snail tissue temperatures negligible (Broekhuysen, 1940). Container water temperature was monitored with a thermistor probe extended through the foam test tube plug or a small hole in the jar cap and connected to a YSI model 43-TD tele-thermometer or an eomega 866 Thermometer. Bath water temperature was monitored with a laboratory-grade mercury thermometer or separate thermistor probe.

Each HCT determination began at room temperature (19–26°C, dependent on laboratory ambient temperature). Prior to HCT determination, snails were allowed to attach to container walls and actively locomote. Individuals remaining inactive (i.e., not pedally attaching) during determinations where not included in HCT computations, occasionally reducing sample size below the initial 30 or 36 individuals placed in chambers (Table 1). Number of individuals displaying heat coma symptoms in each container was recorded at every 1°C increase in chamber water temperature. Container water temperature was increased at 1°C 5 min^{-1} until all previously active individuals in all subsamples displayed heat coma symptoms. Thereafter, containers were removed from the bath, partially decanted, and allowed to cool to room temperature. Snails remained in the containers and their recovery observed after a 1–12 h post-treatment return to room temperature (i.e., observed for re-attachment and/or active locomotion).

Included in the data set were HCT determinations for seven species of Jamaican littorinoidean snails (*Cenchritis muricatus, Tectarius antonii, Nodilittorina dilatata, Nodilittorina ziczac, Nodilittorina angustior, Nodilittorina riisei* and *Nodilittorina mespillum*, Table 1) determined by Britton (1992) utilizing the same methodology described above. Across all 60 tested species, HCT was determined for a total of 1,945 individuals.

RESULTS

Correlation of Species' Heat Comma Temperature with Latitude

A high proportion of individuals (> 90–95%) in all tested species recovered from heat coma on cooling to room temperature. For some species, individual subsamples were removed from the bath at sequentially higher temperatures subsequent to entering heat coma. Among these species, lethal acute temperature exposures occurred approximately 3–7°C above HCT, indicating that heat coma is a reversible, nonlethal condition in intertidal gastropods as it is in freshwater gastropods (McMahon 1976, McMahon & Payne 1980).

Mean HCT values among the 60 tested species ranged from a low of 26.4°C for the low-shore littorinoidean, *Littorina mariae*, from Robin Hoods Bay, England (54.61°N) to a high value of 46.9°C for the high-shore littorinoidean, *Nodilittorina ziczac*, from Jamaica (18.4 N) (Table 1). Across all tested individuals, HCT was negatively correlated with latitude (Fig.1A). The relationship between individual HCT and latitude as the controlled variable was best modeled by a quadratic equation:

$$\text{HCT (°C)} = 39.83 + 0.29\ (\text{°Lat}) - 0.0083\ (\text{°Lat}^2)$$
$$(n = 1{,}945,\ \text{d.f.} = 2,\ r^2 = 0.681,$$
$$F = 2071.0,\ P < 0.00001),$$

whose r^2 value indicated that correlation with latitude explained 68% of observed HCT variation (Fig. 1A). Fitting of HCT data for all tested individuals in the superfamily, Littorinoidea (25 species) to a quadratic equation against latitude as the controlled variable yielded the following result:

$$\text{HCT (°C)} = 41.99 + 0.30\ (\text{°Lat}) - 0.0091\ (\text{°Lat}^2)$$
$$(n = 836,\ \text{d.f.} = 2,\ r^2 = 0.855,$$
$$F = 2455.4,\ P < 0.00001),$$

whose r^2 value indicated that correlation with latitude explained 86% of HCT variation (Fig. 1A). Fitting of HCT data for all tested individuals in superfamilies other than the Littorinoidea (35 species) to a quadratic equation against latitude as the controlled variable yielded the following result:

$$\text{HCT (°C)} = 39.59 + 0.25\ (\text{°Lat}) - 0.0078\ (\text{°Lat}^2)$$
$$(n = 1109,\ \text{d.f.} = 2,\ r^2 = 0.409,$$
$$F = 382.75,\ P < 0.00001),$$

whose r^2 value indicated that correlation with latitude explained 41% of HCT variation (Fig. 1). Mean HCT values for littorinoidean species and nonlittorinoidean species fell close to that predicted by quadratic fits of HCT to latitude (Fig. 1A).

Differences in the HCT among Taxonomic Groups

The elevated intercept and slope values of quadratic equations relating HCT to latitude among individuals of littorinoidean and nonlittorinoidean species suggested that, over tested latitudes, littorinoidean species had generally higher HCT than nonlittorinoidean species. This hypothesis was tested by Analysis of Covariance (ANCOVA) of HCT with taxonomic groups as treatments (i.e., Superfamily Littorinoidea versus nonlittorinoidean species) and both latitude of collection and latitude of collection squared as covariates. Use of latitude and latitude squared as covariates in this analysis removed the influence of the negative quadratic relationship with latitude on treatment mean HCT values (see above), allowing the direct effects of the treatments to be statistically assessed. The analysis yielded species' mean HCT values that were "adjusted" to eliminate latitude effects, hereafter referred to as "adjusted mean HCT" values. ANCOVA revealed that the adjusted mean HCT of littorinoidean snails (±95% confidence limits of the mean) (41.1°C ± 0.446, n = 836) was significantly greater than that of nonlittorinoidean species (38.43°C ± 0.209, n = 1,109) (n = 1945, d.f. = 1, F = 401.7, $P < 0.00001$) (Fig. 1B).

ANCOVA with latitude and latitude^2 as covariates also revealed differences in HCT among the seven superfamilies represented in the data set (n = 1945, d.f. = 6, F = 169.6, $P <$ 0.00001). A *post hoc* Scheffe pair-wise comparison test revealed significant differences ($P < 0.05$) among superfamily adjusted mean HCT values (Fig. 2). The Littorinoidea had a higher adjusted mean HCT (42.2°C ± 0.446, n = 836) than the other six superfamilies represented. Adjusted mean HCT of the Cerithoidea (40.8°C ± 0.237, n = 423) and Neritoidea (40.6°C ± 0.277, n = 284) where not different, but were significantly greater than those of the Muricoidea (39.0°C ± 0.808, n = 126), Ellobioidea (38.6°C ± 0.386, n = 96), Trochacea (36.6°C ± 0.287, n = 150) and

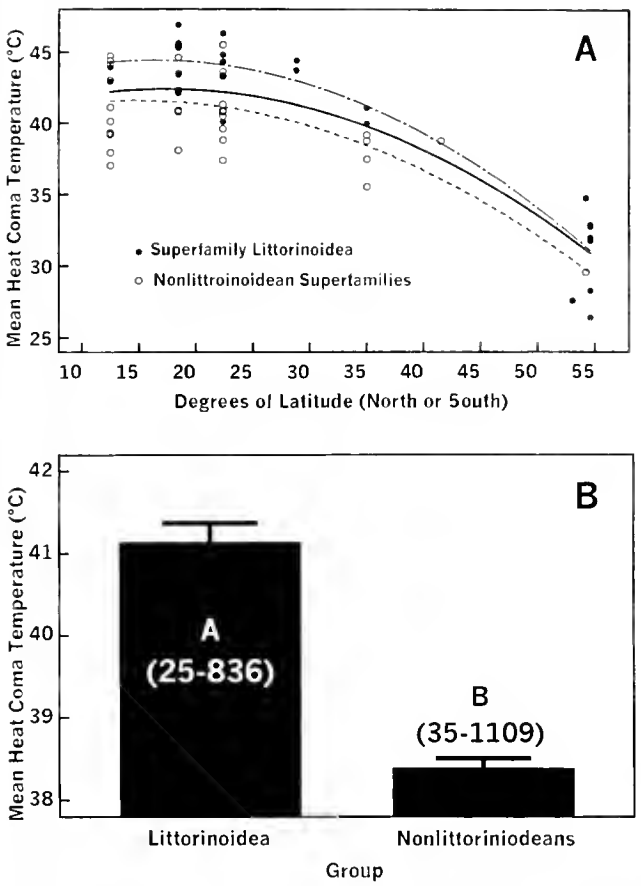

Figure 1. A. Relationship between heat coma temperature (HCT) (vertical axis) and degrees of latitude of collection (horizontal axis) among subsamples of 60 species of intertidal snails. Solid circles represent the mean HCT values for species in the superfamily, Littorinoidea, while open circles are those of species in nonlittorinoidean superfamilies. The solid line represents the best quadratic regression fit of HCT to latitude of collection for all tested individuals, the dot-dashed line, the best fit for littorinoidean snails and the dashed line, the best fit for nonlittorinoidean snails (See Results for regression parameters). B) Adjusted mean heat coma temperatures (HCT) (vertical axis) for littorinoidean and nonlittorinoidean snails. Different letters inside or above histograms indicate significant difference ($P < 0.05$) between means. Numbers within or above the histograms represent the number of species represented in the sample (left of dash) and number of individuals (right of dash) on which means were based. Error bars are 95% confidence limits of the mean.

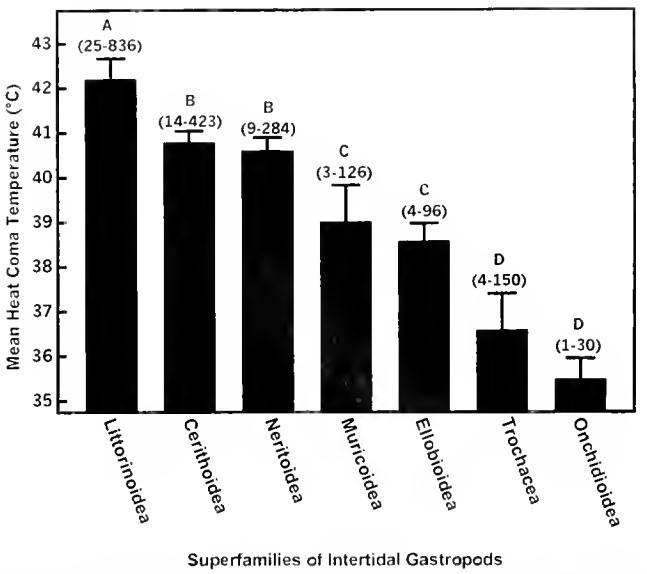

Figure 2. Adjusted mean heat coma temperatures (vertical axis) for snails representing seven different superfamilies of intertidal gastropods (horizontal axis). Vertical bars above histograms represent 95% confidence limits of the mean. Different letters above the histograms indicate significant differences between means ($P < 0.05$). Numbers above the histograms represent the number of species represented in the sample (left of dash) and number of individuals (right of dash) on which means were based.

Onchidioidea (35.5°C ± 0.457, $n = 30$). The adjusted mean HCT of the Muricoidea and Ellobioidea were not different, but were significantly less ($P < 0.05$) than those of the Littorinoidea, Cerithoidea and Neritoidea and greater than those of the Trochacea and Onchidioidea ($P < 0.5$). The adjusted mean HCT of the Trochacea and Onchidioidea did not differ and were significantly lower ($P < 0.05$) than those of all five other superfamilies (Fig. 2).

Differences in HCT among Zonation Levels and Habitat Types

ANCOVA with latitude and latitude^2 as covariates revealed significant differences in adjusted mean HCT of individuals relative to zonation level ($n = 1945$, d.f. = 2, $F = 340.3$, $P < 0.00001$). A *post hoc* Scheffee pair-wise comparison test indicated that the adjusted mean HCT of low-shore (37.5°C ± 0.515, $n = 380$), mid-shore (39.4°C ± 0.320, $n = 750$) and high-shore snails (41.4°C ± 0.362, $n = 815$) differed significantly from each other ($P < 0.05$), thermal tolerance increasing with zonation level (Fig. 3A).

ANCOVA with latitude and latitude^2 as covariates also revealed significant differences in adjusted mean HCT of individuals relative to habitat (n = 1945, d.f. = 2, $F = 23.9$, $P < 0.00001$). A *post hoc* Scheffee pair-wise comparison test indicated that the adjusted mean HCT of rocky shore (40.2°C ± 0.292, $n = 1,370$), mangrove (41.1°C ± 0.228, $n = 479$) and salt marsh snails (41.7°C ± 0.486, $n = 88$) all differed significantly ($P < 0.05$), rocky-shore snails being least thermally tolerant and salt-marsh snails, most tolerant (Fig. 3B).

A multiple factor ANCOVA with latitude and latitude^2 as covariates and zonation level and taxonomic group (i.e., littorinoidean versus nonlittorinoidean snails) as treatments, revealed significant differences in the adjusted mean HCT of snails by zonation level (d.f. = 2, $F = 154.1$, $P < 0.00001$) and taxonomic group (d.f. = 1, $F = 23.5$, $P < 0.00001$) with significant interaction between treatments (d.f. = 2, F = 48.9, $P < 0.00001$). Adjusted mean HCT values and 95% confidence limits for each treatment combination were: low-shore littorinoideans, 35.1°C ±0.832, $n = 47$; mid-shore littorinoideans, 39.8°C ±0.963, $n = 136$; high-shore littorinoideans, 39.4°C ±0.463, $n = 653$; low-shore nonlittorinoideans, 35.5°C ±0.389, $n = 333$; mid-shore nonlittorinoideans, 36.7°C ±0.259, $n = 614$; and high-shore nonlittorinoideans, 39.2°C ±0.362, $n = 162$ (Fig. 4A). *Post hoc* Scheffe pair-wise comparisons indicated that adjusted mean HCT for all snails significantly increased ($P < 0.05$) with zonation level (i.e., across low-shore, mid-shore and high-shore zones) (Fig. 4A). Adjusted mean HCT did not differ among littorinoidean and nonlittorinoidean snails in either the low-shore or high-shore zones, but

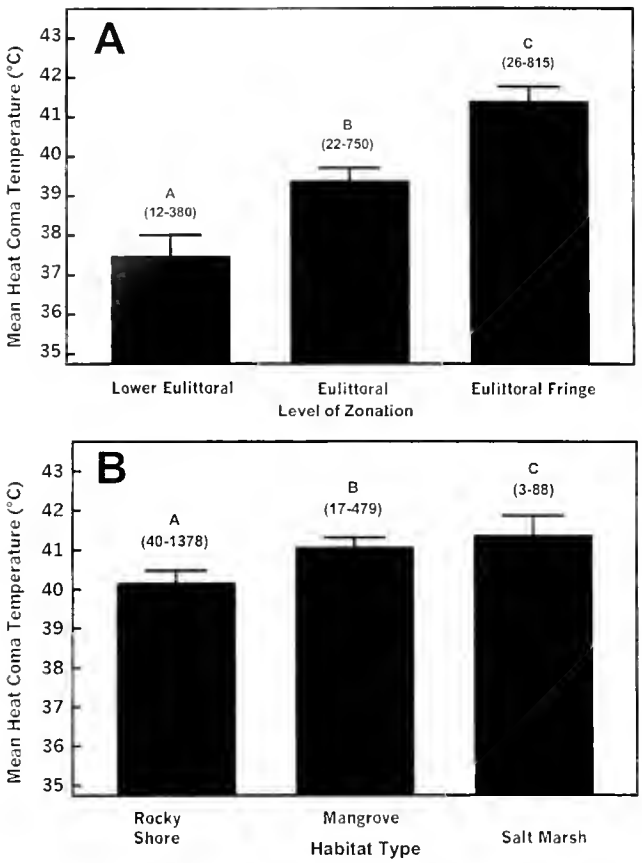

Figure 3. (A) Adjusted mean heat coma temperatures (vertical axis) for intertidal snails relative to zonation level (horizontal axis). (B) Adjusted mean heat coma temperatures (vertical axis) for intertidal snails relative to habitat type (horizontal axis). In both figures, vertical bars above histograms represent 95% confidence limits of the mean. Different letters above the histograms indicate significant differences between means ($P < 0.05$). Numbers above the histograms represent the number of species represented in the sample (left of dash) and number of individuals (right of dash) on which means were based.

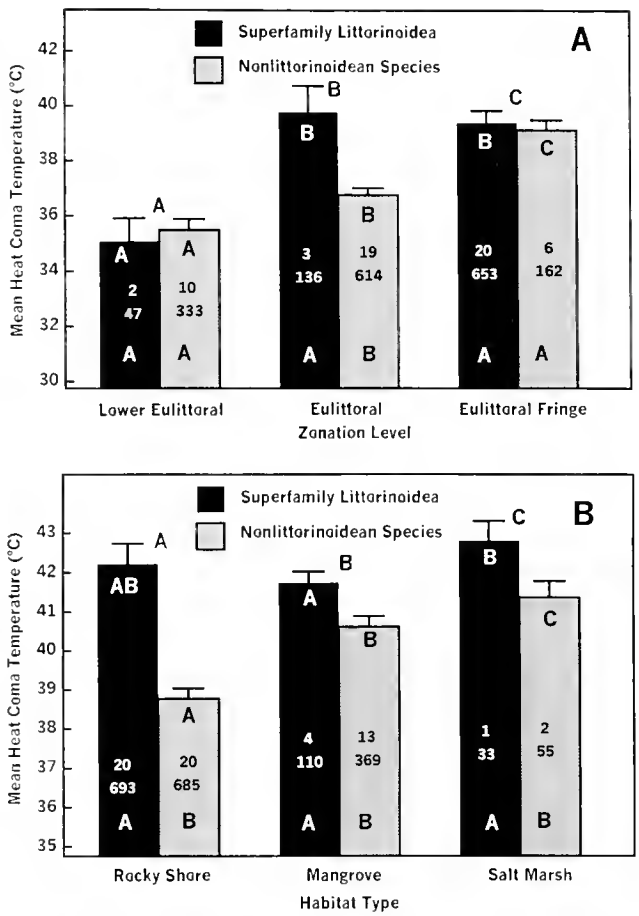

Figure 4. (A) Adjusted mean heat coma temperatures (HCT) (vertical axis) for intertidal snails relative to zonation level (horizontal axis) among individuals within (black histograms) and without (gray histograms) the superfamily Littorinoidea. (B) Adjusted mean heat coma temperatures (vertical axis) for intertidal snails relative to habitat type (horizontal axis) among individuals within (black histograms) and without (gray histograms) the superfamily Littorinoidea. For both figures, vertical bars above histograms represent 95% confidence limits of the mean. Different letters at the base of the histograms indicate significant differences between mean HCT ($P < 0.05$) for littorinoidean versus nonlittorinoidean snails within a specific habitat. Different letters near the top of the histograms indicate significant differences between mean HCT ($P < 0.05$) for littorinoidean and nonlittorinoidean snails, respectively, across different habitats ($P < 0.05$). Different letters above pairs of histograms for littorinoidean versus nonlittorinoidean snails indicate significant differences in the combined mean HCT for both groups across different habitats. Numbers within the histograms represent the number of species represented in the sample (upper number) and number of individuals (lower number) on which the means were based.

was significantly greater ($P < 0.05$) among littorinoidean versus nonlittorinoidean mid-shore snails. Within the Littorinoidea, adjusted mean HCT was significantly lower in low-shore snails ($P < 0.05$) relative to mid-shore or high-shore species among which adjusted mean HCT did not differ. Among nonlittorinoidean snails, adjusted HCT increased significantly ($P < 0.05$) across all zonation levels (Fig. 4A).

A multiple factor ANCOVA with latitude and latitude^2 as covariates and habitat type and taxonomic group (i.e., Littorinoidea versus nonlittorinoideans) as treatments revealed significant differences in the adjusted mean HCT of snails among different habitats (d.f. = 2, $F = 21.4$, $P < 0.00001$) and taxonomic groups (d.f. = 1, $F = 89.2$, $P < 0.00001$) with significant treatment interaction (d.f. = 2, $F = 29.9$, $P < 0.00001$). Adjusted mean HCT values and 95% confidence limits for each treatment combination were: littorinoideans on rocky shores (42.2°C ± 0.508, $n = 693$), littorinoideans in mangroves (41.7°C ± 0.277, $n = 110$), littorinoideans in salt marshes (42.8°C ± 0.495 $n = 33$), nonlittorinoideans on rocky shores (38.8°C ± 0.275 $n = 685$), nonlittorinoideans in mangroves (40.6°C ± 0.279, $n = 369$), nonlittorinoideans in salt marshes (41.4°C ± 0.423, $n = 55$) (Fig. 4B). A *post hoc* Scheffe pair-wise comparison test indicated that adjusted mean HCT for all snails differed significantly ($P < 0.05$) among habitats, with rocky shore species having the lowest adjusted mean HCT, mangrove species having intermediate HCT and salt marsh species having the highest HCT (Fig. 4B). In all three habitats, littorinoidean species had significantly higher ($P < 0.05$) adjusted mean HCT values than nonlittorinoidean species. Within the Littorinoidea, adjusted mean HCT of rocky shore snails was not different from that of either mangrove or salt-marsh snails, however that of mangrove species was significantly lower than that of salt-marsh species ($P < 0.05$) (Fig. 4B). In contrast, adjusted mean HCT significantly varied ($P < 0.05$) among nonlittorinoidean

species in all three habitats, being least in rocky shore species, intermediate in mangrove species and greatest in salt marsh species (Fig. 4B).

DISCUSSION

Review of the literature indicates that the thermal tolerance of intertidal invertebrates tends to increase with decreasing latitude, species adapting to warmer, lower-latitude habitats by evolving increased tolerance (Vernberg & Vernberg 1972). Only two studies have examined intertidal gastropod upper thermal limits comparatively across geographically separate areas. Tolerance times on chronic exposure to lethal temperatures increased in intertidal gastropod species from lower latitudes among geographic areas including: Woods Hole, Massachusetts (41.5°N); Ocean Springs, Mississippi (30.4°N); and Bimini, Bahamas (24.9°N) (Fraenkel 1968). In contrast, intertidal snail acute upper thermal limits were 0.5–3°C higher at the higher latitude of Hong Kong (22.4°N) compared to that of snails from the lower latitude of Dar es Salaam, Tanzania (8.6°S) (Stirling, 1982). Such conflicting data either results from examination of too few geographic sites and/or relatively narrow latitudinal ranges. Further, use of different thermal tolerance determination techniques by different investigators prevents direct comparison of data across latitudes. In the present study, the same technique for determination of acute thermal tolerance was applied across 60 species from 10 geographically separate sites over a broad latitudinal range of 42.1° (i.e., 12.5–54.6°) encompassing temperate, subtropical and tropical shores. The resulting data indicated that, while species' HCT increased dramatically from temperate to subtropical shores (25–55° latitude), it did not further increase below 25°, resulting in the negative quadratic relationship between HCT and latitude depicted in Fig. 1A. Interestingly, the 25° latitude threshold below which species' HCT stabilized lies quite close to the 23.45° north and south latitudes of the Tropic of Cancer and Tropic of Capricorn, demarcating the tropics.

Within the tropics, temperatures are maximal and annual temperature ranges, minimal, compared to subtropical and temperate habitats. Accordingly, thermal selection pressures in the tropics should not vary latitudinally while outside of the tropics it should decrease with increasing latitude. Thus, Fraenkel (1968) recorded increasing thermal tolerance with decreasing latitude among snails on temperate and subtropical shores (24.9–41.5°N) while Stirling (1982) did not find a similar trend on two tropical shores. Alternately, the thermal tolerance of tropical intertidal snails may lie close to the physiological maximum for gastropods, making it unresponsive to latitudinally mediated thermal selective pressures within tropical latitudes. The acute upper thermal limits of tropical intertidal snails recorded in this study lie near the maxima recorded among the majority of invertebrates with the exception of species restricted to atypically warm habitats such as hot springs (Precht et al. 1973).

Littorinoidean snails have generally been reported to be most thermally tolerant taxon in previous comparative studies of gastropod thermal tolerance on rocky shores (Broekhuysen 1940, Evans 1948, Southward 1958, Fraenkel 1966 and 1968, Stirling 1982, Cleland & McMahon 1990, McMahon 1990, Britton 1992), in mangroves (McMahon & Britton 1985) and in salt marshes (Table 1, see mean HCT values for *Littoraria irrorata*, *Melampus bidentatus*, *Neritina reclivata*). This observation was confirmed by this study in which the adjusted mean HCT for littorinoidean snails was 2.7°C greater than that of nonlittorinoidean snails. Further, the adjusted mean HCT of littorinoidean snails at 42.2°C was significantly greater than those of snails in the six other superfamilies tested (range = 35.5–40.6°C) (Fig. 2). McMahon (1990) hypothesized that the elevated upper thermal limits of intertidal littorinoideans relative to other intertidal snail taxa reduces their dependence on evaporative cooling to maintain body temperatures below critical thresholds during insolation, thus, maximizing their tolerance of emersion by minimizing water loss rates. Thus, the high temperature tolerance of littorinoideans, confirmed in this study, may contribute significantly to their world-wide dominance of the upper eulittoral fringe - maritime zones of rocky shores and mangroves. Indeed, both laboratory (McMahon 1990, McMahon & Yipp 1992) and field studies (Lewis 1963, Vermeij 1971) indicate that high-shore gastropods, particularly littorinoideans, appear to be much less dependent on evaporative cooling to regulate body temperature when emersed in elevated air temperatures than mid- and low-shore species. Interestingly, snails in the superfamilies, Cerithoidea and Neritoidea, had insignificantly different adjusted mean HCT values of 40.8°C and 40.6°C, respectively, which, while significantly lower than those of the Littorinoidea, were significantly greater than the adjusted mean HCT of snails in the other four tested superfamilies (Fig. 2). Along with the Littorinoidea, the Cerithoidea and Neritoidea make up the majority of upper eulittoral fringe-maritime zone species in rocky shore and mangrove habitats, suggesting that elevated thermal tolerance is a universal physiological adaptation among high-shore gastropod species.

The observation that thermal tolerance increases with increasing shore height in intertidal gastropods (Underwood 1979, McMahon 1990) is strongly supported by this study. Thermal tolerance increased significantly with zonation level, low-shore, mid-shore and high-shore snails displaying a progressive increase in adjusted mean HCT of 37.5°, 39.4°, and 41.4°C, respectively (Fig. 3A). Increased thermal tolerance among mid- and high-shore species appears to be a resistance adaption to rapid tissue heating by insolation during tidal excursions. Insolation heats snail tissues equivalently within 30 minutes emersion into direct sunlight in either region (Southward 1958, Grainger 1969). Thus, the higher thermal tolerance of high-shore species reduces reliance on evaporative cooling, increasing emersion tolerance by minimizing water loss (McMahon 1990, McMahon & Yipp 1992, see previous). This pattern of thermal tolerance increasing with zonation level was maintained in both littorinoidean and nonlittorinoidean snails. Among nonlittorinoidean species, adjusted mean HCT was 35.5°, 36.7° and 39.2°C for low-, mid- and high-shore snails, respectively (Fig. 4A), indicative of increasing selective pressure for thermal tolerance with shore height. A different vertical tolerance pattern emerged among littorinoidean snails in which adjusted mean HCT values of mid- and high-shore snails were not different at 39.8° and 39.4°C, respectively, but were both greater than that of low-shore snails at 35.1°C (Fig 4A). Mid- and low-shore species in the subfamily Littorininae appear to have evolved from ancestors occupying the upper eulittoral fringe - maritime zone (Reid 1989, 1996). The results of this research support this hypothesis. Eulittoral littorinoidean species appear to have retained the elevated thermal tolerance characteristic of their high-shore ancestors, suggesting that there may be little selective pressure for its reduction among species evolving from high shore into mid-shore habits. Indeed, the extreme temperatures experienced during insolation may be similar in mid- and high-shore habitats, with only the duration of exposure differing between them (Southward 1958,

Grainger 1969). Thus, among mid-shore species, the adjusted mean HCT of littorinoidean snails (39.8°C) was significantly greater than that of nonlittorinoideans (36.7°C) (Fig. 4A). In contrast, invasion of thermally stable low-shore habitats appears to have resulted in evolution of a reduced thermal tolerance among low-shore littorinoidean species, their adjusted mean HCT (35.1°C) being insignificantly different from that of low-shore nonlittorinoidean species (35.5°C) (Fig. 4A).

There were also significant differences in adjusted mean HCT relative to habitat. That of rocky-shore snails was lowest at 40.2°C, intermediate in mangrove snails at 41.1°C and greatest in salt-marsh snails at 41.7°C (Fig. 3B). While the biological significance of this 1.5°C HCT range among these habitats is debatable, much clearer patterns emerged when differences were separately analyzed among littorinoidean and nonlittorinoidean snails. Adjusted mean HCT was similar among littorinoidean snails from rocky shore, mangrove and salt marsh habitats, ranging from 41.7°C (mangrove) to 42.8°C (salt marsh) (Fig. 4B). There appears to be little selective advantage in the 1.1°C HCT range among these habitats. The relatively minor habitat differences in the thermal tolerance of littorinoidean snails may again reflect their evolutionary history with the majority of mangrove and salt-marsh littorinoidean species likely to have evolved from temperature tolerant high rocky-shore ancestors (Reid 1989). Therefore, it appears that the elevated thermal tolerance of primitive, ancestral, high rocky-shore littorinoideans may have been retained by species evolving from them into mangrove and salt-marsh habitats, reflected by the significantly elevated adjusted mean HCT of littorinoidean relative to nonlittorinoidean snails in all three habitats (Fig. 4B).

In contrast to littorinoidean snails, there were clear habitat differences in the adjusted mean HCT of nonlittorinoidean species. Among nonlittorinoideans, rocky-shore snails had the lowest adjusted mean HCT (38.8°C), with that of mangrove snails being intermediate (40.6°C) and that of salt-marsh snails being greatest (41.4°C), yielding an adjusted mean HCT habitat range of 2.6°C (Fig. 4B). This result suggests that there may be differences in thermal selection pressures among the three tested habitats for nonlittorinoidean snails. Unlike littorinoidean species, the majority nonlittorinoidean intertidal taxa may have radiated up the shore from less thermally tolerant low-shore species, evolution of increased thermal tolerance allowing penetration of mid- and high-shore habitats (McMahon 1990). Rocky shores, particularly boulder shores, offer microrefugia from insolation and thermal stress on vertical rock surfaces, in crevices and beneath boulders. There are much fewer refugia from thermal stress in mangals, particularly among species inhabiting mangrove tree trunks or leaves (McMahon & Britton 1985) perhaps accounting for their greater mean HCT relative to rocky-shore species. However, mangrove snails are generally protected from insolation by the mangal canopy. In contrast, mid-shore and high-shore salt-marsh snails generally inhabit the stems of marsh grasses (McMahon and Russell-Hunter 1981, McMahon 1992), where they are exposed to intense insolation and have no access to thermal refugia. Thus, the increased thermal tolerance of nonlittorinoidean snails from mangrove and salt marsh habitats may have been evolved in response to increased thermal selection pressures and reduced access to thermal refugia in these habitats relative to generally more heterogeneous rocky shores.

ACKNOWLEDGMENTS

Dr. Joseph C. Britton of Texas Christian University graciously provided raw data from his HCT determinations on seven high-shore littorinoidean species from Jamaica for inclusion in the data set and suggestions for improvement of the manuscript. Dr. Peter J. and Gillian Mill most hospitably provided food, lodging, equipment, field assistance, advice, and laboratory space at the University of Leeds during my investigations of the thermal tolerance of British intertidal snails. M. Colette McMahon, with great patience and perseverance, provided field collection and laboratory assistance for many of the species' HCT determinations included in the data set.

LAGOONAL LITTORINIDS: SHELL SHAPE AND SPECIATION

P. J. MILL,* A. P. CLARKE, D. C. SMITH,† J. GRAHAME, AND C.S. WILDING
School of Biology, University of Leeds, Leeds, LS2 9JT, United Kingdom

ABSTRACT Variables related to shell shape have been measured in littorinids from brackish lagoons and coastal sites. After removal of size related effects, the data were analyzed using multivariate techniques. On Canonical Variate 1 there was good separation of the shells of the lagoonal animals from those of animals from the coast and a tidal lagoon. The former, for example, had lighter, and therefore thinner, shells for any given shell size and a smaller jugosity of the aperture lip. The lagoonal shells from Golam Head and the coastal animals from Robin Hood's Bay could each be separated clearly from the other samples. Although there are clear morphometric differences in the shells, it is not possible without appropriate breeding experiments to raise the lagoonal animals from *L. saxatilis* var. *lagunae* (*L. tenebrosa*) to species status. The importance of conserving lagoonal habitats is considered in terms of the preservation of biodiversity.

KEY WORDS: Littorinids, brackish lagoons, *Littorina saxatilis* var. lagunae

INTRODUCTION

There are three clearly recognizable taxa of rough periwinkles on European shores, the ovoviviparous *Littorina saxatilis* (Olivi), and the oviparous *L. arcana* Hannaford Ellis, and *L. compressa* Jeffreys. The last two taxa are non-contentious with regard to their species status. However, *L. saxatilis* has a wide range of habitats and includes populations of differing shell morphology some of which are found in discrete environments. This has led to various attempts to separate taxa from within this complex. Two of these are worthy of further investigation, i.e. *L. neglecta* Bean, which is found in the barnacle zone living sympatrically with "normal" *L. saxatilis* (*L. saxatilis* B) (Grahame et al. 1995, Hull et al. 1999), and *L. tenebrosa* (Montagu) which occurs in brackish lagoons (Barnes 1993). Two other forms within *L. saxatilis*, H and M, have also been recognized (Hull et al. 1996).

The subject of this paper is on littorinids that inhabit brackish lagoons. There are two problems. Firstly, the use of "*tenebrosa*" is confusing and is hence probably inappropriate (Barnes 1993). In the past it has been used in a very broad sense to include any littorinid with a high-spired shell occurring in sheltered locations including lagoons (Forbes & Hanley 1853). It has also been used in a much more restricted way to include only those littorinids which (a) have a small (usually <6 mm high), very fragile, smooth, plumply-whorled shell which is black or brown and often reticulated, and (b) live permanently submerged on macrophytes (such as *Chaetomorpha*) in brackish lagoons (Muus 1967).

Secondly, the situation is compounded by the presence in some lagoons of littorinids which fit the above description of *L. tenebrosa* whereas in others there are animals which live on the substrate, fit the wider definition of Forbes & Hanley (1853) and may be referred to as *L. saxatilis s.s.* (e.g. Barnes 1987). Furthermore, both forms have been reported as occurring in the same lagoon in some instances (Smith 1982), although Barnes (1993) was only able to find *L. saxatilis s.s.* in the Fleet, Dorset and Cemlyn Lagoon, Anglesey, at which sites *L. tenebrosa* had also previously been reported (Seaward 1980; Barnes 1987).

Muus (1967) and Smith (1982) suggested that the "*tenebrosa*" animals are probably a distinct species, whereas Barnes (1993) concluded that, on the basis of shell variables, this is not the case and that, although the two forms appear to be reproductively isolated, they should be referred to as *L. saxatilis* var. *lagunae*. Reid (1996) also could find no case for species status for this form. In a preliminary study on five allozyme loci, Gosling et al. (1998) concluded that the two forms are genetically differentiated. However, in a more detailed investigation of 12 polymorphic enzyme loci, Wilson et al. (1999) found no allele unique to either form, and concluded that, although there is a barrier to gene flow between them, they are not distinct species.

Barnes' (1993) conclusions were based on five measurements of shell variables and two of operculum variables. The present study extends the number of measured variables and the number of populations in an attempt to clarify the situation, particularly since ecological barriers can result in populations diverging to species status in spite of close similarities at the molecular level (Morell 1999).

MATERIAL AND METHODS

Samples of lagoonal littorinids were obtained from both tidal and isolated habitats (Table 1, Fig. 1). In eastern England 28 lagoons at nine sites were visited. Littorinids were found in only five of these, representing four sites. They were also found in the Fleet in southern England and at Golam Head in the west of Ireland.

The Fleet is a tidal lagoon, open at its eastern end to the English Channel; the sample was taken from gravel on the seaward side of the lagoon near its eastern end (East Fleet). At Golam Head the sample was taken from the landward end of the lagoon near a small freshwater inlet and about 100 m from the seaward end. The animals were completely submerged on the alga *Chaetomorpha*. At its seaward end there are rocks which are continuous with those of the adjacent shore. At Alderton the lagoon is surrounded by shingle on its seaward side and is separated from the sea by a shingle dune about 6 m high. The animals occurred over a short stretch on this side; they were found on small stones near and at the water's edge and on the surface of the mud. Lagoonal littorinids were found in two lagoons at Cley which again were separated

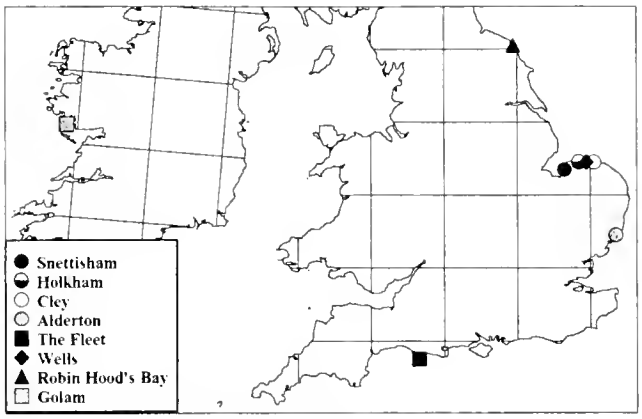

Figure 1. Location of sampling sites in Britain and Ireland.

from the sea by a gravel dune about 7 m in height. They occurred both on algal (*Chaetomorpha*) mats and on stones. At Holkham the lagoon was on the landward side of a very mature dune about 8 m in height covered in trees (Scot's Pine, Holm Oak, and Birch) and bushes. Similarly, the lagoon itself was largely surrounded by trees and bushes. The animals were found on the seaward side of the lagoon completely submerged on the alga *Chaetomorpha*, although some were also found on submerged wood. At Snettisham the lagoon was separated from the sea by a mature sand dune about 6 m in height. The animals were found completely submerged on stones well away from the edges of the lagoon.

At Golam Head tidal incursions occur on spring tides (Wilson et al. 1999). At Snettisham, sea water incursions are unlikely and would certainly be rare; at Alderton and, particularly, at Cley they would probably be even less likely, while at Holkham the only possible connection with sea water would be underground through the substrate. All of the lagoonal sites except Holkham were open and devoid of tall vegetation in their immediate vicinity. There were no coastal sites with littorinids in the close proximity of Alderton, Cley or Snettisham; the nearest coastal site to Holkham is 2.35 km away at Wells-next-the-sea. The condosity of the water was checked at Alderton and Cley and was in excess of 85% seawater.

Other samples were taken from rocky shores on the coast or, in the case of Golam Head, at the entrance to a lagoon (Table 1, Fig. 1). The sample from Golam Head was taken at the seaward end of the lagoon where the rocky shore merged with the edge of the lagoon, providing a very sheltered habitat. This was about 100 m from the site where the lagoonal sample was collected. The sample from Wells-next-the-sea was the closest site to the lagoon at Holkham (2.35 km). Robin Hood's Bay was chosen as representing a typical, somewhat sheltered, east coast boulder site.

The conventional measurements used in previous studies of

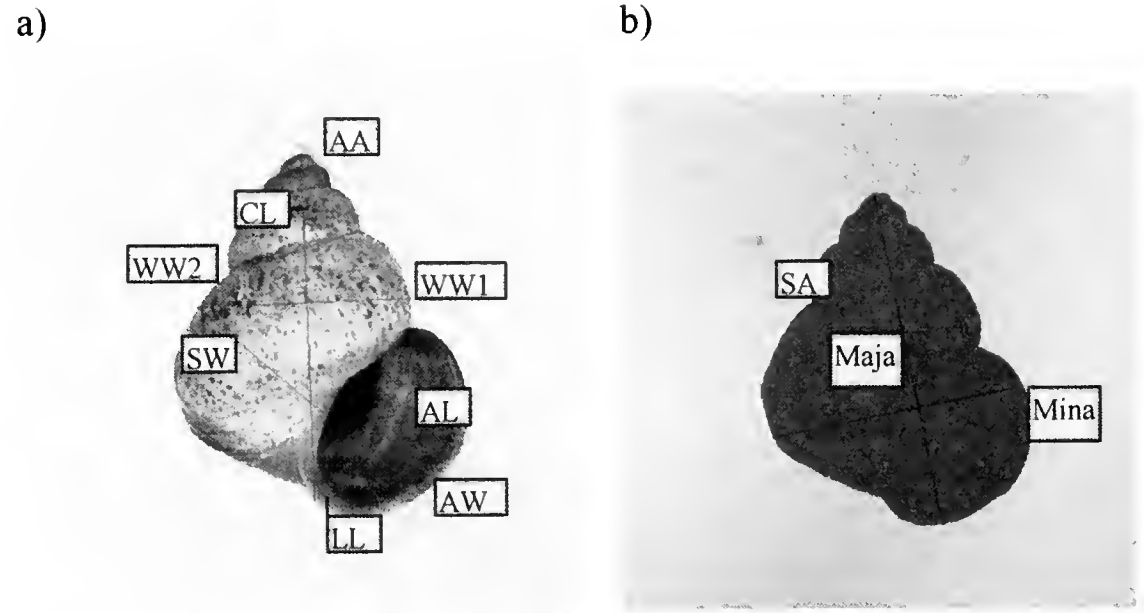

Figure 2. The measurements made on (a) the shell profile and (b) the shell silhouette. AA, apical angle, AL, aperture length (excluding the lip); AW, aperture width; CL, columella length; LL, lip length; Maja, major axis; Mina, minor axis; SA, surface area (in profile); SW, shell width (excluding aperture width); WW1, whorl width 1 (width of whorl at right angles to the columella axis); WW2, whorl width 2 (across the suture between the first and second whorls). In addition shell weight was measured.

littorinids were made, i.e. columella length, lip length, aperture length, width of first whorl at right angle to the columella axis, width of shell minus the aperture, aperture width, width of the suture between the first two whorls and the apical angle (Grahame et al. 1995). Three additional measurements were made, i.e. major axis (maximum linear dimension), minor axis (maximum linear dimension at right angles to the major axis) and shell profile area (Fig. 2). The shells were also weighed.

Canonical Discriminant Analysis, Principal Component Analysis, Factor Analysis and Discriminant Analysis were all carried out on the data after removing the effects of size by standardizing using the geometric mean (except of course for apical angle). Discriminant analysis was also carried out on the raw data.

RESULTS

The animals from Holkham and Golam Head were identified provisionally as *L. tenebrosa* on the basis that they lived permanently submerged on *Chaetomorpha*, their shells were less than 8 mm high and, particularly in the case of those from Holkham, were plumply whorled (Fig. 3a, b). Animals from East Fleet, Alderton and Cley possessed shells which were much more pointed (Fig. 3d-f); those from East Fleet reached 9 mm, while those from Alderton and Cley reached about 13 mm and 14 mm in height respectively; they were not permanently submerged. The shells of animals from Snettisham were somewhat intermediate (Fig. 3c); they were rather less bulbous than the Golam and Holkham animals, were found on stones not algae, but were permanently submerged and were less than 7 mm in height.

The shells of the coastal animals from Golam, Wells and Robin Hood's Bay were all fairly pointed and had a clear jugosity (relative aperture lip length) (Fig. 3g-i). Of the lagoonal animals, only the shells of those from East Fleet had anywhere near the same degree of jugosity. The Robin Hood's Bay shells reached a height of about 12 mm; those from Golam and Wells reached about 16 mm.

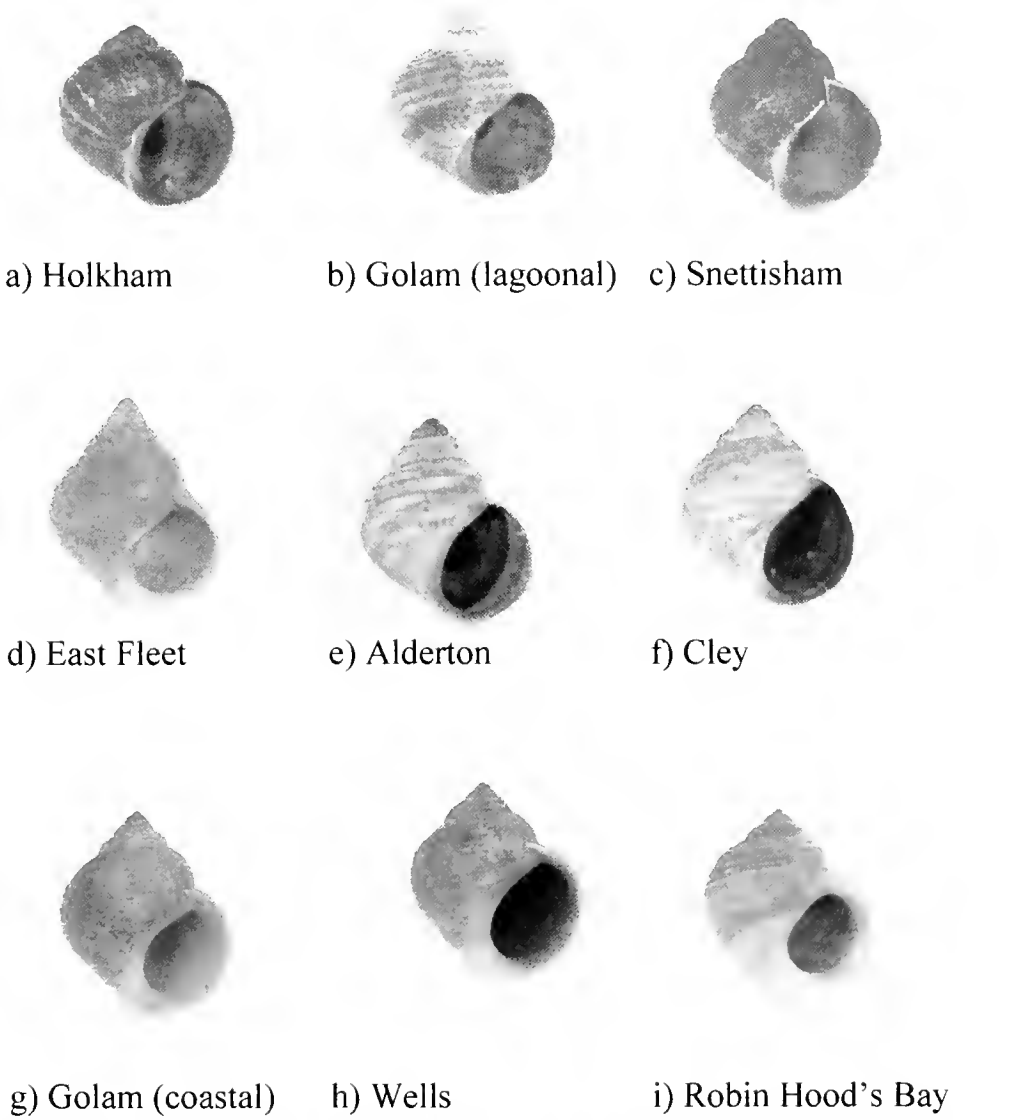

Figure 3. Profiles of shells from the localities stated. All shells are adjusted to the same overall width. Actual columella lengths are: (a) 5.1 mm, (b) 5.1 mm, (c) 5.5 mm, (d) 6.5 mm, (e) 7.2 mm, (f) 6.3 mm, (g) 11.5 mm, (h) 9.0 mm, (i) 9.2 mm.

Dark shading, highest positive values; *light shading*, highest negative values.
* Not a high value using Principal Component Analysis and Factor Analysis.

Canonical Discriminant Analysis indicated that 51% of the variation was attributable to CAN 1, with lip length and shell weight being opposed to surface area, whorl width 1 and major axis length (Table 2). Twenty three percent of the variation was attributable to CAN2, with whorl width 2 and shell width opposed to aperture width and apical angle, and 18% to CAN3, with apical angle opposed to whorl width 2. Principal Component Analysis and Factor Analysis yielded broadly similar results, except that the second and third factors of the Canonical Discriminant Analysis were reversed in order of importance in the other two analyses. However, Whorl Width 2 in PRIN 3 and FACTOR 3 (corresponding to CAN2) was of minor importance. Some of the important relationships revealed by these analyses were explored further.

When shell weight was plotted against major axis length (see CAN1) the regression slopes fell into two clear groups, the shells from the coastal samples, together with those from East Fleet, having steeper slopes than the other (lagoonal) shells (Fig. 4a). Pooling the data from the two groups gave regression lines with a slope of 0.0448 for the lagoonal shells and 0.0604 for the coastal + East Fleet shells (Fig. 4b). There was virtually no overlap between the two sets of data points and the Spearman Rank Correlation Coefficient (r_s) was ≥0.977 in both cases. A plot of lip length against major axis length (see CAN1) separated clearly the coastal samples from the others; for any given major axis length the former always had a longer lip (i.e. greater jugosity). The East Fleet shells were confirmed as having lip lengths intermediate between those of coastal and the other lagoonal samples (Fig. 5a).

Plotting aperture width against shell width (see CAN2) did not separate the samples entirely along coastal versus lagoonal lines. Robin Hood's Bay shells were more similar to those of lagoonal animals, except for lagoonal Golam shells that were grouped with those from East Fleet, coastal Golam, and Wells (Fig. 5b).

The shells from Holkham, Snettisham, Golam (lagoonal) and Robin Hood's Bay had the most obtuse spires, the angle decreasing with increase in Whorl Width 2 (see CAN3). Those from East Fleet were noticeably the most pointed but the angle increased with increase in Whorl Width 2. Thus the separation was again not strictly coastal versus lagoonal (Fig. 5c).

CAN 1 expressed most clearly the separation of coastal and lagoonal animals and this is seen when the three canonical variates

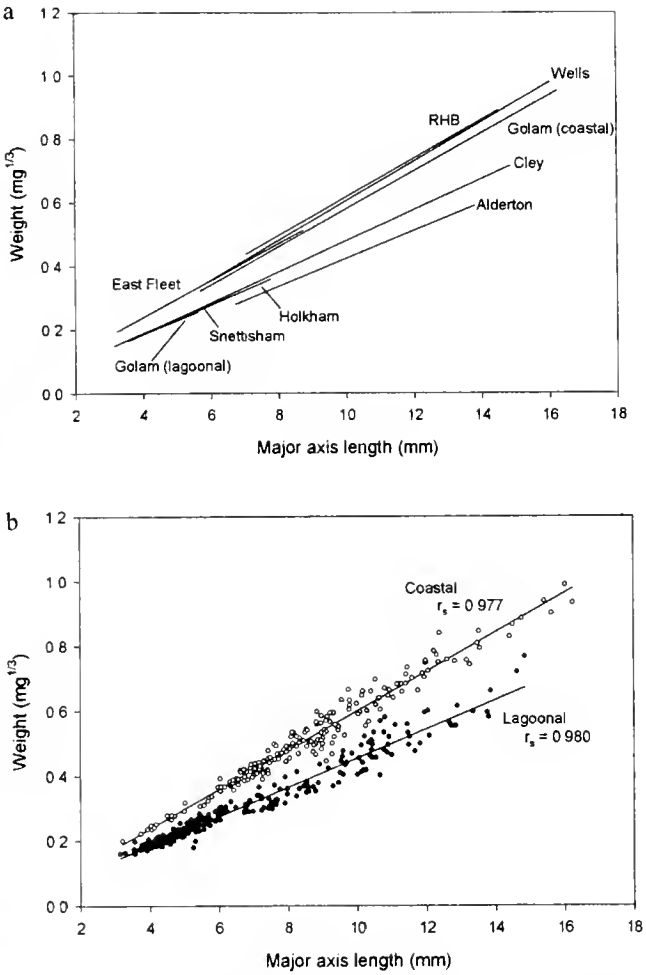

Figure 4. (a) Shell weight ($mg^{1/3}$) plotted against major axis length (mm). Regression lines for each of the nine populations. RHB, Robin Hood's Bay. (b) Shell weight ($mg^{1/3}$) plotted against major axis length (mm). Plots of individual measurements and regression lines for the pooled data. Open circles, coastal sites + East Fleet; filled circles, other lagoonal sites.

are plotted against each other (Fig. 6a). The shells from East Fleet, however, fall into the "coastal" group and indeed there is considerable overlap between them and those from Golam (coastal) and Wells. The coastal shells separate out along the CAN2 and CAN3 axes in the order East Fleet, coastal Golam, Wells and Robin Hood's Bay. The Robin Hood's Bay shells separate out almost completely from the above three samples; the box surrounding the cluster of 50 shells from this site contains only one other shell (from Wells) (Fig. 6a). Amongst the lagoonal shells, the only group that could be separated by rotation of the axes was that from Golam (lagoonal), along the CAN2 and CAN3 axes (Fig. 6b); the box surrounding the cluster of 54 shells contains only one other shell (from Alderton).

Finally a Discriminant Analysis was carried out on the size-adjusted data (Table 3). As expected from the above, the most consistent samples were those from Robin Hood's Bay and Golam (lagoonal), where 98% and 94% of the shells respectively were self classifying. Except for East Fleet, no misclassifications occurred between lagoonal and coastal shells. The shells from Cley showed the greatest degree of misclassification, with 20% classifying to Alderton, 12% to Holkham and 8% to Snettisham. Snettisham shells also had a high proportion of misclassifications, with 19%

Canonical Variable axes at the mid point. ┼, Alderton; *, Cley; ▲, East Fleet; ▼, Golam coastal; ♦, Holkham; ■, Robin Hood's Bay and Golam lagoonal; ●, Snettisham; ✖, Wells. (a) The shells on the left are the coastal + East Fleet, and are separated from the lagoonal shells along the CAN1 axis. The square encloses the 50 Robin Hood's Bay shells plus one from Wells. (b) The square encloses the 54 lagoonal Golam shells plus one from Alderton.

classifying to Holkham, 9% to Cley and 3% to each of Alderton and East Fleet. Amongst the coastal samples, the highest proportion of misclassifications were from the coastal Golam shells, with 24% misclassifying to Wells and 11% to East Fleet. Twelve percent of Wells shells also misclassified to East Fleet. Of the East Fleet shells, 11% misclassified to coastal Golam and 2% to Cley. In most cases, using the raw data (i.e. not excluding size) reduced the proportion of misclassifications.

DISCUSSION

The *Littorina saxatilis* complex includes a wide variety of shell morphs and the taxon is thought to be undergoing differentiation

TABLE 3.

Discriminant analysis of the data after removing the effects of size by standardizing using the geometric mean.

(Fretter 1980, Ward & Warwick 1980) which might have arrived at, or in the future reach, species status for one or more of the morphs. This process is thought to be aided by direct development (Van Marion 1981; Janson 1982; Grahame & Mill 1989) and hence poor dispersal ability (Ward & Warwick 1980; Janson 1983; Janson & Ward 1984; Faller-Fritsch & Emson 1985). However, *L. saxatilis* is a rapid colonizer of offshore islands (Johannesson & Johannesson 1995). Furthermore, two other, closely related taxa, *L. arcana* and *L. compressa*, both show comparatively little variation in shell morphology and yet are direct developers. The main reproductive difference between *L. saxatilis* on the one hand and the other two species on the other, is that the former is ovoviviparous whereas the latter are oviparous.

It is clear from the data that the shells in this study can be separated into coastal + the Fleet and lagoonal, and CAN1 provides an axis for this separation. Lagoonal animals have a lighter shell than correspondingly sized coastal animals; also lagoonal shells lack the jugosity found in coastal populations. The position of the Fleet animals is not surprising as this lagoon is tidal and the sample was taken within a few hundred meters of the lagoon entrance. Of the other lagoonal animals, those from Golam (lagoonal) and Holkham satisfy the strict criteria of Muus (1967) for *Littorina tenebrosa*. However, although the shells from Golam (lagoonal) are clearly separable from those of other lagoonal samples, those from Holkham are not. This is somewhat surprising in view of the subjective impression of the shells (Fig. 3). However, this may be due to the (apparent) intermediate shape of the shells from Snettisham between those from Alderton and Cley on the one hand and those from Holkham on the other.

Barnes (1993) has concluded that there is currently insufficient evidence to accept a species status for *L. tenebrosa* (*sensu* Muus 1967) but that it is clearly distinguishable both in shell characteristics and habitat from *L. saxatilis s.s.* He suggested the varietal name *L. saxatilis* var. *lagunae* for the former.

Although, in the current study, the shells from Golam (lagoonal) separate out from those that came from other lagoons, there appears to be a gradation in shape, size and habitat in the lagoonal populations. It would not be surprising if we are witnessing different degrees of divergence in different lagoonal populations. This might be related to the age of the lagoon and hence to the period of their separation from coastal animals. Only those from Golam and Holkham fulfil all of the criteria for the status of *L. saxatilis* var. *lagunae* but others may have changed partially along this route, particularly those from Snettisham. At Snettisham the animals were found apparently permanently submerged but occurred on the substrate (rocks) rather than on macrophytes. At Cley they were on both the substrate and on floating mats of *Chaetomorpha*, and at Alderton were found on the substrate around the edge of the lagoon. Furthermore, in the last two sites, the animals were not permanently submerged and they reached a size similar to that achieved by the coastal animals. The gradation is reflected in the Canonical Discriminant Analysis, where the two taxa do not separate on the CAN2 axis; indeed the Holkham and Golam (lagoonal) shells fall into different groups when aperture width is plotted against shell width. Similarly, they do not separate on the CAN3 axis. Thus, when apical angle is plotted against whorl width 2, the Snettisham shells align with those from Holkham and Golam (lagoonal), but those from Cley and Alderton are more similar to the Wells and coastal Golam shells respectively.

The current view of speciation is generally that of Mayr (1942) in which a geographical barrier develops between populations, isolating them reproductively from each other. Following this, divergence occurs between the populations, even if the separated habitats are identical, and separate species ultimately evolve. However, there is another possible route for speciation, ecological speciation. Although the idea is not new, it has been brought into focus recently that ecological barriers rather than geographical ones may also be important for speciation (Morell 1999). Thus, ecological pressures could favor changes that eventually cause populations to become reproductively isolated in the absence of geographical barriers. It may be expected that populations that are ecologically separated but genetically similar to each other would be more likely to interbreed than comparable ones that have been separated geographically. However, this is not necessarily the case and size differences between genetically similar populations may be sufficient to produce reproductive isolation (Morell 1999).

It is entirely possible that this is the case with *L saxatilis* var. *lagunae* and *L. saxatilis s.s.*, since the former has clearly developed sexual maturity at a size much smaller than occurs in the latter. Indeed Barnes (1993) has suggested that *L. saxatilis* var.

lagunae may have a paedomorphic origin, as Raffaelli (1979) suggested for another taxon within the *L. saxatilis* complex, i.e. *L. neglecta*, and that, in the case of the former, small size is a requirement of living on submerged macrophytes such as *Chaetomorpha*. It follows from the above that *L. saxatilis s.s.* should interbreed with North American *L. saxatilis* but not with *L. saxatilis* var. *lagunae* occurring in the same lagoon. However, caution is required until the appropriate breeding experiments have been attempted. Furthermore, if, as seems to be the case, parallel evolution is occurring in two or more lagoons, and if the individuals in these populations can interbreed with each other but not with adjacent *L. saxatilis s.s.*, then it follows that any resulting "species" will have a polyphyletic origin.

In only one lagoon (Golam) were both *L. saxatilis* var. *lagunae* and *L. saxatilis s.s.* recorded and they were separated by some 100 m, the former occurring at the landward end of the lagoon, the latter adjacent to the rocky shore. It seems highly likely that the two populations are isolated reproductively (Wilson et al. 1999).

From a conservation point of view it is irrelevant as to whether or not we are dealing with two separate species or two morphs. It could be argued that, if priorities have to be decided, for example because of costs, it is more important to conserve at the species level. However, maximum biodiversity must be preserved so that evolutionary processes are allowed to continue. Brackish lagoons are a nationally rare habitat and have been accorded a "priority habitat type" under Annex 1 of the EU Habitats and Species Directive (Bamber 1998). It may be that many lagoons are very teneral, lasting only tens, or at best hundreds, of years (Bamber 1998), but others may be sufficiently permanent to allow complete separation of species to occur. Hence, it is vital that these lagoonal habitats be conserved.

IS LIFE ON A TROPICAL SHORE REALLY SO HARD?: THE ROLE OF ABIOTIC FACTORS IN STRUCTURING A SUPRALITTORAL MOLLUSCAN ASSEMBLAGE

DWAYNE MINTON* AND DEBORAH J. GOCHFELD†
Hofstra University Marine Laboratory, Priory, St. Ann, Jamaica, West Indies

ABSTRACT Interactions between biotic and abiotic factors are considered to be the principal mechanisms controlling the dynamics of rocky shore communities. Unfortunately, little research has examined how these factors affect community structure of tropical rocky shore assemblages. We examined the effects of wave action and desiccation on a rocky shore molluscan assemblage on the north shore of Jamaica. This assemblage exists entirely above mean high water (MHW), where physical factors were expected to be more important than biological factors. We compared the molluscan assemblage along ten vertical transects exposed to different levels of wave action and desiccation potential. In all, nineteen species of mollusk were observed, thirteen of which occurred on >50% of our transects. We found no differences in species number, individual densities, or the vertical distribution of the species between transects with differing levels of wave action or desiccation potential. Correspondence analysis revealed differences in assemblage structure, but the differences were not associated with wave action or desiccation, suggesting that these physical factors are not operating at the spatial scale studied. However, gastropod mollusks preferentially occupied pit and crevice microhabitats, which are believed to mediate physical stresses. The distribution of these rocky shore mollusks may be the result of the availability of, and competition for, these sheltered microhabitats.

KEY WORDS: Community structure, rocky shore, mollusks, Littorinidae, *Cenchritis*, *Nodilittorina*, *Tectarius*

INTRODUCTION

The supralittoral fringe, the region on the shore above mean high water (MHW), is often characterized as an especially harsh environment in which species are regulated by physical, instead of biological, factors (Underwood 1979, Lang et al. 1998). High temperatures, desiccation, salinity extremes, UV exposure and mechanical wave stress are all potential abiotic factors that can structure the supralittoral community (Garrity 1984, Lubchenco et al. 1984). These physical factors are considered more extreme along tropical than temperate shores (Moore 1972), and may be a stronger regulating mechanism on these tropical communities (Menge et al. 1986, Menge and Sutherland 1987). Unfortunately, few studies have examined community-level dynamics of the supralittoral fringe habitat in the tropics.

The supralittoral fringe in the Caribbean supports a diverse and conspicuous molluscan assemblage. These species exist in overlapping vertical zones, beginning at or near MHW, and experience varying degrees of wave action, but are seldom, if ever, immersed. Desiccation, heat stress, and mechanical wave action have all been shown to affect the behavior of supralittoral gastropods, resulting in limited cyclic activity (Garrity 1984), selective use of microhabitats (Garrity 1984, Peckol et al. 1989), evaporative cooling (Vermeij 1971), formation of multilayer aggregations (Garrity and Levings 1984), and the establishment of shore-level size gradients (Vermeij 1972). How these physical factors affect the structure of the entire molluscan assemblage, however, is poorly understood.

This paper examines the effects of wave action and desiccation on the distribution of molluscan species on an exposed rocky shore on the north shore of Jamaica. Although several species of this assemblage have been the focus of previous research (Britton 1992, Lang et al. 1998, Gochfeld and Minton 2001), no work has examined community-level dynamics of the entire assemblage.

MATERIALS AND METHODS

The exposed rocky shore near the Hofstra University Marine Laboratory, Priory, St. Ann, Jamaica, is a micro-karsted limestone platform rising approximately three meters above MHW and extending landward from 10 to 25 m. It is often exposed to high swell, but is seldom inundated, remaining, for the most part, dry throughout the year.

We selected and permanently marked ten transects (Fig. 1). Transects ran from MHW landward to the position of first vegetation (usually *Rachicallis americana* (Kuntze, 1891), *Coccoloba uvifera* (Linnaeus, 1758), or *Borrichia arborescens* (Linnaeus, 1758)). MHW was easily identified as the lower boundary of a yellow band of microscopic algae (Brattström 1980). Transects varied in length from 190 to 570 cm, were spaced at least 2 m apart, and extended over approximately 100 m of shoreline. Studies on movement of supralittoral gastropods (Gendron 1977, Peckol et al. 1989, Williams 1995, Williams and Morritt 1995, Gochfeld and Minton 2001) suggest that our transects were sufficiently far apart that individual snails would be unlikely to move between them.

We determined the level of wave energy at each transect line by counting wave impacts over five minute intervals on four different days. If a wave impacted above the MHW, it was counted as a strike. If a wave or its resulting splash landed above the yellow (splash) zone on the rock, it was counted as a severe strike. We conducted all ten surveys on a given day within 30 minutes of each other by randomly dividing the transects between two observers. A preliminary investigation showed no significant bias between the observers. Based on the average number of wave strikes, we divided the transects lines into high energy and low energy sites. We compared the number of strikes for the two groups using a one-tailed, two-sample *t*-test with different sample variances.

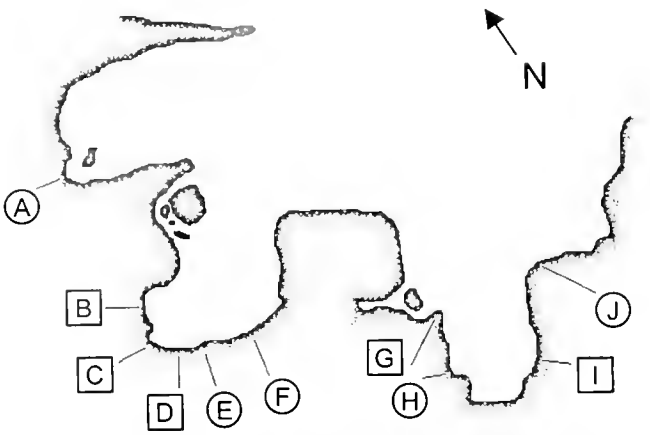

Figure 1. Locations of 10 permanent transects on the exposed shore near the Hofstra University Marine Laboratory, Priory, St. Ann, Jamaica. Squared letters are high energy transects; circled letters are low energy transects.

Desiccation potential on each transect line was measured as the amount of water evaporated from wet sponges after one hour on the shore. Two pre-weighed, 15 × 15 cm sponges, were placed on each transect and wetted with 20 g of water. One sponge was placed at the uppermost end of the transect; the second was placed at the point corresponding to the mid-point of the splash zone. Where necessary, sponges were held in place by monofilament line tied to the rock. After one hour, sponges were placed in labeled re-sealable plastic bags, stored in a cooler and returned to the lab where they were re-weighed using an electronic balance. Prior to use in the field, sponges were dried at 60°C for at least 12 hours. Because we expected wave action to have an effect on desiccation potential, the experiment was repeated on seven calm and seven rough days. Data were analyzed using a three-way ANOVA with transect type (high and low wave energy), vertical shore height (splash zone and above splash zone), and sea condition (calm and rough) as factors.

The slope of the substratum was determined at 15 cm intervals along each transect using a hand-made inclinometer consisting of a t-square, carpenter's level, and pivoting protractor. The device performed adequately, and we were able to reproduce transect profiles on graph paper and estimate the vertical height above MHW at any point along the transect line. Additionally, air and rock temperatures at the uppermost end of each transect line were made using a hand-held thermometer. Rock temperatures were measured by placing the thermometer bulb directly on the rock surface.

To estimate the percent cover of the available microhabitats on our transect lines, we divided a 25 × 25 cm quadrat into a grid with 16 points using string and used the point intercept method to estimate the percent cover of three microhabitat types: (1) exposed surfaces; (2) pits, defined as depressions in the rock large enough to hold a single adult snail of approximately 1 cm length; and (3) crevices, defined as indentations in the rock of sufficient size to hold multiple adult individuals. Quadrants were placed at every meter along each line, and the microhabitat beneath each of the 16 points was determined.

All mollusks within 0.5 m on either side of each transect line were identified to species and their position along the transect line recorded. Several small (<3 mm) individuals of striped littorinids (genus *Nodilittorina*) were found on the shore, and because of difficulties identifying these individuals to species, we designated them as *Nodilittorina* spp. For all coiled gastropods (i.e. littorinids, neritids, etc.), we also recorded the type of microhabitat which they occupied. For each transect line, we determined the position of the splash zone. Using the graphical transect profiles, we converted the positions on the transect lines to vertical heights above MHW. Transects were surveyed over five consecutive days in January 1998 with one randomly selected high and low energy transect surveyed each day.

We tested for differences in species densities, vertical position on the shore, and the vertical breadth of a species' distribution (i.e. range) using MANOVA. Because of limited replication, we reduced the number of dependent variables in the analysis and examined only the five species that occurred on the greatest number of transect lines. Significant results were followed up with multiple univariate ANOVA.

Community structure was compared between transects using correspondence analysis on the species count data, as recommended by Jackson (1997). Only species comprising at least 1% of the total assemblage were included in the analysis.

Data for microhabitat use by transect type was obtained by pooling individuals from the five high and five low energy transects and computing the percent of snails occupying each of the three microhabitats. We examined snail microhabitat use data for differences between high and low energy sites for each of the three microhabitats using *t*-tests.

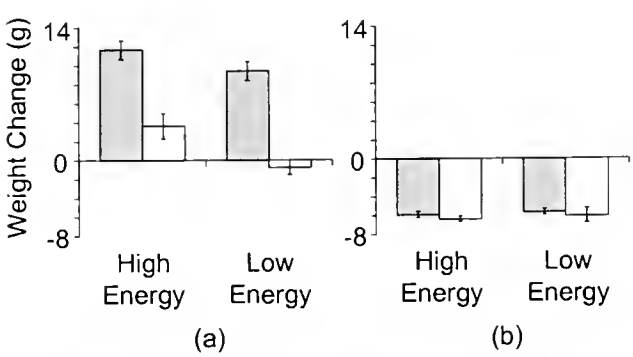

Figure 2. Mean (±SE) change in weight of sponges on high and low energy transects. Sponges were placed at two vertical heights on the shore: (a) in the splash zone; (b) above the splash zone. Solid bars represent replicates conducted on rough days (n = 7). Open bars represent replicates conducted on calm days (n = 7).

RESULTS

High energy transects experienced a significantly greater number of wave strikes (47.9 ± 21.4) compared to low energy transect lines (11.5 ± 8.59; one-tail, two-sample *t*-test, $t = 7.06$, $p < 0.0001$, d.f. = 24). We observed considerable variation in the number of wave strikes from day to day, but regardless of the ocean conditions on any given day, the five high energy transects always experienced greater wave exposure than the low energy transects.

High energy transects also experienced a significantly greater number of severe wave strikes (2.35 ± 3.88) compared to low energy transects (0.5 ± 0.827; one-tail, two sample *t*-test, $t = 2.08$, $p = 0.025$, d.f. = 20). Day to day variation in the number of severe wave strikes was high; on one day, we recorded no severe wave strikes at any of our transects lines, but on another day, we recorded as many as 15 severe wave strikes in a five minute interval at a high energy transect compared to a maximum of one strike at our low energy transects.

Desiccation potential depended upon transect type (high energy or low energy), shore height (in or above the splash zone), and sea conditions (rough or calm) (Table 1). Sponges placed above the splash zone lost on average 5.92 ± 1.62 g of water, regardless of transect type or surf conditions. Change in weight for sponges placed in the splash zone varied with surf conditions and transect type. On rough days, sponges in the splash zone gained an average of 10.49 ± 5.5 g of water regardless of transect type (Fig. 2). On calm days, no significant change in sponge weight was observed (1.45 ± 6.27 g), but sponges at high energy transects often gained water while sponges at low energy transects usually lost water. This result, however, was not manifested in a significant three-way interaction in the ANOVA (Table 1).

Nineteen species of mollusk were recorded during this study (Table 2). All were gastropods, except for two species of polypla-

TABLE 2.

Mean height on the shore (±sd) and density (±sd) for all mollusk species on a Jamaican shore.

Species	Transects occupied		Mean height on shore (cm)	Mean density (Indiv./m^2)	Total individuals
Nodilittorina dilatata (d'Orbigny, 1842)	high	5	69.2 (11.6)	0.311 (0.274)	495

cophorans. The number of species did not differ significantly between high energy (11.40 ± 1.67) and low energy (9.80 ± 3.63) transects (two sample *t*-test, $t = 0.89$, $p = 0.41$, d.f. = 5). *Nodilittorina dilatata* (d'Orbigny, 1842) and *Cenchritis muricatus* (Linnaeus, 1758) were the most abundant snails at both high and low energy transects, forming >30% of each assemblage. The majority of species present formed less than 5% of the assemblage.

Few differences were found in the species composition between high and low energy transects. Thirteen species occurred on >50% of the transect lines. Three species (*Nodilittorina ziczac* (Gmelin, 1791), *Acanthopleura granulata* (Gmelin, 1791), and *Notoacmaea antillarum* (Sowerby, 1831)) occurred on 90% of the transect lines and two species, *Nodilittorina dilatata* and *C. muricatus*, were present on every transect line. Four species (*Thais rustica* (Lamarck, 1822), *Thais* sp., *Diodora cayenensis* (Lamarck, 1822), and *Fissurella barbadensis* (Gmelin, 1791)) were each represented by a single individual and another, *F. nodosa* (Born, 1778) was represented by two individuals. With the exception of *F. barbadensis*, these rare species were found on high energy transects.

The first two components from the correspondence analysis explained 70.8% of the variation (Table 3). A scatter plot of the components (Fig. 3) showed six of the ten transects clustering near the origin. Transects D, E, and F fell outside the cluster as a result of a low component 1 value. *Cenchritis muricatus* contributed most heavily to component 1 (Table 3) and formed a large proportion of the community on these transects (68.8, 77.1 and 41.7%, respectively). Transect 1 is also distinguishable from the cluster due to a low component 2 value. Component 2 receives a large contribution from *Nodilittorina riisei* (Mörch, 1876), and to a slightly lesser extent from *Nodilittorina* spp. and *N. dilatata* (Table 3). The assemblage at Transect 1 is differentiated from other transects by its relatively low percentage of *N. dilatata* (32.5%) and its high percentage of *N. riisei* (25.1%).

Total mollusk densities did not differ significantly between high energy and low energy transects (Mann-Whitney test; $W = 27$; $p = 1.000$). Densities of the five most common species (*Acanthopleura granulata*, *Cenchritis muricatus*, *Nodilittorina dilatata*, *N. ziczac*, and *Notoacmaea antillarum*) also were not significantly different (MANOVA, $\Lambda = 0.353$, $p = 0.367$, d.f. = 5,4). Unfortunately, we did not have sufficient replication to include all species in our analysis, and some trends could not be tested statistically. Densities of *Nodilittorina riisei* on high energy transects were twice those observed on low energy transects, although variation was high. The opposite trend was noted for *Tectarius antonii* (Philippi, 1846) and *Chiton tuberculatus* (Linnaeus, 1759) (Table 2). Again, variation was high, requiring that these observations be viewed with caution.

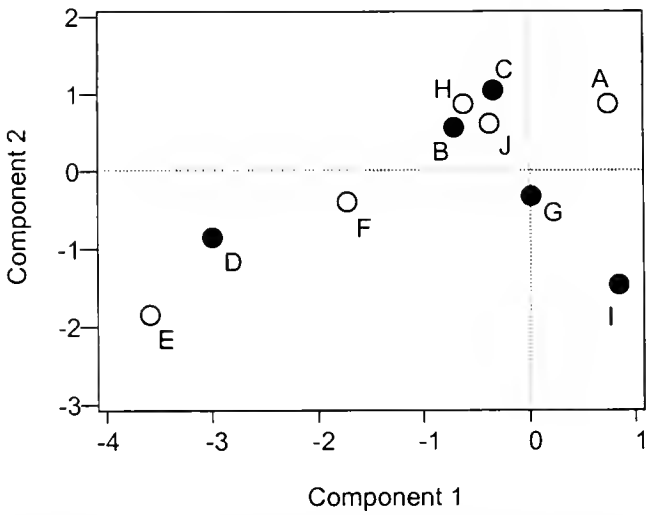

Figure 3. Scatter plot of the scores for components 1 and 2 from the correspondence analysis of the molluscan assemblage. Each point represents one transect line. Open circles are low energy transects; solid circles are high energy transects.

The vertical height on the shore for the five most common species did not differ between high and low wave energy transects (MANOVA, $\Lambda = 0.097$, $p = 0.504$, d.f. = 5,1). No difference between high and low energy transects was observed for the vertical ranges of *A. granulata*, *Nodilittorina dilatata*, *N. ziczac*, and *Notoacmaea antillarum* on the shore (MANOVA, $\Lambda = 0.508$, $p = 0.758$, d.f. = 4,2). We excluded *C. muricatus* from this analysis because its distribution extended beyond the upper limit of our transects.

The five most common species occupied three distinct positions on the shore (ANOVA, $F = 88.68$, $p < 0.001$, d.f. = 4,42; followed by Tukey pairwise comparisons with an overall error of 0.05) (Fig. 4). *Cenchritis muricatus* occurred at the highest shore position, with an average height of 115.67 cm above MHW. *Nodilittorina dilatata* and *N. ziczac* occurred on the mid-shore at average vertical heights of 71.46 and 61.54 cm, respectively. *Acanthopleura granulata* and *Notoacmaea antillarum* occurred lowest on the shore, at 13.13 and 15.55 cm, respectively.

Coiled gastropods preferentially occupied pit microhabitats, regardless of microhabitat availability or vertical position on the shore ($\chi^2 = 428.2$, d.f. = 2, $p < 0.0001$). The exceptions were *C. muricatus*, which showed no preference for pits over crevices and *Nerita versicolor* (Gmelin, 1791), which preferentially occupied crevices at high energy transects (Table 4). Overall, 70.9% of the observed gastropod occupied pits, 23.9% occupied crevices, and only 5.2% occupied exposed surfaces. Conversely, exposed surfaces accounted for >70% of available microhabitats at all levels of the shore (Fig. 5). The availability of microhabitats did not vary between high and low energy transects.

Use of exposed surfaces by gastropods was significantly higher

TABLE 3.

The coordinate (Coor) and contribution (Cont) values for the first two components of the correspondence analysis.

	Component 1		Component 2	
Species	Coor	Cont	Coor	Cont
Nodilittorina dilatata	0.228	0.074	0.198	0.159

Proportion explained	.5259		.1822	
Cumulative	.5259		.7081	

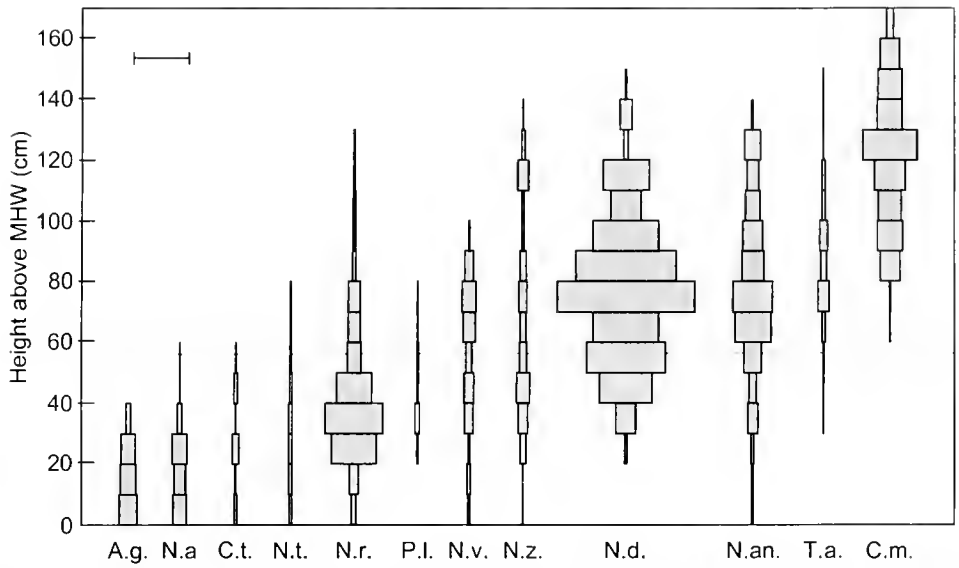

Figure 4. Distribution of the 12 most abundant species of supralittoral mollusks on the exposed shore near the Hofstra University Marine Laboratory, Priory, St. Ann, Jamaica. Dashed line represents the approximate upper limit of the splash zone. Bar in the upper left corner is equivalent to 10 individuals per m^2. A.g. = *Acanthopleura granulata*; N.a. = *Notoacmaea antillarum*; C.t. = *Chiton tuberculatus*; N.t. = *Nerita tessellata*; N.r. = *Nodilittorina riisei*; P.l. = *Planaxis lineatus*; N.v. = *Nerita versicolor*; N.z. = *Nodilittarina ziczac*; N.d. = *Nodilittorina dilatata*; N.an. = *Nodilittorina angustior*; T.a. = *Tectarius antonii*; C.m. = *Cenchritis muricatus*.

on high energy transects than on low energy transects (*t*-test, $t = 2.73$, $d = 8$, $p = 0.022$). No significant differences were observed for pit or crevice use between high and low energy transects.

DISCUSSION

Wave action and desiccation stress have been identified as important abiotic stresses structuring intertidal communities (Garrity 1984, Menge et al. 1986), particularly for rocky shore gastro-

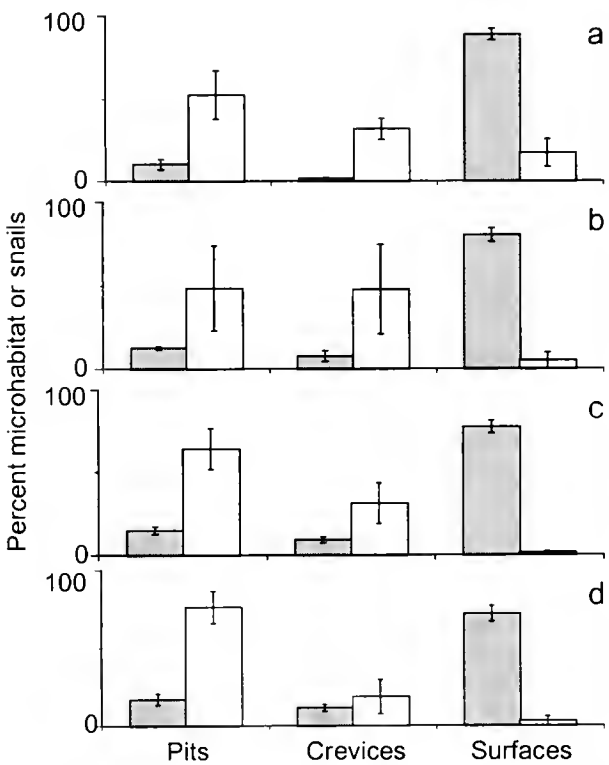

Figure 5. Percent microhabitat availability and use by supralittoral mollusks at four heights above MHW. Data are means (±SE) for 10 transect lines. Solid bars represent the relative abundance of pits, crevices, and exposed surfaces available to snails and open bars represent the percent of snails occupying pits, crevices, and exposed surfaces. (a) 4 m above MHW; (b) 3 m above MHW; (c) 2 m above MHW; (d) 1 m above MHW.

pods occupying the supralittoral fringe. On exposed shorelines, the splash zone directly above MHW is subject to intense mechanical stress from wave action. The ability to adhere to the substrate when under severe impact from waves should be a major factor controlling the distribution of species (Rafaelli and Hughes 1978), as individuals knocked from the substrate are likely to be swept away, crushed, or fall victim to predation (Levings and Garrity 1983, Garrity and Levings 1984).

Many supralittoral gastropod species remain emersed, which may reduce predation from subtidal predators (Levings and Garrity 1983, Garrity and Levings 1984). Emersion also increases their risk of desiccation and heat coma from exposure to high temperatures. Temperatures on exposed rocky shores in the tropics are often sufficient to cause mortality in supralittoral gastropods (Garrity 1984, Garrity and Levings 1984). Laboratory studies on the heat coma temperatures (HCT) of five species of Caribbean littorinids from Jamaica, indicate that daily temperatures at the study site can exceed the lethal limits for these species (Britton 1992). During this study, ambient rock temperatures of 45°C exceeded the lethal levels for two of the five littorinid species.

Our results suggest that neither wave action nor desiccation are important factors structuring the molluscan assemblage at this location. Species numbers, densities, assemblage composition, and the range of distribution of individual species were constant across the physical factors investigated. Correspondence analysis revealed that four transects were different from the others (Fig. 2), but three of these transects (D, E, and F) were related more by geographical proximity to one another than by transect type, and this suggests that relatively small scale, localized events are acting on the assemblage.

Other studies have correlated habitat heterogeneity with the distribution of rocky shore mollusks (Peckol et al. 1989), and we observed a significant preference among the supralittoral gastropods for the less abundant pit and crevice microhabitats over exposed surfaces. Because our transects did not vary in microhabitat availability, the absence of differences in the molluscan assemblage between high and low energy transects could be explained if microhabitat availability is the primary factor structuring the community. Unfortunately, microhabitat availability alone is not an adequate mechanism: microhabitats should act indirectly on community structure by altering mortality levels caused by physical or biological mechanisms.

Pit and crevice microhabitats may be cooler and more humid than exposed surfaces, resulting in lower desiccation stress and ambient temperature (Levings and Garrity 1983, Garrity 1984). These microhabitats may also provide protection from mechanical stress (Raffaelli and Hughes 1978), reducing the likelihood of individuals being swept from the substrate when struck by waves.

Patterns of microhabitat use between high energy and low energy transects suggest that pits and crevices may be important in alleviating desiccation stress. On high energy transects, nearly all species were found more frequently on exposed surfaces (Table 3). If pits and crevices were important in reducing the risk of being swept from the shore by wave action, we would expect fewer snails on exposed surfaces at high-energy sites. As this was not the case, we believe wave action to have an insignificant direct effect on the distributions of these species. Indirectly, high wave action may lower desiccation potential and rock temperature compared to low energy sites and therefore, individuals on exposed surfaces would be less likely to suffer mortality from desiccation along high energy transects.

In contrast to our findings, Lang et al. (1998) found little preference for pits and crevices over exposed surfaces for *Nodilittorina angustior*, *N. riisei*, and *N. antonii* in research conducted on nearly the same area of the Jamaican shoreline. However, rock temperatures during this earlier study were approximately 6°C lower than during our study and were well below the measured HCT for these species; this may have allowed the species to distribute themselves in a more random manner over the rock surface.

McMahon (1990) has suggested that mollusks occupying the supralittoral fringe have sufficient physiological tolerances to high temperature and desiccation that these factors play little role in determining zonation patterns. Britton (1992) found only a weak relationship between desiccation resistance and HCT and the relative positions on the shore for seven species of Caribbean littorinids. The littorinid species examined possessed high desiccation resistance and were able to survive from 12 to 30 days of emersion (Britton 1992). Interestingly, the lowest HCT was for *C. muricatus* (42.1°C), the littorinid occupying the highest position on the shore.

Unfortunately, methods used to determine HCT temperatures entail submerging the animal in a heated water bath. In nature, these species are seldom, if ever, submerged. This casts doubt on the ecological relevance of this type of study (Garrity 1984). Mortality of supralittoral gastropods in the tropics has been linked to elevated temperatures (Levings and Garrity 1983), and even if desiccation and temperature are not directly responsible for mortality, they may indirectly lead to mortality via some other factor (Menge and Sutherland 1987). Therefore, any means of ameliorating temperature stress would be advantageous to the individual.

We do agree, however, with McMahon's (1990) contention that the distributional patterns observed for tropical rocky shore mollusks may be the result of a suite of factors, including the physical, biological, and physiological environment. Because pits and crevices account for <30% of the available habitat, competition for these microhabitats may be an important factor controlling species distributions and ultimately, community structure. The interaction of biological (i.e. competition and predation) and physical (i.e. desiccation and temperature stress) factors may be responsible for the distribution of supralittoral gastropods on exposed tropical shorelines.

ACKNOWLEDGMENTS

We thank Joseph Britton and Robert McMahon for useful discussion that improved this research. Eugene Kaplan, Sandra Walters, Sandra Ross and the staff of the Hofstra University Marine Laboratory provided facilities and encouragement, and Dirk assisted in the field. Joseph Britton and an anonymous reviewer made helpful comments on the manuscript. This research was supported by a grant to D.M. from the Conchologists of America.

EFFECTS OF TEMPERATURE AND DESICCATION ON TISSUE URIC ACID DYNAMICS IN *LITTORINA SAXATILIS* (OLIVI)

DELMONT C. SMITH

Department of Biological Sciences, State University of New York, College at Brockport, Brockport, New York 14420

ABSTRACT Previous studies have shown (Smith & Smith 1998) that the tissue concentration of uric acid in *Littorina saxatilis* varies considerably on a seasonal basis. In order to investigate possible physical parameters that might account for this variation, periwinkles were kept in controlled temperature rooms at 25°C or 10°C, and either immersed in seawater or dry (emersed). The combination of 25°C and emersion caused the highest concentration of uric acid, and 10°C and immersion the lowest. Returning emersed snails to seawater caused the tissue uric acid concentration to decline. This re-immersion also produced an increase in ammonia excretion. It appears that uric acid accumulates during emersion, which would mitigate water loss, and that this uric acid is re-converted to ammonia for excretion during subsequent immersion. The time course for these changes is such as to accommodate the natural cycle of immersion/emersion.

KEY WORDS: *Littorina saxatilis*, uric acid, ammonia, temperature, desiccation

INTRODUCTION

Research on the influence of environmental factors on uric acid concentration in intertidal gastropods began with the classic papers by Needham (1935, 1938) with substantial contributions later by Potts (1967). These workers demonstrated that species located high in the intertidal zone contain a relatively greater amount of uric acid than those from lower. Previous reports indicate (Smith et al.1995) that shore location results in differences in uric acid levels within species (*Littorina saxatilis* and *L. arcana*), with crevice-dwelling animals having a lower uric acid concentration than animals collected from the surface of boulders.

The principal end product of nitrogen metabolism has long been recognized to be related to the amount of water that is available for its excretion. Aquatic animals are able to excrete toxic ammonia since water is plentiful and can readily flush ammonia from the body. Terrestrial species of gastropods (and other animals), however, are ureotelic or uricotelic (Delauney, 1931, Needham, 1935), since urea and uric acid are relatively non-toxic and can therefore be permitted to accumulate and ultimately be excreted with a minimal volume of water. The disadvantage of urea and uric acid is that they are metabolically more costly to synthesize than ammonia. Uric acid is the most costly, but is also the most conservative of water. Since it is highly insoluble, it may be stored in tissues without detrimental osmotic effect, and may, in those animals that excrete uric acid, be excreted in crystalline form with very little water loss. Whether in fact periwinkles actually excrete uric acid as such is questionable; Heil and Eichelberg (1983) reported that the only excreted metabolite they were able to detect in *L. littorea* was ammonia.

Littoral gastropods may be thought of as being intermediate between aquatic and terrestrial snails since they are subjected to alternating periods of immersion with plentiful seawater, and of emersion with the possibility of dehydration. Under such conditions it is to be expected that seasonal changes would have a significant effect on the accumulation of uric acid since the presumed factors that stimulate uric acid accumulation, namely increased temperature and desiccation, will be increased in summer and reduced in winter. This has been shown in land snails (Jezewska et al. 1963; Laziradou-Dimitriadou & Kaloyianni, 1989), and, in an earlier paper (Smith & Smith 1998) we were able to show that there is indeed a much greater concentration of uric acid in winkles in summer than in winter. Although it seems reasonable to assume that the physical parameters that lead to accumulation of uric acid in the summer are temperature and desiccation, it is necessary to test the effects of these factors under controlled laboratory conditions. For this reason, winkles were brought to the laboratory to be maintained in controlled conditions of temperature and desiccation in order to independently test these factors on the animal's uric acid content. Further, the ultimate fate of this uric acid, conversion to ammonia, was investigated.

MATERIALS AND METHODS

Collections

Samples of *Littorina saxatilis* were collected from a boulder field at Filey Brigg, North Yorkshire, on the northeast coast of England (British National Grid Reference TA 133814; this location is labeled "B" in Smith et al. 1995). All animals used in this study were collected between February 10 and April 19,1999.

Treatments

The animals were transported to the laboratory where they were maintained in temperature controlled rooms either at 10° (designated here as "C") or 25° (designated as "H"). In each of these rooms animals were separated into either a dry aquarium ("D") or an aquarium where they were kept submerged in seawater ("W") by means of a nylon net attached to the walls of the aquaria at the surface of the water. With each collection of winkles, a number of algae-covered stones were taken from the same shore and were placed on the bottom of the aquaria (Warwick 1983). This made it possible to keep the winkles in good condition well beyond the duration of the experiment. The winkles were maintained in these conditions for at least 48 hours before being assayed for uric acid.

In order to determine whether and how much animals that had been adapted to dry conditions would reduce their uric acid con-

E-mail: dsmith@brockport.edu

centration upon re-immersion, a sample of 45 C/D animals was transferred to C/W conditions. An equal sized sample of H/D was transferred to H/W and forty-eight hours after transfer, each sample was assayed for uric acid.

Most determinations were done after 48 hours in the chosen temperature/moisture conditions. To determine whether the rate of uric acid accumulation during desiccation would occur within a time frame that corresponds to typical emersion cycles in nature, winkles were placed in H/D and then uric acid concentration in samples of 15 animals immediately measured, at 3 hours, 6 hours, 18 hours, 28 hours, and 48 hours.

Uric Acid Determination

This method is the same as that reported in earlier papers (Smith *et al* 1995, Smith & Smith 1998). The shells were cracked and the body was removed under a dissecting microscope. The body was weighed and then homogenized in 100 µl of phosphate buffer (pH 7.8) at room temperature. After centrifugation the supernatant was removed and frozen for later analysis for uric acid.

The supernatant was assayed using a modification of the Sigma Diagnostics procedure no. 685. This procedure essentially follows the method of Duerr (1967) and utilizes uricase to promote the oxidation of uric acid to allantoin, CO_2 and H_2O_2. The H_2O_2 then reacts, in the presence of peroxidase, with 4-aminoantipyrine and 3,5-dichloro-2-hydroxybenzenesulphonate to form a quinoneimine dye. The intensity of the color formed is proportional to the concentration of uric acid and is read at 520 nm. Concentration is reported as µg of uric acid per gram of wet tissue weight (µg g^{-1}).

Body Weight

The wet weight of four samples of 20 winkles was obtained by weighing each animal individually after blotting external water with filter paper. Each group of snails was then placed in one of the four-temperature/ moisture conditions for 5 days, at which time the animals were individually weighed once more. This was to determine possible changes in body weight, especially in those animals that had been subjected to desiccating conditions.

Ammonia Production

Forty-five animals were subjected to H/D for 48 hours; another 45 animals were placed in H/W for the same period of time. They were then placed, in groups of 15 animals, in 30 ml of seawater at 25°C. Their rate of ammonia production was determined by measuring the concentration of ammonia in the seawater over a 4 h period using an Omega ammonia colorimeter. The rate of production was expressed as µM NH_3 g^{-1} h^{-1}.

Statistics

Non-parametric methods were used for all statistics reported in this paper: two-way analysis of variance using the method of Tukey, comparison of individual means by the Mann-Whitney rank sum test, and paired tests by the Wilcoxan method.

RESULTS

Temperature and Desiccation Effects

The effects of the four combinations of temperature and moisture treatments: 10°C and immersed (C/W), 25°C and immersed (H/W), 10°C and dry (C/D), 25°C and dry (H/D) are illustrated in Figure 1. The bar labeled "pre" is the mean uric acid concentration

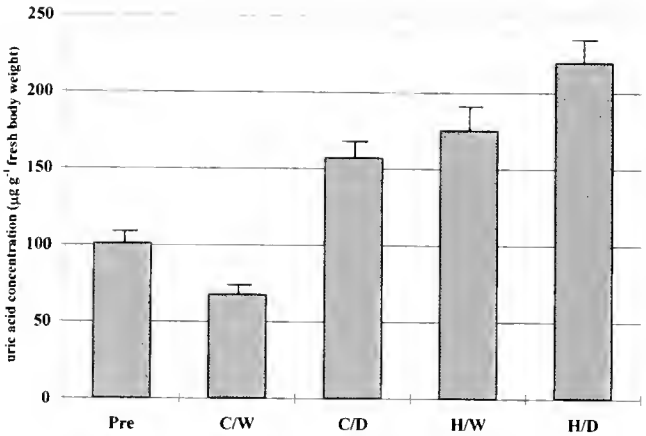

Figure 1. Mean (± SEM) wet tissue uric acid concentration (µg g^{-1}) in Littorina saxatilis maintained at the indicated conditions of temperature and moisture for 48 h. Pre = control fresh from the shore (N = 42); C/W = 10°C immersed (N = 39); C/D = 10°C emersed (N = 45); H/W = 25°C immersed (N = 38); H/D = 25°C emersed (N = 36).

of 42 periwinkles measured immediately upon arrival at the laboratory. The fact that this is higher than the next bar, which is the mean of 39 animals 48 hours after immersion in seawater at 10°C, is probably because the animals had already been emersed for some hours by the time they arrived at the laboratory, since the collections were taken at about the time of low water. The C/W winkles showed the lowest concentration of uric acid, and the H/D animals the highest.

Table 1 shows the results of statistical testing of the data by the Tukey non-parametric method. Clearly, both temperature and desiccation have highly significant effects on uric acid concentration, but there is no interaction between the two factors. Testing between individual means (Mann-Whitney) reveals highly significant differences ($P < 0.001$) when comparing C/W vs C/D, H/W vs C/W, and C/W vs H/D; significant differences ($P = 0.022$) with H/D vs H/W and H/D vs C/D; and no significant difference between H/W and C/D.

Effect of Re-hydration

It was clear that desiccation leads to an increase in uric acid concentration. What if the animals are now re-immersed in seawater? Samples of winkles ($n = 45$) were kept in H/D and C/D conditions for 48 hours to raise their uric acid concentration. After 48 hours half of the surviving animals in each sample were assayed for uric acid and the remaining animals in each sample were immersed in seawater at the same temperature and assayed for uric acid 48 hours later. The results are shown in Figure 2. ANOVA of the data of Figure 2 is highly significant ($P < 0.001$). Testing of

Desiccation	177169	28.8	<0.001*
Interaction	20116	3.3	n.s.

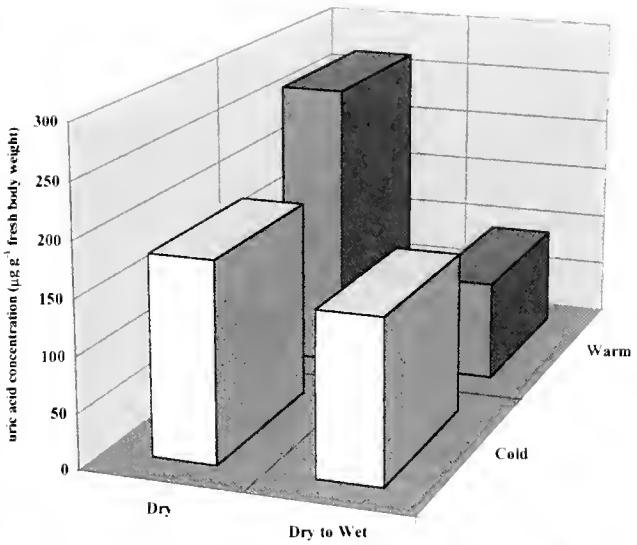

Figure 2. Effect of transfer of Littorina saxatilis after 48 h desiccation ("dry", either warm [25 C] or cold [10 C]) to 48 h immersion in seawater ("dry to wet", either warm or cold) on mean wet tissue uric acid concentration (μg g^{-1}). N = 19 (C/D), 24 (C/D to C/W), 18 (H/D), 15 (H/D to H/W).

individual sample responses to re-hydration shows a highly significant ($P < 0.001$) reduction in uric acid when winkles are moved from H/D to H/W, but the response to a move from C/D to C/W is considerably less ($P = 0.17$); not statistically significant at $\alpha = 0.05$.

Weight Loss during Desiccation

Upon desiccation, animals will almost certainly have some reduction in weight as a result of water loss. To determine whether such loss of weight is sufficient to account for the concomitant increase in uric acid concentration, four groups of 45 snails were initially weighed, then each group put into one of the four temperature/moisture conditions for 5 days. Table 2 shows that the animals that had been kept submerged had a very slight (not significant) gain in body weight. Desiccated animals had a significant ($P < 0.001$) weight loss. However, if the % change in weight is compared with the % change in uric acid as a result of desiccation (data from Fig. 1) it is clear that the loss of body weight cannot account for the large increase in uric acid concentration. Animals kept C/D had a 6.2% weight loss, but a 43.0% increase in uric acid concentration; those animals maintained H/D had a 6.0% weight loss but a 79.8% gain in uric acid.

Rate of Increase in Uric Acid during Desiccation

The determinations described in the preceding sections were done following 48 h of exposure to the chosen temperature/moisture conditions. Winkles were placed in H/D and then samples of 15 snails were immediately assayed, at 3 h, 6 h, 18 h, 28 h, and 48 h. This was done to determine whether the uric acid accumulation that is due to desiccation would occur within the time constraints of a typical immersion/emersion cycle in nature. The results are illustrated in Table 3, and show that there is indeed a significant increase in uric acid by 6 h, within the emersion time of a normal tide cycle for these animals.

Ammonia Production

Forty-five periwinkles were conditioned to H/D for 48 h to increase their uric acid concentration. The control was an equally sized sample held at the same temperature but kept immersed. After 48 h, groups of 15 animals were placed in 30-ml seawater and their ammonia production was measured over a 4-h period. The 45 animals that had been H/D had an ammonia production rate of 0.41 μM NH_3 g^{-1} h^{-1}, while the H/W controls produced at a rate of 0.25 μM NH_3 g^{-1} h^{-1}. These rates are consistent with those reported by Uglow and Williams (2001) for Hong Kong littorines. Statistical testing between these means was not done, since, although 45 animals were in each sample, they were combined into groups of 15, and 3 experimental and 3 control samples are insufficient for statistical testing.

DISCUSSION

Shore location and seasonal effects suggest that the determining physical causes of increased uric acid concentration are probably temperature and desiccation. This hypothesis is borne out by the experiments reported here using temperature-controlled rooms to carefully control the temperature of periwinkles that were either completely submerged in seawater or kept in dry conditions. Both increased temperature and desiccation caused significant gains in uric acid burden of *L. saxatilis*. While no interaction between these two physical factors was demonstrated, one would expect that the effect of temperature would be manifested by an enhancement of the drying effect. However, the actual loss of body weight due to desiccation was in fact rather slight, and was no greater at 25°C than it was at 10°C. Possibly, then, the temperature effect is to metabolically increase the rate of synthesis of uric acid.

Heil and Eichelberg (1983), and Eichelberg and Heil (1989) have suggested that uric acid serves as a temporary storage form of nitrogenous wastes in *Littorina littorea* during times of water lack and low salinity. They were unable to detect any excreted form of nitrogen other than ammonia. If the uric acid were a temporary

storage form, then one would expect it to be depleted once water becomes plentiful again. I have found this to be the case: re-immersion in seawater causes significant reduction in uric acid concentration. The fact that animals that were warm as well as dry had the highest concentration of uric acid, and then had the lowest concentration after immersion in warm water, further bears out the metabolic role of temperature. Once the metabolic pathways that degrade uric acid become active, they appear to proceed faster at a higher temperature than at a lower temperature. The temporary storage of uric acid avoids the loss of water that would accompany excretion of nitrogenous wastes in any form, but especially if the nitrogen is excreted in the form of ammonia.

Subjecting animals to desiccation has the possible effect of causing water loss, which would cause a relative rise in concentration of all materials in the body. Not only did the experiments reported here rule out any such effect on uric acid concentration (since the concentration of uric acid increased so much more than the body weight decreased), but the desiccation had a remarkably small effect on body weight. Even after 5 days in dry conditions, the animals only lost about 6% of their original weight, indicating the effectiveness of the opercular seal as well as the water sparing effect of uric acid storage.

Littorina saxatilis lives rather high in the intertidal zone. Therefore, these animals spend a great deal of time out of the water. Many individuals may be submerged only during spring tides. The time course for uric acid change during desiccation was shown to be sufficiently rapid to account for the changes in uric acid that probably occur during natural immersion/emersion cycles, especially during neap tides when many individuals may not be immersed for days, since the range in concentration I obtained within 48 hours approximates the range reported on a seasonal basis (Smith & Smith 1998).

It is interesting to consider what might serve as the signal to convert nitrogenous wastes to uric acid. Since the actual water loss was rather slight (about 6% after 5 days), and the increase in uric acid was significant within hours of emersion, it is unlikely that water loss can be the signal for the metabolic change. Winkles withdraw into their shell within minutes of water being withdrawn, and remain so until re-immersed. Possibly the same signal that stimulates withdrawal also serves to alter nitrogen metabolism. A possible stimulus for uric acid production could be a lowering of pH in emersed animals. When emersed individuals withdraw into the shell they become partially anaerobic in their metabolism. Anaerobic metabolism leads to a decrease in metabolism and perhaps stimulates uric acid production.

My results support the thesis of Eichelberg and Heil (1989) that winkles are not truly uricotelic if uricotelic is taken to mean being an excretor of uric acid. Winkles do synthesize uric acid as a water conserving means during times of emersion, but they apparently convert this uric acid back to ammonia in order to be excreted, and this only when water is again plentiful. Such enzymatic conversion of uric acid to ammonia should be possible, since Daguzan (1967) detected all the enzymes required for uricolysis in *L. littorea*, and it seems reasonable to expect that the same enzymes are present in *L. saxatilis* as well.

ACKNOWLEDGMENTS

I wish to thank the School of Biology, Leeds University, for the opportunity to spend a sabbatical leave there from January to May 1999. Also thanks to Drs. P.J. Mill and J. Grahame for their hospitality and advice.

THE EFFECTS OF EMERSION ON AMMONIA EFFLUX OF THREE HONG KONG *NODILITTORINA* SPECIES

R. F. UGLOW[1,*] AND GRAY A. WILLIAMS[2]

[1]*Department of Biological Sciences, University of Hull, Hull HU6 7RX, United Kingdom;* [2]*Department of Ecology & Biodiversity and The Swire Institute of Marine Science, The University of Hong Kong, Hong Kong*

ABSTRACT On moderately-exposed Hong Kong shores, the nodilittorinids, *Nodilittorina trochoides* and *N. radiata* occur in the high-splash zone and *N. vidua* slightly below this level, extending into the eulittoral. These species experience long emersion times and high rock and air temperatures. After exposure on the natural rock for 0 min (awash and active, control animals) or 1, 4 or 22 h emersed, groups of animals (n = 6) were re-immersed and their ammonia effluxes (weight-normalized for fresh tissue mass) measured after 0.5, 1.0 and 2.0 h. Re-immersed groups had initial (30 min) effluxes of 3.91, 6.01 and 3.53 μmoles $NH_4 \times g^{-1} \times h^{-1}$ for *N. trochoides*, *N. radiata* and *N. vidua* respectively, which were high compared with the final values of 1.66, 2.02 and 0.32 μmoles $NH_4 \times g^{-1} \times h^{-1}$ for the same species after 2 h of re-immersion. There were clear inter-specific efflux differences and the handling procedure evoked enhanced ammonia excretion rates possibly as a stress response. Re-immersed animals had lower effluxes than control groups and, generally, such rates were negatively related to the duration of the preceding emersion period. Effluxes of *N. vidua*, measured 30 min after re-immersion were always higher than those measured at 1 or 2 h but this occurred with the other species only after they had been emersed for 1 h. Rates at all three sampling times following 4 or 22 h of emersion were very similar. The more eulittoral *N. vidua* may continue to produce ammonia during emersion periods of >1 h but the high-shore species do not. The energetic cost implications of this difference in post-emersion effluxes may be that emersion tolerance, hence vertical height on the shore, is limited for *N. vidua*. No evidence of a switch from ammonotely to uricotely was found for any species, but the production of non-excreted uric acid is not precluded.

KEY WORDS: Ammonia, effluxes, emersion, *Nodilittorina* spp., tropical rocky shore

INTRODUCTION

Three common *Nodilittorina* species occur high on Hong Kong rocky shores (Oghaki 1985, Reid 1992, Williams 1994, Mak 1996) and have littoral distributions that result in lengthy periods of emersion and, during neap tide cycles, individuals may be continuously emersed for some days (Williams 1994). Summer daytime temperatures in Hong Kong can be high and rock surface temperatures >50°C are not exceptional; conditions which enhance the risk of desiccation (see Williams and Morritt 1995, Williams and McMahon 1998). Each of the *Nodilittorina* species exhibit measures which are known to aid the maintenance of a balanced heat budget, including the development of a dried mucus "anchor" moving to forage while awash and ceasing activity shortly after becoming emersed (see Garrity 1984, Britton 1992). All three species are principally ammonotelic, a mode of producing and removing nitrogenous metabolic waste that is inexpensive energetically but which entails a loss of water that would be intolerable for a non-aquatic species. The fact that these nodilittorinids are numerous and dominate high shore regions in the tropics is clear evidence that they have evolved means to tolerate protracted periods when nitrogen metabolism continues but normal means of removing the ammonia produced are probably impractical because of the entailed water losses. As ammonia is toxic, it is of interest to know how these animals deal with their nitrogenous wastes at such times and a closer examination of the interspecific and intraspecific means used may improve our understanding of small-scale distributional differences shown by these, and similar, high shore invertebrates.

Several studies on the effects of emersion on bivalves have been made (e.g. Widdows et al. 1985, Schick et al. 1988, Sadok et al. 1999) which indicate considerable metabolic and behavioral variability can occur in these animals. Literature is limited on nitrogen metabolite fluxes of intertidal gastropods in general and no information on such fluxes in *Nodilittorina* spp. could be found. Switching biochemical pathways so that an increased relative proportion of other forms of metabolic waste is produced is energetically an expensive option, were a species able to do this, but would effectively reduce water loss, hence desiccation stress, and thereby decrease the risks of associated toxicity or tonicity. Consequently, much of the emphasis of the study of nitrogenous waste removal in gastropods in general, and littoral species in particular, has concentrated on the relative rates of production, storage and release of uric acid in relation to ecological preferences and water conservation (Delauny 1931, Needham 1935, 1938). Terrestrial gastropods are principally uricotelic and it is logical to speculate that high-shore gastropods may have developed so that the proportions of ammonia and uric acid produced may be intermediate between the terrestrial and aquatic representatives. Smith and Smith (1998) found that summer levels of soluble uric acid concentrations in *Littorina saxatilis* were significantly higher than winter levels, partly because of higher desiccation levels, but they suggest, mainly because of increased protein catabolism rates in summer.

*Corresponding author. E-mail: R.F.Uglow@biosci.hull.ac.uk (R.F. Uglow); hrsbwga@hkucc.hku.hk (G.A. Williams)

Whichever nitrogenous metabolic end-products are produced, their rates of production are reflections of metabolic rate. Comparisons of nitrogen fluxes between emersed and immersed littoral animals are complicated because emersed animals eventually cease locomotory movements resulting in general levels of slow metabolism.

These preliminary studies on three *Nodilittorina* spp. were made to determine the weight-specific ammonia efflux rates of normal (immersed) animals and to examine whether post-emersion ammonia effluxes are influenced by the emersion duration. It is not known whether brief, but inevitable, handling procedures constitute a stress sufficient to alter normal effluxes or what the magnitude and duration of these changes may be. Consequently, the ammonia effluxes of groups of each of the three species were assessed in terms of time elapsed since being handled and of preceding emersion duration. As ammonia is the product of respiring tissue and because a large proportion of the total wet weight of each animal comprises the non-respiring shell, the relative weights of shell and flesh were determined using a representative sub-sample of each species. All effluxes given here are thus corrected to a tissue mass basis.

MATERIALS AND METHODS

Nodilittorina trochoides (Gray 1839), *N. radiata* (Eydoux & Souleyet 1852) and *N. vidua* (Gould 1859) were collected while awash on the falling tide at Cape d'Aguilar, Hong Kong (22°N, 114°E) in July 1996. Eighteen individuals of each species were individually transferred to Eppendorf tubes containing 1.4 ml of the ambient seawater as a control group (awash) and the time was recorded. Fifty-four individuals of each species were also collected and placed on rock above the high water mark immediately in front of The Swire Institute of Marine Science. After 1, 4 and 22 h of emersion, three sets of six individuals of each species, one animal per tube, were transferred to Eppendorf tubes containing 1.4 ml of ambient seawater and the time recorded.

For each set of animals, after 30, 60 and 120 min, six individuals of each species were removed from their tubes, damp dried, weighed to the nearest 0.1 mg and replaced on the shore at the appropriate tidal level. The labeled Eppendorf tubes with the water samples were frozen (−20°C) until required for analysis.

Separately, a sample (n = 54) of freshly caught animals of the three species were damp-dried, weighed (± 0.1 mg), killed in boiling water and the flesh removed from the shells which were re-weighed (± 0.1 mg). A fresh tissue weight vs. total wet weight relationship was determined for each species.

Water samples were analyzed for dissolved total ammonia ($NH_4 = NH_3 + NH_4^+$) and uric acid (as urate). Ammonia concentrations (as total volatile base, TVB) were quantified using a flow injection/gas diffusion technique (Hunter and Uglow 1993) using a 500-ml sample loop. Calculated ammonia concentrations were transformed to weight-specific effluxes (μmoles $NH_4 \times$ g flesh weight$^{-1} \times h^{-1}$). Uric acid concentrations were determined as urate using Sigma diagnostic kit No 685.

Data were analyzed using Two Way Analysis of Variance (ANOVA). When significant differences were detected, the Tukey multiple range test was applied to compare means. All statistical analyses were performed at the 5% significance level.

RESULTS

Tissue weight vs. total weight relationships for the three species show that in each case, the relationship was linear and thus allowed the estimation of flesh weight from a simple wet weight determination (Table 1).

The weight-specific ammonia efflux data of the freshly-caught, non-emersed (control) animals decreased progressively (Fig. 1), particularly during the first 30 minutes, such that the 120 min values were significantly less than those measured at 30 min ($P < 0.05$ in each case). Presumably, such decreases illustrate a progressive recovery from the brief, initial handling shock and that the 60 and 120-min values better represent the normal, emersed effluxes of the species. The animals were crawling when captured and the ammonia concentration in any extra-corporeal water that they may have had would have been similar to that of the ambient water. The apparently high initial effluxes shown by *N. radiata* are probably not a reflection of the general activity of this species when first caught as it was noticeable that *N. vidua* was much more active than the other two species. The 120-min effluxes also indicate that those of the most eulittoral *N. vidua* are significantly less ($P < 0.05$) than those of the two higher shore species. The data were uncorrected for losses that may have occurred due to bacterial consumption. Presumably, some losses will have occurred in this way in the 1 and 2 h samples, but such losses were negligible in seawater blanks and it is assumed, therefore, that such losses would not alter the main findings substantially.

The two highest zoned species, *N. trochoides* and *N. radiata* had ammonia excretion rates following 1 h of emersion which were either similar or slightly less ($P > 0.05$) than those of their control groups (Fig. 2a–b). Longer periods of emersion evoked re-immersion effluxes that were significantly lower than those of the control groups ($P < 0.05$ in all cases).

Quite a different pattern of post-emersion ammonia efflux rate was found to occur in the species with the lowest vertical distribution, *N. vidua* (Fig. 2c). The control value for this species was significantly ($P < 0.05$) less than those of the other two species and, after each of the three emersion periods, the reimmersed efflux rates were significantly higher than the control group in all instances except for the 120 min post 4 h emersion group. The 1 and 4 h emersed groups showed a pattern of progressively diminishing post-emersion efflux rates but the 22 h emersed group maintained a reasonably constant, high efflux (*c.f.* the control group). None of the animals excreted measurable amounts of urate during these experiments.

The 120-min efflux data were analyzed using Two way ANOVA which revealed no significant differences due to species or emersion duration, but a significant species × emersion time interaction, suggesting that the rates of re-immersion adjustment differed between species. Tukey tests revealed that the mean efflux of freshly-captured *N. radiata* was significantly different from that of freshly-captured *N. vidua* and that the mean effluxes of the 22 h emersed *N. vidua* were significantly higher than those of 22 h emersed *N. trochoides* or *N. radiata*.

TABLE 1.

Relationships between total wet weight (X) and fresh tissue weight (Y) for 3 Hong Kong *Nodilittorina* spp.

Species	Regression details
Nodilittorina vidua	Y = 0.127X + 0.004 r = 0.9298
Nodilittorina trochoides	Y = 0.159X + 0.001 r = 0.8500
Nodilittorina radiata	Y = 0.093X + 0.002 r = 0.7300

n = 54 in all cases.

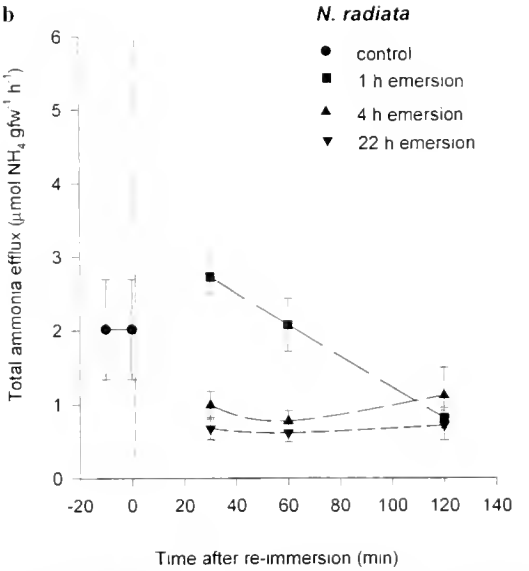

Figure 2b. Weight-specific ammonia efflux of *Nodilittorina radiata* at various post reimmersion times following emersion of 1h, 4h or 22h. Values are presented as means ± S.E. for separate groups of (n = 6) animals in each case. (T = 29.4 C, S = 30).

DISCUSSION

These preliminary findings reveal that considerable interspecific and intraspecific variability of ammonia efflux occurs amongst these littoral gastropod species and that some of the variability can be attributed to the positions that the animals are found on the shore. Brief handling and emersion evoked high ammonia effluxes after being handled and emersed for a very short period of time. These "shock" response rates persisted for at least 30 minutes and possibly, 120-min rates better represent the "normal" immersed, active effluxes of these species (Table 2). The control rates used here were those measured at 120 min following the brief handling procedures and were 1.66 ± 0.29, 2.02 ± 0.68 and 0.32 ± 0.08 μmoles $NH_4 \times g^{-1}$ flesh weight $\times h^{-1}$ respectively for *N. trochoides*, *N. radiata* and *N. vidua*. Ammonia has an oxycalorific value of 0.0689 cal × μmole^{-1} (Brafield and Solomon 1972) and, on the broad assumption that *N. trochoides*, *N. radiata* and *N. vidua* were immersed for 4, 5 and 12 h × d^{-1} respectively at the collection site, the daily calorific loss through this route when immersed would amount to 0.46, 0.70 and 0.26 cal × g^{-1} × d^{-1} for the three species. The equivalent ammonia losses would be 6.64, 10.10 and 3.84 μmoles $NH_4 \times$ g flesh weight^{-1} × d^{-1}. Duerr (1968) found no urea produced but 0.3–6.0 μmoles $NH_4 \times$ g wet tissue^{-1} × d^{-1} produced by seven species of marine prosobranchs and Crisp

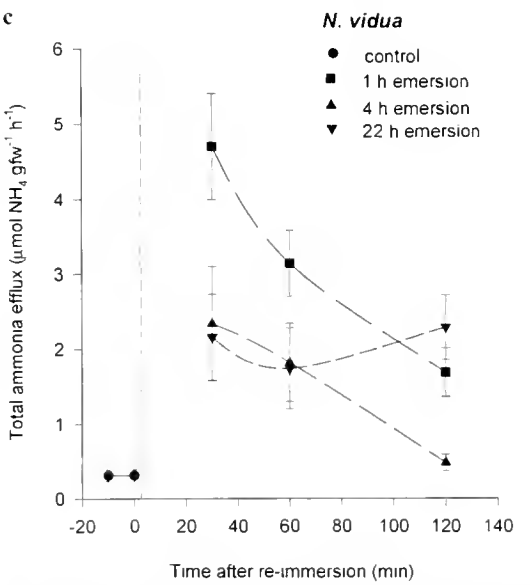

Figure 2c. Weight-specific ammonia efflux rates of *Nodilittorina vidua* at various post reimmersion times following emersion of 1h, 4h or 22h. Values are presented as means ± S.E. for separate groups of (n = 6) animals in each case. (T = 29.4°C, S = 30).

TABLE 2.

Ammonia efflux (μmoles $NH_4 \cdot g^{-1} \cdot h^{-1}$) of 3 *Nodilittorina* species collected *in situ* at high tide whilst awash and given no emersion.

Measurement period (min)	*N. trochoides* Mean ± S.E.	*N. radiata* Mean ± S.E.	*N. vidua* Mean ± S.E.
30	3.91 ± 0.48	6.01 ± 0.69	3.52 ± 0.42
60	2.21 ± 0.44	2.25 ± 0.55	0.83 ± 0.17
120	1.66 ± 0.29	2.02 ± 0.68	0.32 ± 0.08

Groups of n = 6 animals were used in each case (T = 29.4°C, salinity = 30).

et al. (1981) found that control group animals of the carnivorous gastropod, *Nassarius reticulatus* excreted ca. 0.76 μmoles $NH_4 \times$ g wet tissue$^{-1} \times h^{-1}$ (= 18.20. d^{-1}). Further studies will refine these estimates and will include estimates of the volatilised ammonia excreted during the emersion periods and the variability corrected for actual duration of the emersion periods experienced during the various tidal cycles at the collection site.

Clearly, the ammonia excretion rates following emersion vary according to species and the duration of the emersion period. After 1 h of emersion, the subsequent efflux rates for the first 30 min were as high (*N. radiata*) or higher (*N. vidua*) than the relevant control values. This suggests that ammonia production in these species had not only continued over this emersion period, though possibly at a lessened rate, but that it had been stored in a form and a site such that it was rapidly available for excretion as ammonia. During the 30 min following re-immersion after all the emersion times tested, *N. vidua*, excreted ammonia at rates which exceeded their control values but, in *N. radiata* showed this behavior after the 1 h emersion period only and *N. trochoides* did not show this behavior at all. These interspecific differences may relate to normal tidal distributions as the more eulittoral *N. vidua* will spend relatively much less time emersed than the high-shore *N. trochoides*. Consequently, the trade- off between the need to conserve water and to tolerate supra-normal ammonia concentrations is less critical in eulittoral species than for high shore species. Some of the post-emersion ammonia efflux that occurred in *N. vidua* and *N. radiata* may have been attributed to the flushing of ammonia-enriched mantle cavity water—but this was unlikely to have accounted for the entire amount. Similar occurrences have occurred with virtually all the crustacean and mollusc species we have examined and the source of this rapidly expelled ammonia is still under investigation. They are distinct from the effluxes derived from the general metabolic increase derived from handling.

The facility to reduce or cease ammonia production during periods of anaerobiosis is probably a prerequisite to successful colonisation of the high littoral levels where, at and above mean high water level at Spring tide (MHWST), prolonged emersion events are frequent. Additional studies will be needed to examine more critically the interspecific variability of emersion-dependance of volatilised ammonia losses and of uric acid production. No uric acid was found to be excreted in the 22 h emersions used in these tests but the production and storage of uric acid during emersion periods of this length are not precluded and such storage has been shown to vary seasonally in *Littorina saxatilis* (Smith and Smith 1998). The freshly-caught specimens of all three species showed an enhanced ammonia efflux following brief handling but this response is abolished if the handling is preceded by emersion for 4 h or more in *N. radiata* or for 1 h or more in *N. trochoides* but persists in *N. vidua*. In the last example, the rapidly excreted ammonia could represent the release of that produced during emersion and stored at some site such as the mantle cavity reservoir. In this instance, such reservoirs act less as a means of ensuring a modicum of aerobiosis during emersion, than as a latrine to which potentially toxic wastes can be consigned until they are flushed away on re-immersion. The techniques used appear to be suitably sensitive to allow accurate estimates of nitrogenous effluxes to be measured using the small volumes of water, or other fluids, which are often all that are available for analyses. They thus lend themselves to better estimations of energy fluxes in these types of animals, whether emersed or immersed, and to complement oxygen consumption studies which, often, are technically difficult, expensive or not feasible to use for certain types of energy flow studies.

TRANS-ZONAL MOVEMENTS IN WINKLES, *LITTORINA LITTOREA* (L.): REASONS AND CONSEQUENCES

G. F. WARNER*

Centre for Marine Sciences, The University of the West Indies, Mona, Kingston 7, Jamaica, West Indies

ABSTRACT Two years of monthly samples of *L. littorea* at three levels on an estuarine shore at Southampton, U.K. have provided evidence of long-term movements up and down the shore. Increased population densities at the middle level of winkles in their second year of growth indicate movements of young winkles toward the center of their zonation range. Increases in population densities of older winkles at the higher and lower levels indicate later dispersion away from the center of the zonation range. Evidence of movements between the middle level and the lower level is provided by the presence or absence in the shell of bore-holes made by the polychaete *Polydora ciliata* (Johnston) which recruits mainly on the lower shore. At the upper level, fluctuating population densities and observations of feeding fronts in the spring indicate seasonal migrations, down in winter and up in spring. Advantages and disadvantages of living at upper or lower levels are discussed and related to differences in growth rates and predation risk.

KEY WORDS: *Littorina littorea*, movement, migration, zonation, age

INTRODUCTION

Littorina littorea is one of the best known members of the Littorinidae (Fretter & Graham 1994, Reid 1996, McQuaid 1996a, b). It is a widespread and common species both regionally and locally, occurring on both sides of the North Atlantic on a variety of substrata. Its preferred habitat is toward the middle and lower zones of sheltered rocky shores but the precise zonation varies somewhat from place to place (Underwood 1973) and extends from the upper regions of some shores into the sub-littoral of others. *L. littorea* also occurs on muddy and estuarine shores where there are pebbles and shells to cling to (Moore 1937, Warner 1997).

There have been many studies on populations of *L. littorea* that have produced a variety of conclusions concerning settlement and subsequent movements. Some authors observed settlement within the zone occupied by the adults (Moore 1937, Williams 1964) while others have reported sub-littoral settlement followed by upshore migration of juveniles during their first year of life (Smith & Newell 1955, Lambert & Farley 1968). Seasonal migrations up the shore in the spring and down in the winter have also been observed (Lambert & Farley 1968, Williams & Ellis 1975). In apparent contrast, short-term maintenance of zonation by "homing" of individual winkles has been reported (Newell 1958, Gendron 1977) as well as short-term "random" movements (Petraitis 1982). In some cases, differences in zonation of the various size-classes have been observed in which larger winkles occurred more commonly on the lower shore (Moore 1940, Smith & Newell 1955, Williams 1964, Lambert & Farley 1968, Fish 1972, Gendron 1977, Warner 1997). Little explanation has been offered other than that the lower shore may be "optimal" for *L. littorea* (Williams 1964). However if this were so, one would expect more winkles of all sizes to live there.

In the work reported here, individual ages of *L. littorea* were estimated by counting annual growth rings on the shells (Black 1973). Growth check marks may be caused by a variety of factors (Ekaratne & Crisp 1982), but at this site annual growth rings are prominent and appear to result from the temporary slowing of growth from late winter to May (Warner, in prep). Using these age estimates, age-specific zonation patterns were investigated. These patterns, and additional observations, are used here to infer orientated movements and as a basis for discussion of the balance of costs and benefits of living in any particular zone.

METHODS

The study site was at Netley on the northern shore of Southampton Water, which is an elongated, sheltered inlet on the south coast of England, receiving input from several rivers. The surrounding land is urbanized and industrial with considerable shipping activity. The tidal range is up to 5 m and the salinity is normally about 30‰. Wide mud and gravel flats are exposed at low spring tide, the distance from high to low water being about 300 m. Three sampling sites were established (Warner 1997). The upper site was close to mean tide level at 2.7 m above Chart Datum, the habitat was damp stony gravel with sparse *Enteromorpha* sp. and *Fucus* sp.; this site was chosen as the highest site where a sample of winkles could reliably be collected at all times of year. The middle site was 80 m further down the shore at 1.4 m above CD where the substratum was wet muddy sand with gravel on which grew a mixed algal community including *Chondrus crispus* Stackhouse. The lower site, close to MLWS, was a further 80 m down the shore at 0.7 m above CD where the substratum was wet mud with stones and shells and a sparse algal community similar to that at the middle site.

Samples of *L. littorea* were collected at approximately monthly intervals at each site from November 1995 to March 1998. Samples were collected within 50 × 50 cm quadrats, all winkle shells being collected from 2 or more quadrats at each site until more than 30 live individuals had been collected. 3,218 live winkles were collected in total (there was no indication that this regular removal of snails had any effect on the population on this extensive beach). All dead winkle shells were also collected from within the quadrats from January 1996. Winkles were killed by boiling (ca 30 sec) soon after collection and were extracted from their shells. The shells were dried and scored for the occurrence of epifauna, especially for the presence of *Polydora ciliata* (Warner 1997). Epifauna were scraped off and the length of the shells

*E-mail: gfwarner@uwimona.edu.jm

measured with calipers to an accuracy of 0.1 mm. Annual growth rings (Black 1973) were recognized as prominent growth check marks on the body whorl separated by several mm of shell growth. New annual growth rings were added in May/June of each year as new rapid growth recommenced following spawning (Warner, in prep). Winkle shells at this site become progressively eroded (Warner 1997), making younger and older sections of shell easily distinguishable, and accentuating the ring in between. Annual growth rings were counted to estimate age at 2+ years and above; O+ and 1+ shells showed no annual growth check but these cohorts were distinguishable by non-overlapping size ranges. It was assumed that each new year of life started at the end of May (the end of the spawning season — Williams 1964, Grahame 1975; personal observation at this site).

Additional information on winkle dispersion and movements in the upper part of the zonation range was collected just above the upper site in the vicinity of a line of aggregated winkles, parallel to the shoreline, which was observed in May and June of each year. This line coincided with the lower edges of wide patches of the green alga *Enteromorpha* growing on the pebbles. In 1997, winkle numbers were counted on a 4 m long transect of 16 contiguous 25 × 25 cm quadrats positioned normal to this line. In 1998, the position of the line of winkles was marked with 4 pegs 10 m apart and revisited twice at 14-day intervals; on each visit the position of the line in relation to each peg was measured. Aspects of mortality were studied by collecting dead shells as described previously. These were measured and examined for damage resembling that caused by crab predation (large, irregular holes in the body whorl or spire — verified by personal observation of green shore crab, *Carcinus maenas* (L.), predation on winkles in aquaria) and for bore holes of *P. ciliata*.

RESULTS

Relative Movements of Different Age Classes

The distributions of the various ages at the three levels on the shore, summed over the entire sampling period and expressed as percentages, are shown in Figure 1. These age distributions are very significantly different from each other (contingency test, $\chi^2 = 295$, d.f. = 14, $p = 0.000$), showing an association between level and age. The differences include proportionally fewer age 1+ winkles at the upper and lower sites, and more 1+ winkles at the middle site. There were also proportionally fewer 3+, 4+ and 5+ winkles at the middle site, more 2+ and 3+ at the upper and more 3+, 4+, and 5+ winkles at the lower site. These data could be explained by movement of 1+ winkles toward the middle site, mainly from lower locations, and dispersal of older winkles from the middle site both up and down the shore. Total winkles collected at any one age increased from 0+ to 2+, then declined, but winkles estimated at more than seven years old were found at all sites. Winkle density was much higher at the middle site than at the upper and lower sites (Table 1).

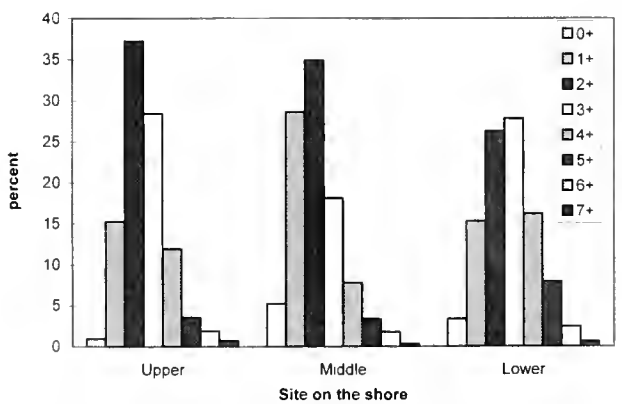

Figure 1. The percent frequency of different age classes of *L. littorea* at three sites on the shore, showing an association between level and age (contingency test on raw data, $\chi^2 = 295$, d.f. = 14, p = 0.000). At the middle site, there were relatively higher proportions of younger winkles (age 1+ years), and lower proportions of older winkles (ages 3+ and 4+ years).

Indirect evidence for movement of juvenile winkles toward the middle of their zonation range, and of older winkles away from the middle, was also provided by a biological marker: the bore holes of *P. ciliata*. Examination of live winkles showed *P. ciliata* holes in a proportion of shells at all levels (Table 1). However, infection was high at the lower site and much lower elsewhere, leading to the conclusion (Warner 1997) that settlement of *P. ciliata* is mainly restricted to the lower shore. The pattern of *P. ciliata* infection of winkles is that the worms prefer to settle on older areas of shell which lack periostracum (Warner 1997). In 0+ winkles, no *P. ciliata* borings were found at any site. In 1+ winkles, the only area of shell which is "old" and thus suitable for settlement is the relatively small area of the spire, since the whole body whorl is young and smooth. This leads to a characteristic pattern of infection in juveniles on the lower shore in which borings are often found only in the spire. Figure 2 shows the percent distribution of *P. ciliata* infection in winkles of different ages from the lower and middle sites (the upper site had too few bored winkles for feasible analysis). In both cases, there is a highly significant association between age and bore-hole distribution (contingency tests, lower: $\chi^2 = 203$, d.f. = 6, $p = 0.000$, middle: $\chi^2 = 79$, d.f. = 6, $p = 0.000$, data for >4+ snails contained a zero so was excluded). At the lower site, it is clear that borings only in the spire were common in 1+ winkles. Figure 2 shows that this pattern is gradually eliminated later in life by borings distributed elsewhere on the shell. At the middle site, 1+ winkles with *P. ciliata* borings only on the spire were not common, but a small proportion of 2+ winkles showed this pattern. These may have been individuals that were lower down the shore at an earlier age and moved up at about 1+ years old. In contrast, the relative increase in proportions of unbored 2+ and 3+ winkles at the lower site, shown in Figure 2, provide evidence of downshore movements in older snails.

TABLE 1.

Mean densities at the three sampling sites of live winkles and dead winkle shells, and the percentages of each of these that were bored by *P. ciliata*. Also included are the percentages containing bore-holes of those dead shells that appeared to have been cracked by crabs.

	Upper site	Middle site	Lower site
Live per m^2 ± SD	54.1 ± 28.7	116.7 ± 25.1	41.1 ± 10.8
Dead per m^2 ± SD	8.3 ± 5.7	17.9 ± 13.7	4.8 ± 2.6
% live + bore-holes	4.7	10.2	63.5
% dead + bore-holes	8	35.5	84
% cracked + bore-holes	35	76	97

Calculated from all samples (n = 30 at each level) collected between 1/96 and 3/98.

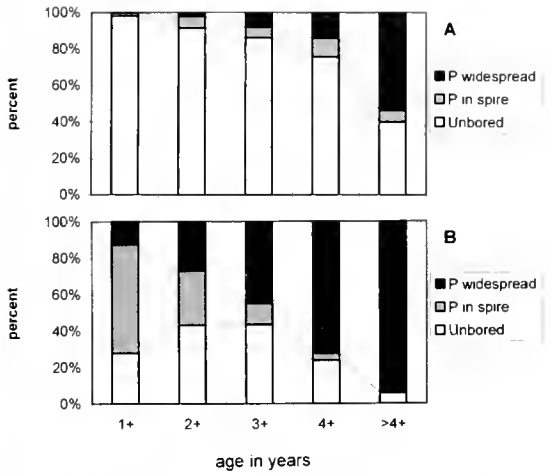

Figure 2. Distribution of bore-holes of the polychaete *Polydora ciliata* on the shells of different age-classes of live *L. littorea* at two levels on the shore, showing that the incidence of boring increases with age, and that on the lower shore, boring in the spire precedes more widespread boring (contingency tests on raw data, lower: $\chi^2 = 203$, d.f. = 6, p = 0.000, middle: $\chi^2 = 79$, df = 6, p = 0.000; data for >4+ snails contained a zero so were excluded). A = middle site, B = lower site; P = *Polydora*.

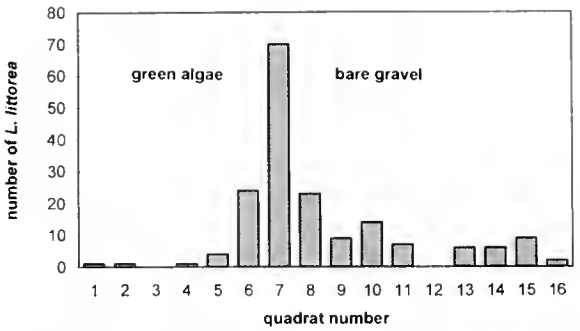

Figure 3. Results of a 4-m long transect, normal to the shoreline, of contiguous 25 × 25 cm quadrats on the upper part of the shore in May 1997, from gravel covered with green algae (higher) to bare gravel (lower, total drop ca. 5 cm), showing a high density of *L. littorea* forming a feeding front at the boundary of the algal growth.

Seasonal Migrations

In May and June, just above the upper site, a line of aggregated winkles parallel to the shoreline was observed to coincide with the lower edges of wide patches of the green alga *Enteromorpha* growing on the pebbles. Figure 3 shows the results of the 1997 transect across this line. In 1998, the line was found to move upshore by a mean distance of 103 cm in 14 days (n = 8, range = 45–169 cm), the winkles having apparently grazed the *Enteromorpha* leaving bare clean pebbles behind. By July, these "feeding fronts" had dispersed but winkles were still present above the upper site, often clustering at low tide beneath sparse clumps of *Fucus*. By November, winkles became rare above the upper site. These observations indicate upshore migration occurring in spring and summer. Since there were no clear seasonal changes in numbers of dead shells, downshore movements presumably occurred in autumn. Fluctuations in monthly population density measurements at the upper site were much greater than at the other two sites (Table 1) and appeared to correlate roughly with the seasons. The lowest densities were recorded between October and March (mean 35.3 m^{-2}, SD = 21.1, range = 7–65, n = 14) and the highest between April and September (mean = 65.6 m^{-2}, SD = 29.7, range = 31–148, n = 16). These means are significantly different (two-sample *t*-test, $t = -3.25$; d.f. = 27; $P < 0.01$).

Some Costs and Benefits of Life on the Lower Shore

Data on growth rates collected during this study show that growth was faster at the lower site than at the other two sites. Winkles of the same age were larger at the lower site, and showed greater annual growth increments at the shell margin than those from higher up the shore. These data will be published elsewhere.

The mean percent of dead shells relative to total (live + dead) shells from the different sites are shown in Figure 4A and are not significantly different. These data show that dead shells occur in proportion to the live population, and suggest that mortality rate is similar throughout the shore, despite differences in age distribution (it was assumed that dead shells "survived" to be sampled equally at the three sites). Figure 4B shows the mean percent of dead shells at the three levels that appeared to have been cracked by crabs. These proportions are significantly different (Single factor ANOVA, $F = 11.9$, d.f. = 68, $p = 0.000$): cracked shells were far more common at the lower site than at higher sites. Table 1 shows the incidence of *P. ciliata* bore-holes in the samples of dead and live shells from the 3 sites. It may be seen that while the incidence of bore-holes in both live and dead winkles decreased up the shore, a consistently higher proportion of dead shells at all sites contained bore-holes, and this proportion was higher still in those dead shells presumed cracked by crabs. The chi-square contingency tests on the raw data showed significant, positive association between being dead and the incidence of bore-holes at both the middle and lower sites ($\chi^2 = 100.7$ and 17.6 respectively, d.f. = 1, $p = 0.000$). Similarly, among dead shells at all three sites there was significant, positive association between the incidence of bore-holes and being cracked ($\chi^2 = 6.6$–23.8, d.f. = 1, $p < 0.01$).

DISCUSSION

Some previous work on *L. littorea* has shown that larvae settle on the shore throughout the zone of the adults (e.g. Williams 1964,

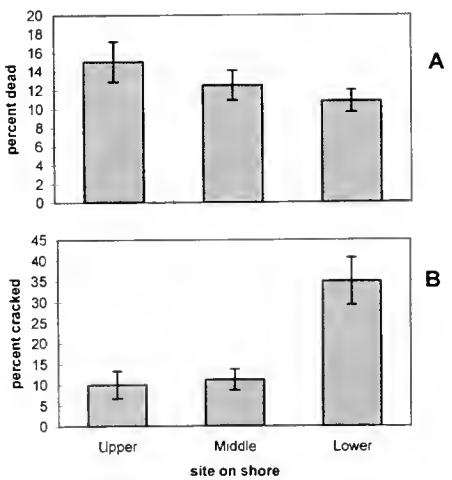

Figure 4. The mean frequencies (±SE) of dead (as percent of live + dead) *L. littorea* at three sites on the shore: not significantly different. B. The mean frequencies (±SE) of cracked (as percent of total dead) *L. littorea* at three sites on the shore, showing a greater proportion cracked at the lower site (single factor ANOVA, F = 11.9, d.f. = 68, p = 0.000).

Underwood 1973), but other authors (e.g. Smith & Newell 1955; Gardner & Thomas 1987) concluded that settlement is mainly sublittoral and is followed by upshore migration. Part of the disagreement appears to be due to the difficulty of finding very small winkles. This problem was evident in the present work, with relatively few 0+ winkles being found at any site (Fig. 1). However, small (5–7 mm) 0+ winkles appeared at about the same time in autumn in the samples at all three sites suggesting that they had been there, unobserved, since settlement. The mixed nature of the substratum at Netley provided many hiding places for tiny winkles (between pebbles, amongst algae, etc). Settlement at Southampton is therefore probably littoral rather than sublittoral, but the data for 0+ winkles (Fig. 1) suggest that recruitment was more frequent in the middle of the zonation range (middle site) than at the upper site at mean tide level.

In older winkles, changes in population density at a site must be due to movements of snails between zones or to differential mortality of snails. Smith & Newell (1955) and Williams (1964) found evidence of an upshore movement of young winkles (first and second year respectively), and Smith and Newell (1955) speculated that a downshore movement of older winkles could account for the presence of larger ones on the lower shore. The demonstration here of an excess of 1+ winkles at the middle site (Fig. 1) suggests active movement of young winkles toward the middle of the zonation range from both lower and higher levels. Smith and Newell (1955) ruled out the alternative of differential mortality of young snails on the grounds that dead shells were found distributed in proportion to the living, and this was also found here (assuming that dead shells were not unequally moved, fragmented or buried at the different levels). Similarly, subsequent dispersal seems the only plausible explanation of the increasing proportions and densities of older age-classes at the upper and lower sites. The data from *P. ciliata* borings (Fig. 2) provided evidence of both the movement upwards of juveniles from the lower shore and the movement down of age 2+ and 3+ winkles from the middle of the zonation range. However, it should be clear from these data that the full extent of trans-zonal movements were not performed by all individuals; winkles of all age groups remained present at all sites, indicating that some moved less than others.

Age-class specific movements may be thought to conflict with movements that have been described as maintaining the particular zones of individuals (Fretter & Graham 1994). These include small-scale circular movements (Newell 1958) and "home" orientated movements following displacement (Gendron 1977). However, the movements described here did not involve all winkles and occurred over a time scale of months to years, thus they can coexist with short-term maintenance of individual shore level, and with the short-term "random" movements described by Petraitis (1982). They also coexist with the winter downshore and spring upshore "migrations"of winkles (Lambert & Farley 1968, Williams & Ellis 1975) which have been observed only in the upper part of the zonation range.

The question remains: What functions do these movements perform in the life of the winkle? Movements in early life toward the middle of the zonation range may serve a "habitat location" function. Movement of older adults away from the center may then be a response to high population density, serving to reduce competition. However, movement up has very different consequences from movement down. Movement up gives access to the spring growth of green algae but also entails an annual retreat from upper levels as temperatures fall in the winter. Movement down brings the benefit of faster growth, probably due to longer immersion allowing longer feeding periods. Since faster growth leads to larger size, it may also lead to greater fecundity in lower shore individuals. However, life on the lower shore also entails increased risk of predation from crabs (Fig. 4) and increases the variety of epibiota, including *P. ciliata*, which settle on the shell (Warner 1997). Almost all dead, cracked (i.e. crab-predated) shells on the lower shore were bored by *P. ciliata* (Table 1) suggesting that borings may increase predation risk by weakening the shell (Buckley & Ebersole 1994). *L. littorea* has few defences against epibiota, some of which have adverse effects through increasing drag on the snails (Wahl & Sönnichsen 1992, Wahl 1996). Thus, there are several reasons for not regarding the lower shore as "optimal" for this species (Williams 1964), despite the faster growth that can be achieved there.

ACKNOWLEDGMENTS

I thank the numerous Reading University undergraduate students who counted winkles for me on various occasions, both for the useful data and for their enthusiastic support.

CORRELATION OF MORPHOLOGICAL DIVERSITY WITH MOLECULAR MARKER DIVERSITY IN THE ROUGH PERIWINKLE *LITTORINA SAXATILIS* (OLIVI)

CRAIG S. WILDING,* JOHN GRAHAME, AND PETER J. MILL

Centre for Biodiversity and Conservation, School of Biology, University of Leeds, Leeds, West Yorkshire, LS2 9JT, United Kingdom

ABSTRACT Two morphological varieties of *Littorina saxatilis*, widespread around the United Kingdom, are a thin-shelled, high-shore morph (*L. saxatilis* H) and a thick-shelled, mid-shore animal (*L. saxatilis* M). Mitochondrial DNA (mtDNA) analysis by PCR-RFLP was used to test whether gene flow between these morphs is restricted. At Galloway, Scotland, replicated sampling (different years and different transects over a distance of 800 m) has been undertaken. One mtDNA haplotype is predominant in H and a different haplotype common in the M animals. Repeatability in space and time suggests a real H/M differentiation. A similar pattern of mtDNA haplotype variation is seen in a single sample of the Swedish E and S morphs of *Littorina saxatilis*. However, this pattern is not evident everywhere. Variation in the mtDNA and four nuclear DNA loci was examined within and between *L. saxatilis* H and M morphs from the south coast of England. Because shape variation in this region additionally separates into three shape groupings (regions identified from multivariate morphometric analysis where shape is more homogeneous within, than between groups), genetic variability was examined within and between these groupings as well as between H and M. On the south coast, an apparent association of shape and mtDNA haplotype is identified, but AMOVA analysis shows no support for the association being with shape grouping or H and M morphs. Although the nature of this shape-genotype association is unknown, a mtDNA haplotype and an allele at the nuclear CAL-2 locus are confined mainly to one shape group. Analysis of association of mtDNA haplotype with H and M morphology suggests a strong correlation can be found in some areas (Galloway, Mumbles (south Wales), and between similar morphs in Sweden) yet no association is seen at others (Ravenscar, UK, Ballynahown, Ireland, and the south coast of England). Thus, unravelling the basis of the H and M forms will require more detailed studies, with replication, as at Galloway, and also with additional molecular markers.

INTRODUCTION

Shell shape in gastropod mollusks is known to be affected by environmental factors. Selection as a result of crab predation or stone damage can produce heavy shells with small apertures, while animals in exposed conditions where crab damage is minimal, but risk of dislodgement by waves is high, tend to have thin shells with wide apertures (Boulding 1990). In *Littorina saxatilis* (Olivi) two forms typical of these morphological extremes are widespread. Hull et al. (1996) referred to the thin-shelled, patulous form, found in high-shore areas as *L. saxatilis* H, and the thick-shelled variant that occurs in the mid-shore as *L. saxatilis* M. Although the basis of this shell polymorphism undoubtedly has a strong environmental component, evidence from embryological characters (Hull et al. 1996) and detection of assortative mating for these morphotypes (Hull 1998, Pickles & Grahame 1999) suggests that there may be a genetic component to the differentiation of *L. saxatilis* H and M. However, the only molecular level study of genetic differentiation between these forms was limited to two sites on the east coast of Yorkshire, England. Random amplified polymorphic DNA (RAPD) analysis showed differing degrees of differentiation at these two sites (Wilding et al. 1998). No wide scale geographic studies have yet been undertaken. This is important since such evidence is necessary to determine the extent of gene flow between these morphs, which is critical for the understanding of their relationships.

Mitochondrial DNA (mtDNA) is a useful molecular marker for such a study because of its high rate of evolution (Avise 1994), and a substantial portion of the *L. saxatilis* mitochondrial genome has been sequenced (Wilding et al. 1999), thus permitting the targeting of primers. Population genetic studies of gastropods have often relied on mitochondrial markers (Kirby et al. 1997, Hellberg 1998, Kyle & Boulding 1998) and Wilding et al. (2000a) have recently examined mtDNA cytochrome oxidase I (CoI) variation in UK and Irish *Littorina*. We also have developed primers for the amplification of four variable nuclear DNA (nDNA) loci in *Littorina saxatilis* (Wilding et al. 2000b).

Here shape variation and genetic variation are examined at four levels. (1) Between *L. saxatilis* H and M in replicated samples from southwest Scotland. (2) Between *L. saxatilis* H and M on the south coast (where nDNA variation is also examined). (3) Between *L. saxatilis* H and M at other locations. (4) Along the south coast of the United Kingdom where three 'shape groupings' are recognized. It is shown that both shape and mitochondrial DNA do vary geographically, but that there is only a limited correlation of the two. There is however evidence for differentiation at the mtDNA level between *L. saxatilis* H and M in some areas of the UK.

MATERIALS AND METHODS

Animals were collected from 17 sites around the UK (Table 1). Images of the shells were captured with a digital camera and used for morphometric measurements. Measuring of shell images was performed using Sigma Scan to measure eight shell variables (Fig. 1). These shell variables were standardized for size using the geometric mean transform (Reist 1985) and then submitted to a canonical variate analysis in SAS v 6.0 (SAS Inc. 1990). The shell was subsequently crushed and a portion of the head-foot removed for DNA extraction using the single-fly DNA extraction protocol of Ashburner (1989). DNA concentration was measured by fluorometry and adjusted to 10 ng.μl^{-1}. A 967 bp segment of mitochondrial DNA spanning the cytochrome oxidase I–cytochrome

conditions of 1 × 94°C, 5 min; 35 × (94°C, 1 min, 55°C, 30 secs, 72°C, 1 min); 1 × 72°C, 5 min were employed. In an initial study, 400 bp of mtDNA were sequenced in 50 individuals from 18 populations (Wilding et al. 2000a). From the resultant sequences variable restriction sites were deduced. Variation was then assessed by RFLP using three restriction enzymes — *Dde*I, *Dra*I and *Hin*dIII (*Dra*I is not variable in *L. saxatilis* but is in other rough periwinkles). Restriction enzyme digestion was undertaken in 15 μl volumes containing 3-5U enzyme in 1X buffer (supplied with enzyme) and 5 μl PCR product. Following digestion, restriction fragments were separated on 2% agarose gels. Variant patterns generated by each enzyme were labeled A, B, C *etc.* and a three letter composite haplotype describes the variation in each animal. An analysis of molecular variance (AMOVA: Excoffier et al. 1992) was used to examine genetic variation from animals along the south coast of England. *Littorina saxatilis* in this region is known to exhibit substantial shape variation which has been shown to partition into three groups (Grahame and Mill 1992, Mill and Grahame 1995), a south-west, a south-central, and a Kent grouping (Fig. 2). Upon this broad-scale variation there is superimposed the H and M differentiation. AMOVA was used to quantify the partitioning of mtDNA variation into a 'shape grouping' component and a 'H and M' component. If substantial variability is accounted for by either of these then the expectation is that these shape differences are indicative of underlying genetic differentiation. If little genetic variability is partitioned into either of these compo-

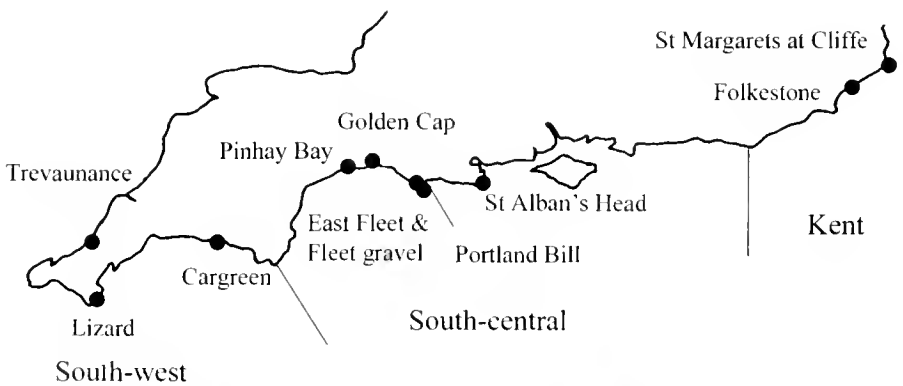

Figure 2. Delineation of shape groupings as described by Grahame and Mill (1992) and Mill and Grahame (1995).

nents then there is no detectable genetic differentiation at the mitochondrial DNA level between these groups. AMOVA was performed in ARLEQUIN v1.1 (Schneider et al. 1997).

In addition to the mtDNA analysis, patterns of nuclear DNA (nDNA) polymorphism have been examined in these animals (Wilding et al. 2000b). Four nuclear loci comprised of two calmodulin introns (CAL-1 and CAL-2), and two anonymous loci (X80 and DELETION) were examined for variation. All nDNA PCR reactions were undertaken in 25 μl of 50 mM KCl, 10 mM Tris-HCl pH 9.0, 1.5 mM $MgCl_2$, 0.1% Triton X-100, 0.01% gelatin, 200 μM each dNTP, 12.5 pmol each primer, 12.5 ng DNA and 0.5 U *Taq* (Super*taq*, HT Biotechnologies). PCR cycling conditions were 1 × 94°C, 5 min; 35 × (94°C, 1 min, 55°C, 30 secs, 72°C, 1 min); 1 × 72°C, 5 min, although for CAL-1 the annealing temperature was increased to 57°C, and DELETION in which annealing was at 57°C and the extension time was reduced to 30 seconds. CAL-1 and CAL-2 polymorphism was examined by *Taq*I and *Dde*I digestion respectively and in X-80 with *Msp*I. Restriction digestion was performed at the appropriate temperature for 2 hours and products were separated on 2% agarose gels. For the DELETION locus, alleles differed due to length variation and this was recognized after PCR products were run on 3% agarose gels. These nDNA data were not suitable for AMOVA analysis (because although the genetic distance between genotypes was calculable for those loci examined by RFLP, the mutational distance between alleles at the length variable DELETION locus was not. Thus the relationships among multi-locus genotypes, necessary for AMOVA analysis, were unclear). Correlation of shape variation with molecular variation was therefore examined using a Mantel test employed in NTSYS through comparison of the population matrix of genetic distance (different genetic distance measures were tested in case of subtle differences due to method employed) with the Mahalanobis distance matrix.

RESULTS

Mitochondrial DNA Variation

A neighbor-joining tree based on all sequences of CoI-CoII from *Littorina* shows two groupings of *L. saxatilis* (Fig. 3). Although there are 13 separate *L. saxatilis* sequences, these cannot all be distinguished using RFLP since there are many variable positions at this locus where there is no restriction enzyme with a recognition sequence spanning the site. However, three enzymes (*Hin*dIII, *Dra*I and *Dde*I) do recognize variable positions in this sequence within the rough periwinkles (Wilding et al. 2000a), although *Dra*I is not variable in *L. saxatilis*. In *L. saxatilis*, *Hin*dIII produced two patterns and *Dde*I four patterns. The four composite haplotypes encountered in *L. saxatilis* were designated AAA, ADA, BBA and BCA.

The most pronounced evidence for association of mitochon-

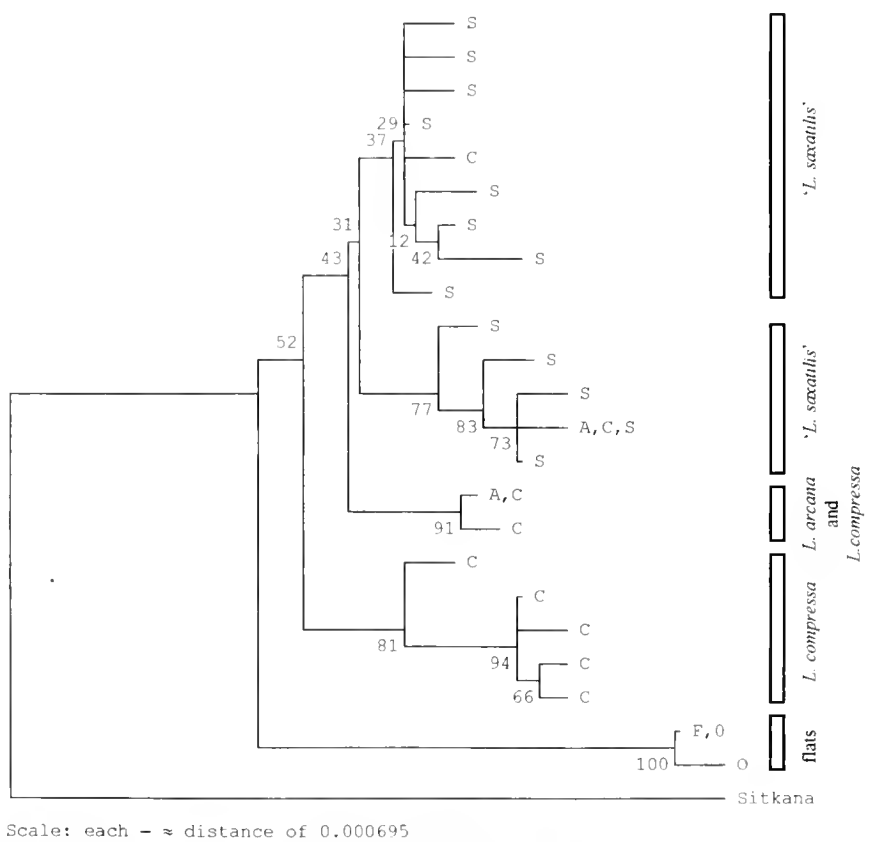

Figure 3. Phylogeny of rough periwinkle CoI sequences (adapted from Wilding et al. 2000a) using neighbor-joining of Jukes-Cantor distances. S = *L. saxatilis*, A = *L. arcana*, C = *L. compressa*, F = *L. fabalis* and O = *L. abtusata*. The two divisions of *L. saxatilis* sequences are denoted, note that some *L. orcana* and *L. compressa* sequences are shared with *L. saxatilis* or cluster in these "*L. saxatilis*" groups. Flats = sequences from the flat periwinkles *L. fabalis* and *L. obtusata*. The outgroup is *L. sitkana*. Numbers on the nodes are bootstrap values from 100 pseodoreplicates.

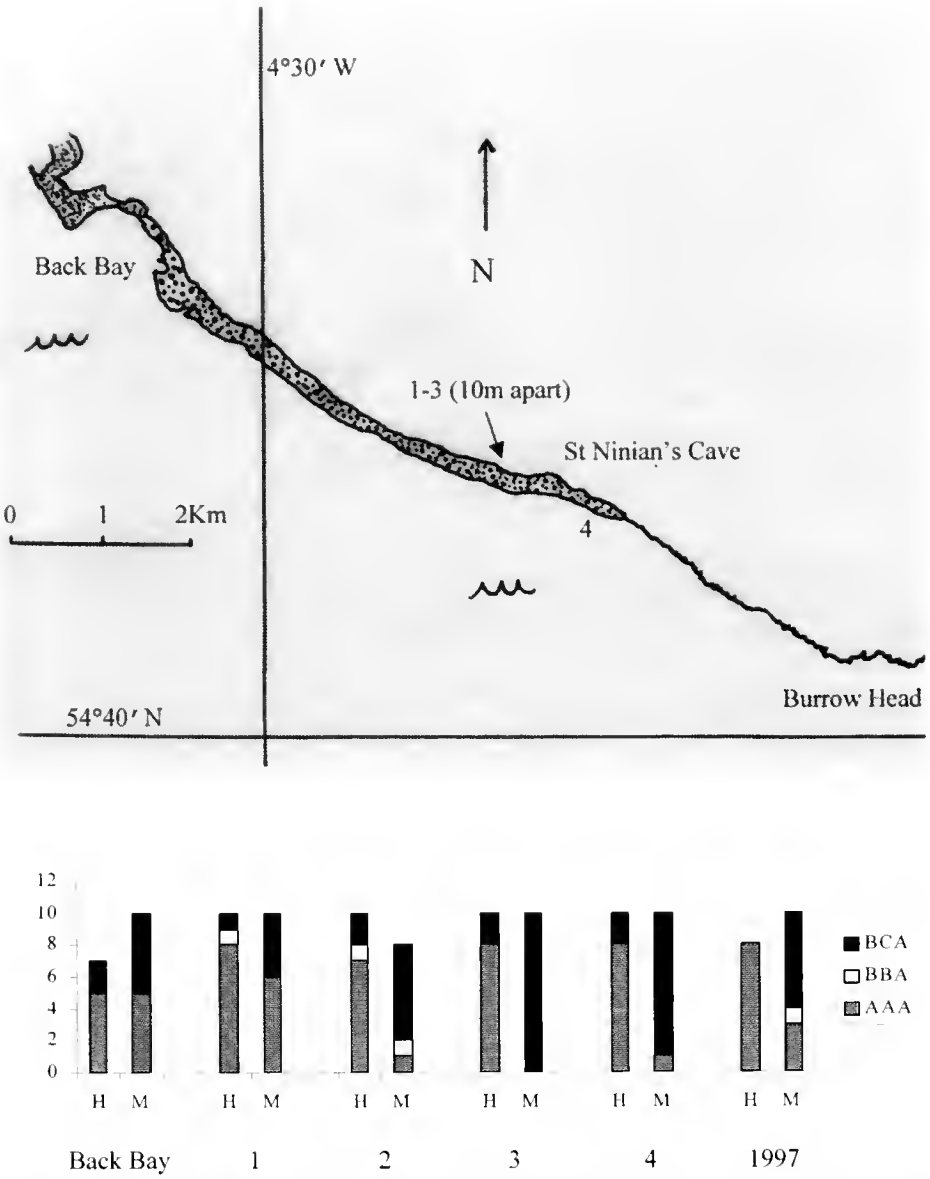

Figure 4. Distribution of mtDNA haplotypes in separate transects, undertaken in 1997 and 1998, at Galloway, southwest Scotland. Sites 1–3 were spaced 10 m apart and are separated from site 4 by approximately 800 m of shingle beach. The 1997 sample was taken from the same site as site 3 of 1998.

drial haplotype with morphology is found at Galloway in southwestern Scotland. Here one collection in 1997 and five collections in 1998 (from different transects) were typed. The AAA haplotype was predominant in *L. saxatilis* H and the BCA haplotype in *L. saxatilis* M (Fig. 4). Additional data from Mumbles (South Wales) also suggests differences between H and M, but at Ravenscar (east coast of England) and Ballynahown (western Ireland) no differences were detectable (Table 2). At Ursholmen, Sweden, differences were detected between the E and S morph of *L. saxatilis*. The E (exposed) morph, like *L. saxatilis* H, is wide apertured and thin-shelled and the S (sheltered) morph thick-shelled. However, unlike *L. saxatilis* H and M, where animals are separated vertically on the shore, E and S are separated locally, by habitat along the shore, being found in exposed and sheltered localities respectively. For the small sample examined, all nine E had the AAA haplotype, and 7 of 8 S had the BCA haplotype. These are the same haplotypes separating the H and M at Galloway.

South Coast of England — Morphological

Littorina saxatilis are shown to cluster into two groups on the basis of shell variation analyzed by canonical variate analysis (Fig. 5). When canonical variate means are plotted, the two groupings are associated with *L. saxatilis* H and M.

South Coast of England — Molecular

The distribution of haplotypes along the south coast within *L. saxatilis* H and M is shown in Table 2 and Fig. 6. There is sub-

stantial variation within both H and M forms of *L. saxatilis* but no obvious difference in haplotypes between the two groups. However, there is some evidence for association of haplotype with shape grouping since the haplotype ADA is found mainly on the south coast in the south central group of shape variation. To investigate if haplotype partitioned with shape, haplotypes were plotted onto a canonical variate analysis of shape. The resultant, apparently random, distribution of haplotypes throughout the morphospace defined by the first three canonical variates shows little association (Fig. 7). Nevertheless, discriminant analysis with cross validation shows that the best classification on the basis of shape variables is back to the parent haplotype group (Table 3) indicating some underlying association of shape and haplotype. However, AMOVA analysis (Table 4) suggests that neither shape groupings nor H and M are the covarying factor.

Variation was also high in the nDNA dataset (Table 2: G_{ST} = 0.1601, H_T = 0.3447, H_S = 0.2895). Mantel comparisons of the morphological Mahalanobis distance (D^2) with Nei's (unbiased) distance and the Prevosti distance from the nuclear-DNA RFLP data showed that, irrespective of the genetic distance matrix employed there is no evidence of association of shape and genotype; p [random z < obs. z] = 0.337 and 0.345 for association with the Nei and Prevosti distance respectively. However, as was found for the mtDNA dataset there is an association between nDNA genotype and shape grouping in that the allele CAL-2^A is found at the highest frequency in the south-central region where the haplotype ADA is encountered.

DISCUSSION

It is apparent that around the coastline of the UK and Ireland there is a separation of *L. saxatilis* into a thin-shelled, patulous, high-shore form (*L. saxatilis* H), and a thick-shelled mid-shore

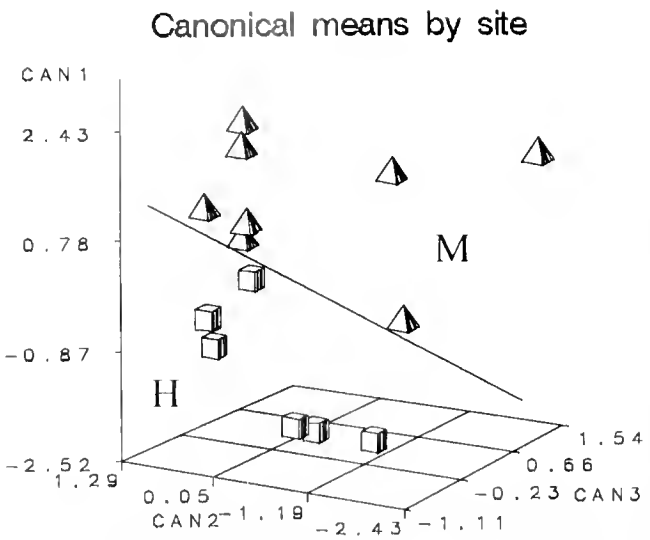

Figure 5. Population means from canonical variate analysis of south coast *L. saxatilis*.

form (*L. saxatilis* M). In this study we examined whether mitochondrial DNA variation provided evidence for genetic differentiation of these morphological varieties. At Galloway, Scotland, where repeated sampling on the shore has been undertaken, definite genetic differences are found between the morphs, with consistently different haplotype frequencies between H and M over both separate years and over multiple transects. Such repeatability shows the pattern is neither a temporal phenomenon, nor a simple distance effect. We found similar genetic differentiation between the Swedish E and S morphs of Janson (1982) which have similar morphologies to H and M. Interestingly, the differentiation was due to differing frequencies of the same haplotypes (high frequency of AAA in H/E and high frequency of BCA in M/S). Differentiation of mtDNA is also suggested at Mumbles (South Wales) where the frequency of AAA in *L. saxatilis* H is 0.3, compared to 0 in M — once again, it is the AAA haplotype which is involved. In contrast, no differentiation is indicated at Ravenscar or Ballynahown, but there is little mtDNA haplotype variation to partition at either of these sites.

On the south coast of England there are two obvious patterns to variation in *Littorina saxatilis* shell shape. On a broad scale, there are three "shape groupings" within which shape, analyzed by multivariate canonical variate analysis, is typically homogeneous but among which shape differs (Grahame & Mill 1992, Mill & Grahame 1995). Superimposed upon this, is the morphological distinction into H and M. Both mtDNA and nuclear DNA variation have been analyzed in samples from along the south coast to examine whether there is evidence that mtDNA differentiates H and M as at Galloway, and additionally if there is any evidence for restriction to gene flow between the shape groupings. Discriminant analysis of shape variation with mtDNA haplotypes as groups suggests a correlation between mtDNA haplotype and some aspect of shape on the south coast. However, there is no detectable association of mtDNA or nDNA with either shape groupings or H and M using AMOVA. Thus although a shape-mtDNA correlation has been detected it is not due to either of the *a priori* groupings considered here. In contrast to this, both an mtDNA haplotype and an nDNA allele at the CAL-2 locus are mainly limited to one of the shape groupings; the south central grouping of shape variation. It is likely that the AMOVA analysis of shape groupings does not detect this as a significant association due to the high variability of mtDNA within the shape groupings, effectively masking the 'between group' component. Nevertheless, the correlation of genetic differences at both the mitochondrial and nuclear DNA level with a known shape-group suggests that there is a real population difference.

Thus the pattern of genetic variation in *L. saxatilis* H and M is not simple. MtDNA evidence does not suggest that *L. saxatilis* H are consistently different from *L. saxatilis* M, although this can be the case on a particular shore. Given that these forms have different embryological characteristics (Hull et al. 1996) and display assortative mating (Hull 1998, Pickles and Grahame 1999) and that, in *Littorina*, there is a known substantial genetic component to shell shape (Grahame and Mill 1993), it is perhaps surprising

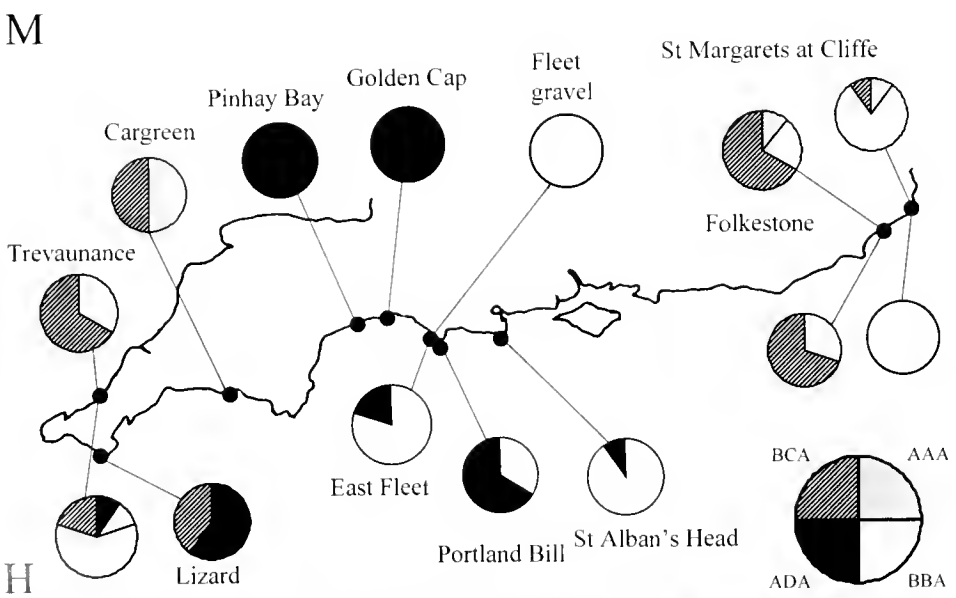

Figure 6. Distribution of the four mtDNA composite haplotypes along the south coast. *L. saxatilis* M are shown above the map and *L. saxatilis* H below.

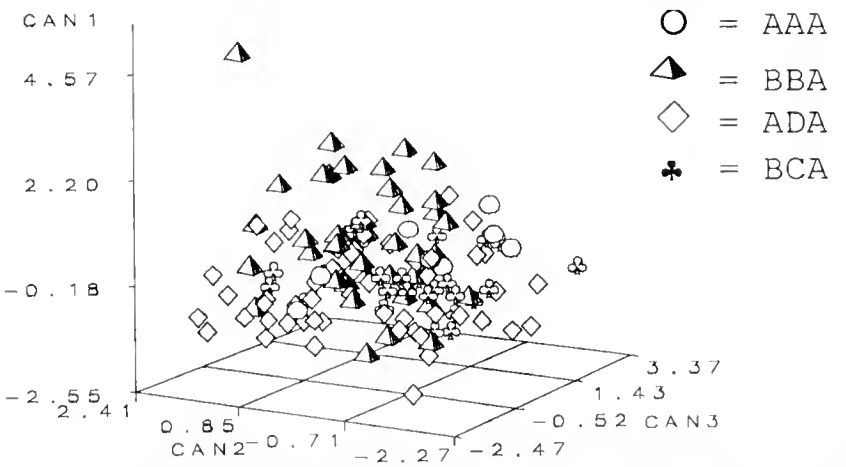

Figure 7. Plotting of haplotype onto canonical variate plot of shape measurements on an individual basis.

that clearer genetic differences have not been detected. However, the rough periwinkle group is itself young (Reid 1996) and sorting of mtDNA in recognized species has not gone to completion (Wilding et al. 2000a). Therefore the pattern within currently recognized species is likely to be complex, as noted here.

Is there a general framework for these observations? Apparently an aspect of the polymorphism of *L. saxatilis* (and perhaps of direct-developing intertidal snails in general) is the repeated appearance of similar phenotypes in different habitat regions of the shore, in response to similar selective pressures imposed by these habitats. Thus in the Galician region of Spain there are found a high-shore, ridged, banded and large morph (RB), and a low-shore, smooth, unbanded and small morph (SU) of *L. saxatilis*. These morphs show a variety of differences, considered to be at least partly genetically controlled, and are partially reproductively isolated (Johannesson et al. 1993). The likely selective factors are considered to be for small and slow growing snails in the lower shore, with larger and faster growing snails in the upper shore (Johannesson, Rolán-Alvarez and Erlandsson 1997). In the British Isles there are completely different morphs, referred to here as H and M, and it may be supposed that an important selective pressure is that of crab predation in the lower shore. Thus, *L. saxatilis* M closely resembles the common morph of *L. compressa* Jeffreys a low shore rough periwinkle, while *L. saxatilis* H is very like the typically higher shore *L. arcana* Hannaford Ellis. These H and M forms are like those in Sweden referred to as E and S (Janson 1982), but while in Britain there is evidence for partial reproductive isolation between H and M (Hull et al. 1996, Hull 1998, Pickles & Grahame 1999), this has not been reported previously for the Swedish animals (Erlandsson & Rolán-Alvarez 1998). Our observation of some difference in mtDNA haplotype frequency between them suggests that the E and S situation should be examined further.

The repeated nature of such phenotypic differences over large spatial scales (~1,000 km) together with the evidence of nascent reproductive barriers, yet superimposed on this undoubted evidence of gene flow between H and M (and E/S in Sweden, RB/SU in Spain), suggests analogy with the parallel speciation scenario proposed by Schluter and Nagel (1995) for sticklebacks. Here the proposed scale becomes important: it may be easier to envisage gene flow in *Littorina* populations along the British coast than between stickleback populations in isolated lakes, but gene flow between snail populations in Spain and Britain may well be very small. In addition the parallel speciation scenario may be applicable even over smaller scales (within Britain, within Galicia). Evidence to date from Galician *L. saxatilis* (Johannesson et al. 1983) and H and M around Britain for neutral loci (Wilding et al. in press) supports the interpretation that populations are more closely related at a site than between sites and yet display the same pattern of morphological differentiation.

The application of additional markers with replicated samples will aid in uncovering the genetic basis underlying *L. saxatilis* H and M. Further repeated sampling, as for that implemented at Galloway, is also needed to test if the patterns at Mumbles and Ursholmen, Sweden are robust to repeated sampling or simply an artifact brought about by the small sample sizes. It is clear that much more needs to be done on the biogoegraphy, behavior, and

TABLE 3.

Discriminant analysis with cross validation on canonical variance with haplotypes as predictors.

	Original haplotype group			
Destination haplotype group	**AAA**	**BBA**	**ADA**	**BCA**
AAA	62.50%	12.50%	12.50%	12.50%
BBA	11.70%	41.70%	23.30%	23.30%
ADA	22.00%	22.00%	41.50%	14.70%
BCA	38.50%	19.20%	25.90%	30.80%

ABSTRACTS OF TECHNICAL PAPERS

Presented at
The 21st Annual Meeting

MILFORD AQUACULTURE SEMINAR

Milford, Connecticut

February 26–28, 2001

CONTENTS

OVERVIEW, 21ST MILFORD AQUACULTURE SEMINAR. **Walter J. Blogoslawski,** U.S. Department of Commerce, National Oceanic & Atmospheric Administration, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, 212 Rogers Ave., Milford, CT 06460

With over 170 registrants representing industry, research, and academic interests, the 21st Annual Milford Aquaculture Seminar had the highest attendance ever for this series of meetings.

This blend of both the theoretical and practical aspects of aquaculture ensured a meeting that permitted attendees to be exposed to areas of the practice of aquaculture outside their own expertise and provided a forum where the latest innovations were introduced and discussed.

The formal papers and posters were presented by persons from 10 U.S. coastal states and the countries of India and Canada. They represented members of three vocational aquaculture high schools, 14 universities, five marine labs, and several state and federal employees involved in shellfish and finfish aquaculture. Topics included aquaculture policy, crop insurance, education, disease, nutrition, and culture techniques. Studies provided information and experiences from laboratory research as well as full-scale commercial installations.

The Seminar has developed a tradition of offering the latest information available in the field in an informal atmosphere. This has succeeded in promoting a free exchange among all with an interest in the success and future of aquaculture. This Seminar continued that approach, allowing all attendees to enjoy and learn from the formal presentations, while also affording informal opportunities to discuss the latest developments pertinent to this important, expanding field.

The meeting was sponsored by the US Department of Commerce, NMFS Milford Laboratory, Milford, CT; abstract printing was courtesy of the US Department of Agriculture, Northeastern Regional Aquaculture Center, N. Dartmouth, MA. Their support is greatly appreciated.

WATER QUALITY AND NUTRITIONAL VALUE OF GREEN WATER VS. CLEARWATER CULTURING OF THE MARINE FISH, *TAUTOGOLABRUS ADSPERSUS*. **Bethann Balazsi,** Southampton College of Long Island University, Southampton, NY 11968, and **Gary H. Wikfors,** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Experiments were designed to test the relative importance of nutritional and water quality factors in green vs. clear water culturing of marine finfish larvae. Two microalgal strains, *Nannochloropsis sp.* (UTEX2341) and *Isochrysis sp.* (T-ISO), were used. Algae were added to fish tanks either in suspension or immobilized in beads or in a dialysis cassette. Two fish, *Tautogolabrus adspersus* (canners), were placed into each tank. Artemia was the food source. Artemia counts were done every day, as were per cent transmittance readings on algal samples from treatments with suspended algae. This was done to determine feeding rates of fish on artemia and of artemia on algae. Water samples were taken periodically throughout the experiment and analyzed for ammonia. The volume displacement was taken as the cunners were added to the tanks, and also at the termination of the experiment.

Immobilized algae in alginate beads was found to be unstable in seawater. Dialysis cassettes were found to be successful for eight days before the dialysis membranes lost integrity. In the dialysis cassette experiment, artemia were replenished 100% when resources were abundant. Algae were replaced each day. It was found that the artemia were cleared within 10 minutes to a few hours, depending on the treatment. The percentage of algae to replace declined in respect to the rate of clearing artemia. Volume displacement measurements did not show any significant growth of the cunner. Algae immobilized in dialysis cassettes removed ammonia from solution, but not as effectively as algae in free suspension. Nevertheless, these findings show dialysis cassettes are a useful tool in understanding how green water cultures work.

Funding provided by a Northeast Fisheries Science Center, Southampton College of Long Island University Cooperative Marine Education and Research (CMER) grant.

EFFECT OF SALINITY ON SURVIVAL AND GROWTH OF EARLY LIFE STAGES OF BLACK SEA BASS. **David Berlinsky, Rachel Howell, Jessica Henderson, Mark Watson** and **Terence Bradley,** University of Rhode Island, Fisheries, Animal, and Veterinary Science, Kingston, RI 02881

The black sea bass, *Centropristis striata*, is currently being investigated as a candidate for commercial aquaculture. One obstacle to production is high mortality rates during early life stages. Environmental salinity has been implicated as an important factor influencing larval survival in numerous species of finfish. The present study was conducted to determine the effects of a range of salinities on the growth and survival of black sea bass at several larval stages. Experiment 1 examined larval survival through yolk-sac absorption (3 days post hatch; dph) at salinities of 0, 5, 10, 15, 20, 25, 30 or 35 parts per thousand (ppt). Ten fertilized eggs were cultured in triplicate at each of the salinities in 500 ml glass containers. At 3 dph, the number of live larvae for each treatment was determined. In experiment 2, 380 actively feeding larvae (8 dph) were cultured in 40 L glass tanks at salinities of 15, 20, 25 or 30 ppt. Each treatment was replicated in triplicate. At 15 dph, the number of surviving larvae was enumerated for each treatment and a sample of 12 larvae from each tank was preserved in 10% neutral buffered formalin for measurement of length. In experiment 3, 200 actively feeding larvae (23 dph) were cultured in 40 L glass tanks at salinities of 15, 20, 25 or 30 ppt. Each treatment was replicated in triplicate. At 32 dph, the number of surviving individuals was enumerated for each treatment and a sample of 12 larvae from each

tank was preserved in 10% neutral buffered formalin for measure of length.

Results from experiment 1 indicate that salinities of at least 10 ppt are required for survival of black sea bass larvae. Survival improved from 42% at 10 ppt to 77% at 15 ppt to >90% at 20–35 ppt. In experiment 2, survival (67%) was higher at a salinity of 30 ppt than at 25 (41%), 20 (47%), or 15 (41%) ppt. No significant differences in growth were observed among treatments. In experiment 3, no significant differences in survival or growth of larvae were observed among the treatments. These studies indicate that black sea bass larvae require at least 10 ppt salinity and become more tolerant to lower environmental salinities with development.

A THEORETICAL ESTIMATE OF THE POTENTIAL IMPACT OF ASIAN SHORE CRAB PREDATION ON MUSSEL SETTLEMENT. Diane J. Brousseau and **Amy Filipowiez,** Fairfield University, Biology Department, Fairfield, CT 06430

The Asian shore crab, *Hemigrapsus sanguineus*, readily consumes juvenile blue mussels, *Mytilus edulis*. In laboratory feeding experiments (n = 59; sexes pooled) each *Hemigrapsus* ate an average of 12.7 ± 11.6 mussels (<10 mm SL) per day over a period of three days. Using this daily consumption rate along with published estimates of mussel recruitment rates in the field (Chipperfield, 1953; Menge, 1978; Petraitis, 1990; Petraitis, 1991) and crab densities at intertidal sites in Long Island Sound (Ahl & Moss, 1999; Gerard et al., 1999), theoretical estimates of mortality due to *Hemigrapsus* predation were calculated. Estimates of mortality ranged from 28–115% of annual mussel settlement, depending on recruitment strength. The average estimate of mortality for all recruitment rates considered (n = 7) was 64%. Under conditions where field consumption rates are comparable to those measured in the laboratory, *Hemigrapsus* has the potential to seriously limit mussel populations in areas where the two species co-occur.

PRELIMINARY INVESTIGATIONS OF CRAB PREDATION ON BAY SCALLOPS. Joseph Choromanski and **Sheila Stiles,** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

In the course of bay scallop aquaculture research conducted at the National Marine Fisheries Service Laboratory in Milford, CT, excess scallops were donated to Connecticut municipal shellfish commissions for free-planting in area waters. The practice of free-planting, or tossing seed scallops (10–40 mm) directly into the water, has come under scrutiny because of the observable decreasing return in the number of adults (>60 mm) caught by recreational fishermen in the towns that have such policies. Field studies of bay scallops have suggested a variety of causes for population fluctuations including habitat loss, genetic inbreeding depression, and predation. It is generally known that crab predation can be a major factor in survival and growth of bay scallops for reseeding or stock enhancement efforts, especially in sites devoid of eel grass, which can serve as a refuge for small scallops.

To evaluate crab predation on scallops, an experimental study was conducted with green crabs (*Carcinus maenas*) in the laboratory. Six treatment aquaria with 10°C flowing seawater were established with a single crab and 10 scallops. A seventh aquarium, with 10 scallops and no crab to check for non-predator related mortality, was used as a control. Four separate trials were run with scallops in each of the following size classes: 10, 20, 30 and 40 mm shell height. Trials were duplicated with a second set of crabs and scallops. Observations were made at 1, 6, 20, and 48 hours for each study. Results indicated that larger-sized scallops had higher survival rates, indicating some degree of refuge from predation by green crabs. In addition, damage to scallop shells was manifested in a characteristic appearance which could be used in identifying mortality by crab predation in the field.

A smaller scale project involved a comparison of bay scallop predation by Asian shore crabs (*Hemigrapsus sanguineus*) versus similar-sized green crabs. Six containers were set up for each crab species with 15 scallops and one crab per container. The shell height of scallops ranged from 6–8 mm and the carapace width of crabs ranged from 18.0 to 25.3 mm. Observations were made after 48 hours when the experiment was terminated. The most notable difference was the number of scallops eaten by the male and female crabs. Generally, male crabs ate all of the scallops in their containers, while the female crabs ate very few to none. This difference could be attributed to the larger size of the claw of the male crabs. There was a slight difference in the number of scallops eaten by the green crabs versus Asian shore crabs. These observations can be used for planning purposes when attempting to enhance or replenish scallop populations.

REPORT ON DESIGN OF PHOTOVOLTAIC-POWERED FLOATING UPWELLER SYSTEM FOR GROWTH OF *CRASSOSTREA VIRGINICA* AND *MERCENARIA MERCENARIA*. Todd Corayer, Block Island Shellfish Farm, Ocean Ave., P.O. Box 1342, Block Island, RI 02807

The intent of this experiment was to design, construct, and evaluate the performance of a floating shellfish upweller which would offer the same growth enhancement opportunities of a traditionally powered unit, yet be completely independent of shoreside power. The unit would be adaptable to salt pond shellfish farms where traditional power was unavailable or cost prohibitive.

The concept and construction was partially funded through an R&D Partnership Award from the Slater Center for Ocean Technology at the University of Rhode Island and through an alternative energy grant from the United States Department of Energy. Block Island Shellfish Farm (BISF) formed a partnership with Chris Warfel PE, owner of Enteeh Engineering, specialists in solar

and wind energy systems, to facilitate the electrical engineering of the upweller.

The upweller consists of single and double-tiered PVC silos with submersible pumps positioned atop. The shellfish were divided between the silos with a test case being established without the aid of a water pump to identify any ancillary growth assistance from the structural design of the upweller. Another test case was located in the abutting lease of Block Island Shellfish Farm (BISF). These test case animals were placed in 1 mm ADPI grow-out bags and maintained along with BISF's inventory of *Crassostrea virginica* and *Mercenaria mercenaria*. Animals in both sites were measured for volume and size changes regularly, and collected data were evaluated against the traditional farm-raised test cage.

Provisions were incorporated into the design to prevent the silos from coming into contact with the pond bottom in situations of extreme low water events. Constructed of pressure treated lumber, the unit was also designed to survive any severe weather which a coastal pond might endure. An insignificant amount of heavy metals leaching was detected as a result of systematic water testing inside the upweller as well as up and down stream.

At this point in our research, regular measurement recordings indicate a successful mating of the photovoltaic cells and the specially designed upweller silos. Essential to the success were animal-to-screen densities and the ability to regulate water flow rates. Experiments are ongoing to refine the structural elements of the unit and the silos to decrease maintenance requirements.

DEVELOPMENT OF THE DIGESTIVE CAECUM DURING THE FIRST LARVAL STAGE IN THE HORSESHOE CRAB, *LIMULUS POLYPHEMUS*. **Yvonne Coursey** and **Mary Kimble**, Department of Biology, University of South Florida, Tampa, FL 33620

The internal development of *Limulus polyphemus* is not complete at the time of hatching from their embryonic membranes. A 1st instar, an animal that has just hatched from its egg casing, does not have a complete digestive system. It lacks the digestive cecum, which branches off from the intestine, and thus can't absorb nutrients. Instead, the 1st instar relies on the yolk present in compartmented areas where the gut will arise. The foregut, which includes the esophagus, crop, and gizzard, is fully formed in the 1st instar. In addition, the hindgut is also present. The intestine and the digestive cecum develop as the animal progresses from a 1st to a 2nd instar, approximately 11–14 days. In this time period the midgut and digestive cecum develop, becoming contiguous with the foregut and the hindgut.

Juvenile horseshoe crabs, 1st and 2nd instars (a 2nd instar is a 1st instar that has molted.), were fixed in Bouin's fluid or a 3% formaldehyde/seawater solution. They were dehydrated through an alcohol gradient series, and embedded in Unicryl® or Spurr's resin. Sections were cut at 3–4μm for light microscopy and 60–90 nm for electron microscopy.

This study determined the internal morphology of 1st and 2nd instars as a precursor to the identification of the site(s) of hemopoeisis in *Limulus polyphemus*. Horseshoe crab blood cells are used to produce *Limulus* amebocyte lysate (LAL), which is used to test for sterility of intravenous solutions. A long-term goal of our research is to establish methods for culturing horseshoe crab cells *in vitro*.

HORSESHOE CRAB AQUACULTURE: RESULTS FROM INITIAL SPAWNING STUDIES. **Carmela Cuomo**, Yale University, Department of Geology & Geophysics, New Haven, CT 06520, and **Paul R. Bartholomew**, SUPERB Technical & Environmental, Hamden, CT 06517

The horseshoe crab, *Limulus polyphemus*, is considered by many to be a living fossil, more for its primitive appearance than for its actual ancestry. The actual species dates back only about 20 million years, although its relatives can be traced back over 200 million years in the fossil record. At the present moment in time it is, perhaps, more important to the biological community than to the geological one. Sea turtles and at least 20 species of Arctic-bound shorebirds feed upon *Limulus* eggs deposited in the shallow tidal flats all along the eastern seaboard of the United States during their spring migrations. Several critical "staging areas" for these birds, including Milford Point, CT, are also known to be "critical habitats" for *Limulus* spawning. Furthermore, *Limulus* adults are harvested for "bleeding" by several biomedical companies. *Limulus* blood is a copper-based blood that coagulates in the presence of gram-negative bacteria. Several companies have developed a biomedical assay, known as *Limulus* amoebocyte lysate (LAL), which is used to test for human diseases (e.g. spinal meningitis and gonorrhea), the purity of pharmaceutical products, and clinical laboratory water purity. The demand for LAL doubled between the 1980s and the 1990s, and doubled again between 1990 and 2000. It is predicted to keep rising well into the 21st century.

Coincident with the increased demand for *Limulus* has been a drastic decline in the *Limulus* populations along the central and northeastern Atlantic Coast of the United States. This decline has been attributed to many factors including over-fishing, declining spawning grounds, deliberate destruction, increased harvesting for LAL, and pollution. In 1998, the Atlantic Marine Fisheries Commission prepared a report on the status of the horseshoe crab populations along the east coast of the United States and a management plan for the fishery. The central goal of this plan was to conserve and protect the horseshoe crab resource in order to maintain sustainable levels of standing stock to ensure both its important role in natural ecosystems, as well as its role in commercial enterprises. Although this is a good initial step, it does not represent the solution to the declining horseshoe crab populations. Breeding grounds are likely to continue to decline due to increased

shoreline development, increased biomedical demands on horseshoe crab, and inability to maintain a steady-state. More fishermen are turning to commercial eel and conch fishing as other fishing stocks decline. The solution to the problem lies in the ability to produce a reliable stock that can be maintained even as natural stocks undergo population fluctuations.

To this end, in the summers of 1999 and 2000, preliminary studies were undertaken at the NMFS laboratory in Milford, CT to test whether or not it was possible to induce *Limulus* adults to spawn in captivity. Various factors were tested for their importance, including sediment grain size, tidal height, light, and tidal regime. The results from this research have proved promising — 4 pairs of adult *Limulus* successfully mated, resulting in the production of thousands of eggs. The eggs were allowed to develop under normal conditions and had a hatching rate of approximately 60% over a two month period. Experiments evaluating the long-term survival and growth of the larvae are presently underway. It is our goal not only to rear the eggs successfully through hatching, but also to rear the hatchlings successfully through at least the first seven molts. It is anticipated that the results from these experiments will translate directly to industry as they will provide horseshoe crabs to companies that need them for years to come.

A COOPERATIVE STUDY ON THE CULTURE OF *CHONDRUS CRISPUS* (RHODOPHYTA) FOR POSSIBLE COMMERCIAL AND BIOREMEDIATION APPLICATIONS IN LONG ISLAND SOUND. John J. Curtis, Sherry W. Lonergan and **Paul J. Trupp,** Bridgeport Regional Vocational Aquaculture School, 60 St. Stephens Rd., Bridgeport, CT 06605; **Jose Zertuche,** University of Connecticut, Stamford, CT 06901, and Universidad Autonoma De Baja California, Ensenada, B.C., Mexico; **Rachel Carmona** and **Charles Yarish,** University of Connecticut, Stamford, CT 06901

As part of an agreement with the University of Connecticut at Stamford, students and staff at the Bridgeport Regional Vocational Aquaculture School are participating in a cooperative study on the feasibility of growing *Chondrus crispus* (Irish Moss) in Long Island Sound for commercial purposes, and as a possible candidate for bioremediation. Dr. C. Yarish, Professor of Ecology and Evolutionary Biology, and Dr. J. Zertuche, a visiting scientist and Professor from Universidad Autonoma De Baja California, formally introduced *Chondrus crispus* culture techniques used on Prince Edward Island, Canada and Baja, California to our school as a project proposal. Since the initial introduction, these scientists and other UConn faculty and staff have visited our school to teach the students the life history and biology of *Chondrus*, and also the design and construction of the equipment necessary for its experimental commercial culture

The first task was to assemble the components necessary to maintain and nurture the *Chondrus* in the laboratory setting. An available .61 × 1.20 × 2.44 m (height × width × length) gel-coated fiberglass tank with a gray interior was selected. To provide aeration and the required water turbulence, a 1 horsepower regenerative blower was used to inject air, through the use of a manifold, into four (4) 1.27 cm PVC pipes. Each 1.27 cm pipe was drilled, in a single horizontal row, with 1.6 mm diameter holes spaced 2.54 cm apart. The drilled pipes were placed in the bottom of the tank with the holes facing upward and running parallel to the 2.44 m of the tank. They are equally spaced from each other and leveled to provide for an equal amount of air discharge for a consistent tumbling action. Suspended above the tank is a 1000-watt metal-halide light fixture delivering 400 μ mol photons m^{-2} s^{-1}, which is on a timed cycle 10:14, L:D cycle. The water is obtained from Long Island Sound and maintained in the tank at a salinity of 27 ppt and at 15 C through the use of a chiller. The water depth is maintained at .36 m to allow for the correct tumbling action and with consistent tissue-to-water volume ratio (<1g /1 L).

The first batch of *Chondrus* was collected by Dr. Zertuche and UConn staff at a site in Stamford, CT and placed in the prepared tank at The School. Students then sorted the *Chondrus* into viable and non-viable plants. Plants with too many (over 50% coverage) epiphytes and epifauna (i.e. oyster drills, star tunicates, snails, and bryozoans), were considered not viable and returned to Black Rock Harbor. The *Chondrus* that was viable was cleaned of as many epiphytes and epifauna as possible and placed in the prepared tanks in the lab. The *Chondrus* was fed twice a week using a 10:1 nitrogen-to-phosphorus ratio. Twenty-four hours after feeding the *Chondrus* in the tank, the tank was drained to remove excess nutrients, cleaned, and refilled with new seawater.

The next task was to construct the equipment that is used to load and unload the *Chondrus* into mesh "stockings" (mussel socks) for outdoor culture. The apparatus was built identical to those used for experimental commercial culture in Mexico. Dr. Zertuche and UCONN staff demonstrated to the students the proper method of loading and unloading the socks. They emphasized the economic importance of a fast and an efficient system to minimize operating costs.

After two weeks in the growout tank, students sorted the *Chondrus* according to size. The larger specimens were used for the outdoor growout segment of our experiment and the smaller sized material was retained in the growout tank. A two-meter square frame, made from 7.62 cm PVC pipe, was constructed to hold the mussel socks at a 0.20 m depth in the water column. Five mussel socks were filled with the *Chondrus* and secured to the raft with wooden button-type fasteners. The raft was deployed in Black Rock Harbor in Bridgeport, CT on December 20, 2000. The *Chondrus* will be weighed to determine the growth, internal levels of carbon, nitrogen, and phosphorus, and water quality parameters as well every four weeks in the winter. In the spring, the interval will be reduced to every two to three weeks to determine the aforementioned parameters as a function of season.

THE EFFECTS OF STOCKING DENSITY IN PEARL NETS ON THE SURVIVAL, GROWTH, AND REPRODUCTIVE POTENTIAL OF THE BAY SCALLOP, *ARGOPECTEN IRRADIANS IRRADIANS*. **Maureen Davidson,** New York State Department of Environmental Conservation, 205 North Belle Mead Road, East Setauket, NY 11733

The stocking densities under which bay scallops (*Argopecten irradians irradians*) are reared may affect survival, growth, and reproductive potential. In order to investigate the influence of stocking density on scallop production, hatchery-reared bay scallops were held in pearl nets at three densities, 80/pearl net, 240/per net and 800/per net for 67 days during the summer. Surviving scallops were counted and shell heights were measured to determine growth. The animals were transferred to lantern nets and stocked at two different densities, 50/tier and 200/tier, and overwintered, grouped by their initial densities in the pearl nets. The following spring survival, shell heights, and gonadal index (a measure of reproductive potential) were determined.

Survival and growth were inversely proportional to stocking density in both pearl and lantern nets. Stocking density in the lantern nets was found to have a greater effect on overwintering survival than did the density in pearl nets. Gonadal indices indicated that scallops initiated spawning at the same time, regardless of density treatment. Once spawning began, bay scallops held at 50/tier in the lantern nets maintained greater gonadal indices and for a longer period of time than those held at 200/tier. There was no significant pearl net effect observed on gonadal index. Bay scallops cultured for direct market should be held at low densities in pearl and lantern nets to maximize growth and survival. Bay scallops raised for resource restoration should be held at moderate densities in pearl nets and low densities in lantern nets to maximize survival and reproductive potential.

DESIGN AND OPERATION OF AN AIRLIFT DRIVEN FLOATING UPWELLER SYSTEM. **Christopher V. Davis,** Pemaquid Oyster Company, P. O. Box 302, Waldoboro, ME 04572

Aquaculturists often employ various types of upwelling systems to expedite the nursery phase of bivalve culture. Land-based systems provide for ease of maintenance and security, but incur high pumping costs. In contrast, Floating Upweller Systems (FLUPSY's) greatly reduce or eliminate pumping costs due to the minimal hydrostatic head required to drive water past the juvenile shellfish. FLUPSY's typically employ centrifugal or axial flow electric pumps to propel water through the system. In contrast, low head airlift pumps are capable of moving large volumes of water, are inherently simple to construct and maintain, eliminate the risk of electrical shock, and have lower operating costs compared to most electrically driven water pumps. Pumping efficiency in airlift systems will be discussed as it relates to the air supply, depth of air injection, lift, diameter of the eduction pipe, and air flow. The design and operation of an airlift-powered FLUPSY operated in Maine will be described.

GROWTH AND MORTALITY OF THE EASTERN OYSTER (*CRASSOSTREA VIRGINICA*) AND THE QUAHOG *(MERCENARIA MERCENARIA VAR. NOTATA)* IN A TAYLOR FLOAT IN MILFORD HARBOR. **Jasmine DeCrescenzo,** Nonnewaug Ellis Clark Regional Ag-Science Technology School, Supervised Agriculture Experience Program, 5 Minor Town Road, Woodbury, CT 06798; **Joseph DeCrescenzo** and **Inke Sunila,** State of Connecticut, Department of Agriculture, Bureau of Aquaculture, P.O. Box 97, Milford, CT 06460

Because of the devastating effects of disease on the natural oyster and clam populations in the Northeast, there has been a growing interest for using hatchery-raised seed. Connecticut receives most of its hatchery-raised stock from neighboring states. The object of this project was to evaluate growth and mortalities of oysters and hard clams during their nursery stage. The shellfish were grown in Milford Harbor, Connecticut during the summer and early autumn of 2000, using the Taylor Float suspended culture system.

Four thousand eastern oysters, *Crassostrea virginica,* (4.5 mm in size) and seven thousand quahogs, *Mercenaria mercenaria* var. *notata,*(4 mm in size) were received from two hatcheries in New York. Both the oysters and clams were divided into two groups, a and b, and placed into a Taylor Float. The float was then placed at the end of a dock in Milford Harbor, which represents a typical estuary that could be used for an aquaculture endeavor. Bivalves were checked on a bi-weekly basis for growth and mortality. The temperature ranged from 15°C to 25.2°C and the salinity from 15.4‰ to 26‰, during the project. Data were collected over a 13 wk period from July into October. Oysters from both groups a and b showed significant growth throughout the project, reaching an average of 37 mm in length at the last measurement. No mortalities were recorded for the oysters. The hard clams grew to 9 mm in length with 19% cumulative mortality at the experiment's conclusion.

From the data collected, oysters showed substantially greater growth in comparison to the clams in the suspended culture. In conclusion, oysters would be a better species of bivalves for growing in the Taylor Float system in the tested estuarine environment. *Mercenaria mercenaria* var. *notata* may be better adapted for growth in full-strength ocean water.

ROTIFER PRODUCTION ON MICROALGAL DIETS: FIRST STEPS TOWARD PROCESS ENGINEERING. **Mark S. Dixon** and **Gary H. Wikfors,** USDOC, NOAA, National MarineFisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; and **Bethann Balazsi,** Long Island University, Southampton College, Natural Science Division, Southampton, NY 11968

Live food production is a critical component in the successful culturing of marine finfish. Consistent production of microalgal biomass, and the efficient conversion of that biomass into live food, leads to reliable nutrition of cultured fish. A series of small-scale experiments was conducted to optimize microalgal diets, define rearing conditions, and explore the potential for process control of production for rotifers (*Brachionus plicatilis*).

The microalgal strain PLY429, *Tetraselmis chui*, yielded the greatest rotifer production when compared to several commonly used strains. A constant density of 6 million microalgal cells per millilter and initial low rotifer stocking densities resulted in rapid reproduction and high overall production. Under these conditions, rotifer populations doubled in as little as two days and reached a maximum density of over 2,000 per milliter in 6 days.

A spectrophotometer was used to monitor algal densities, algal cells were added manually to maintain the target density, and rotifers were counted manually. There is good potential to automate the entire process using "off the shelf" technology. This potential will be explored in upcoming experiments.

DEVELOPMENT OF ASSAYS TO EVALUATE IMMUNE FUNCTIONS OF AMERICAN LOBSTERS (*HOMARUS AMERICANUS*) AND THEIR USE IN FIELD STUDIES. **Shuyun Dong** and **Sylvain De Guise,** University of Connecticut, Department of Pathobiology, Storrs, CT, 06269

In order to develop tools for monitoring heath of American lobsters, we developed assays to evaluate lobster immune functions and validated them in field studies (an EPA study on contamination of lobsters around dredge-material dumpsites and a UConn study monitoring Long Island Sound lobster health).

Hemolymph of lobsters was aspirated and mixed with acid-citrate-dextrose as anticoagulant. Hemolymph appearance was described according to the color of the fluid and hemocytes were counted with a hemocytometer. Phagocytosis of hemocytes was determined by flow cytometry. A cell culture system maintaining lobster hemocytes *in vitro* was established.

Our field study results showed that although hemolymph of lobsters varied from gray to greenish or orange, there was no statistical difference between the different locations. Phagocytosis of lobsters from one location was statistically higher than that from any other locations, and interestingly, hemocyte counts of lobsters from this location were significantly lower than 4 out of the 7 other groups. Even though phagocytic index using two different parameters correlated very well ($r=0.82$), there was no correlation between phagocytosis, hemocyte counts, and hemolymph appearance.

Our lab work demonstrated that sea water with 10% FCS at 12°C represented the best *in vitro* cell culture conditions for lobster hemocytes. Cells adhered to the surface of the 24-well plate and adopted amoeboid shape. Some cells were elongated or fusiform and had prominent filamentous or round pseudopodia. According to cell size and cytoplasm granule, the cells might be differentiated into at least 2 types: hyaline hemocytes and granulocytes. Live cells were found for as long as 48 hours of incubation. Results of analytical toxicology and histophathology will allow the final validation of our field results on the significance of immune function assays. The correlation between immunology and toxicology will provide useful information for the evaluation of lobster health. Our future work will focus on developing other immune function assays such as respiratory burst, NK cell-like activity, hemocyte proliferation, and apoptosis, in addition to experimental immunotoxicology. We expect that those studies will be helpful in understanding the health status of lobsters and identifying the cause(s) and contributing factors involved in the recent Long Island Sound lobster die off.

IMPORTATION OF CHINESE CLAMS CAUSES PROBLEMS IN LOCAL MARKETS. **Gef Flimlin,** Rutgers Cooperative Extension, 1623 Whitesville Rd., Toms River, NJ 08755

In early 2001, there was an importation of frozen molluscan shellfish (clams & mussels) into New Jersey originating from the Republic of China. The state embargoed almost 6,000 cases of clams both whole and half shell which were falsely labeled as cooked or pre-cooked and were found to be raw. Once the State of New Jersey and the US Food and Drug Administration (FDA) investigation revealed that these were not, in fact, cooked clams, the destruction of the products and a national voluntary recall was initiated. The FDA labs later isolated Hepatitis A virus in samples from the shipment implicated in an outbreak.

There is a concern that raw or partially cooked molluscan shellfish is entering the United States under false pretenses as a cooked product. This appears to be a circumvention of the Memorandum of Understanding (MOU) process for a foreign country to be evaluated under the criteria of the National Shellfish Sanitation Program (NSSP) prior to shipping products into the U.S. At the heart of the NSSP is the knowledge that states and countries with FDA MOU's have a program which complies with certain critical water quality criteria including bacteriological, chemical, and marine biotoxin hazards relative to the shellfish and the growing waters. Hazards such as chemicals and marine biotoxins obviously can not be destroyed via cooking.

With the increase of world trade and shellfish aquaculture, it is imperative that the domestic shellfish industry be aware of imported molluscan shellfish and advise the FDA and state depart-

ments of health to force foreign countries to adhere completely to the NSSP Memorandum.

COMPARATIVE EFFICIENCY OF HORMONES ON THE MATURATION AND BREEDING OF INDIAN CATFISH, *HETEROPNEUSTES FOSSILIS*. **Thommai A. Francis,** Department of Fish Farm Management, Fisheries College and Research Institute, Tuticorin, India.

Recent reports show that the ovulation of this species can be induced even during non-spawning season not only through environmental manipulation but also by hormonal stimulation. Various hormones (i.e. carp pituitary extract, human chorionic gonadotropin, mixture of HCG & pituitary extract, leutinizing hormone releasing hormone (LHRH), and ovaprim) were used in the present work to study the maturity and ovulation in *Heteropneustes fossilis*. Among the different hormones, pituitary extract showed higher Gonadosomatic index (GSI) in the injected fish followed by human chorionic gonadotropin. Natural hormones (pituitary extract and human chorionic gonadotropin) influenced the maturity of *Heteropneustes fossilis* better than synthetic hormone analogs.

Among the different hormones used for induced breeding of *Heteropneustes fossilis* better results were obtained from ovaprim. The rate of fertilization (80–84%) was higher in ovaprim-induced fish, while in the case of the other hormones it was less than 78%. Changes in spermatozoa count and the biochemical composition of milt of *Heteropneustes fossilis* were studied by injection of different hormones. Maximum spermatozoa count (3.67×10^6) was recorded in the case of human chorionic gonadotropin followed by the mixture of pituitary and HCG-injected fish (3.21×10^6) and pituitary extract (3.17×10^6). Glucose content of milt was maximum (0.07 mg/0.05 mℓ) in human chorionic gonadotropin-injected fish. Maximum protein content (0.06 mg/0.1 mℓ) was observed from LHRH-induced fish. Data obtained in the experiments were statistically analyzed by analysis of variance.

CHARACTERIZATION OF *VIBRIO CARCHARIAE* AS A PATHOGEN OF SUMMER FLOUNDER (*PARALICHTHYS DENTATUS*). **Eric Gauger** and **Marta Gómez-Chiarri,** University of Rhode Island, Fisheries, Animal and Veterinary Science, Kingston, RI 02881

Vibrio carchariae is a recently identified bacterial pathogen of summer flounder (*Paralichthys dentatus*). As such, little is known about the etiology of the disease which has been given the name Flounder Infectious Necrotizing Enteritis (FINE). Preliminary work on the disease focused on identification of the pathogen, description of clinical and histological symptoms of the disease and determination of a LD 50 at one temperature using intraperitoneal (IP) injection. Current research is focusing on the route of infection and the effects of environmental and other parameters on the virulence of the pathogen.

Disease challenges were conducted at 20, 22 and 24°C, using IP injection. No significant differences in the LD 50 value were seen over this temperature range. Potential routes of infection are being investigated through a set of controlled disease challenges. Groups of fish were subjected to bacterial inoculations approximately 100 times the LD 50 dose for IP injection. Intramuscular injection caused mortalities. However, the clinical signs did not match those of FINE. Immersion was able to cause some infections, but they were limited to surface lesions and did not cause mortalities. Both gastric and intestinal intubation initially failed to produce disease, suggesting that the bacteria may not be able to survive the passage through the digestive system.

A second experiment was conducted at higher stocking densities, immediately after transporting the fish from the main flounder facility at URI. In this experiment, gastric intubation was able to cause mortalities. These results suggest that some sort of stress may be required for the disease to develop. Future work will attempt to clarify the link between stress and disease, investigate the effect of stocking density and water quality on pathogenicity, and also determine other potential routes of infection.

FLOW CYTOMETRY AS A TOOL TO QUANTIFY OYSTER DEFENSE MECHANISMS. **Michael J. Goedken** and **Sylvain De Guise,** Department of Pathobiology, University of Connecticut, Storrs, CT, 06269

The fast-growing oyster aquaculture industry is greatly hindered by two parasites (MSX and Dermo), which can kill up to 80% of the harvest. The relationship between parasites and oyster defense mechanisms is unclear. Two defense mechanisms of the Eastern Oyster (*Crassostrea virginica*) were quantified at the single cell level utilizing flow cytometry. Phagocytosis was measured using fluorescent beads. Respiratory burst activity was quantified as the increase in dichlorofluorescein-associated fluorescence upon stimulation.

These two assays distinguished three populations of hemocytes (granulocytes, hyalinocytes, and intermediate cells) with unique functional characteristics. Granulocytes were most active at phagocytosis and peroxide production while hyalinocytes were relatively inactive. The intermediate cells had moderate phagocytic and respiratory burst activity. Flow cytometry can rapidly, accurately, and directly quantify the morphology and function of a large number of individual cells, and will lead to a better understanding of the yet enigmatic bivalve immune system.

COMPARISON OF TWO TRAP TYPES USED IN A MUNICPAL GREEN CRAB PREDATOR CONTROL PROGRAM. **David W. Grunden,** Shellfish Constable, Town of Oak Bluffs, P. O. Box 1327, Oak Bluffs, MA 02557

This study was conducted in Sengekontacket Pond, a 716-acre salt pond on Martha's Vineyard Island in Oak Bluffs, Massachusetts. Funding was provided through a grant from the Southeastern

Massachusetts Aquaculture Center (SEMAC). The efficiency of two types of traps in catching green crabs (*Carcinus meanus*) was evaluated.

One trap was the traditional eel pot that has been used in the Oak Bluffs Shellfish Department predator control program for the past 15 years. The eel pot is constructed of half-inch mesh vinyl coated wire.

The other trap was a small fish trap manufactured by the Fukui Company. This trap is constructed from a heavy vinyl coated wire frame with half-inch mesh plastic netting.

The traps were baited the same, using fish scraps and heads donated by "Net Result", a local fish market. The number of traps tended and number of bushels caught in each type of trap was recorded each time the traps were tended. From these data, a catch per unit effort was calculated.

The results clearly indicate that the Fukui fish trap is more efficient. Also, despite the higher initial cost of the Fukui trap, it is the more economical trap to use based on the greater trapping efficiency of 2.6 times the traditional eel pot.

EFFECTS OF PHOTOPERIOD MANIPULATION ON REPRODUCTION IN THE BLACK SEA BASS, *CENTROPRISTIS STRIATA*. **Rachel Howell, David Berlinsky,** and **Terence Bradley,** University of Rhode Island, Fisheries, Animal, and Veterinary Science, Kingston, RI 02881

The black sea bass, *Centropristis striata*, is currently being investigated as a potential candidate for commercial aquaculture. As with many new species, one of the most significant constraints limiting commercial production of black sea bass is the lack of a reliable supply of eggs and larvae. A narrow window of annual spawning prevents year-round availability of juveniles for growout and *C. striata* fail to mature and spawn in captivity without hormonal induction. Given that the ability to control the reproductive cycle and the establishment of reliable spawning methods are critical for enhancing production of this species, the primary objective of the present study was to investigate whether black sea bass could be induced to spawn out of season using photoperiod manipulation.

Adult black sea bass were reared under a simulated natural or 6 mo compressed photoperiod regimen. Both groups began the experiment at a minimum day length of 9L:15D and a minimum water temperature of 15°C. Water temperature was increased seasonally with photoperiod and maintained at 18°C once maximum day length was reached (15L:9D). Reproductive development in these fish was monitored by gonadal biopsies and by assay of plasma levels of gonadal steroids (17β-estradiol, testosterone, and 11-ketotestosterone). At monthly intervals, fish were weighed, measured, and bled, and gonadal tissue sampled by biopsy. Following histological processing, biopsy samples were examined to determine the stage of oocyte maturation and maximum follicle diameter. Females with follicles ≥500 μm in diameter were induced to spawn by implantation of 25–50 μg leutinizing hormone-releasing hormone analog ($LHRH_a$). Females reared under the compressed cycle attained follicles 500 μm in diameter and were induced to spawn in March, approximately 2 mo in advance of individuals reared under the simulated natural photoperiod. Males on both cycles began spermiating in late January and continued through the duration of the experiment. Measurement of plasma levels of 17β-estradiol, testosterone, and 11-ketotestosterone are ongoing and will be presented.

AQUA-TOURISM, TURBO-TIDAL UPWELLERS, AND OTHER DEVELOPMENTS IN THE SHELLFISH INDUSTRY ON MARTHA'S VINEYARD IN THE YEAR 2000. **Richard C. Karney,** Martha's Vineyard Shellfish Group, Inc., Box 1552, Oak Bluffs, MA 02557; **John C. Blake,** Sweet Neck Farm, Box 1468, Edgartown, MA 02539; and **Thomas E. Berry,** Martha's Vineyard Shellfish, Box 1660, Edgartown, MA 02539

When polled, shellfish growers in Massachusetts have consistently identified the general public's perception of aquaculture as one of the most important factors affecting the growth of aquaculture in the Bay State. The strong and enduring tradition of active government participation by the Massachusetts citizenry makes a public education project which stresses the benefits of shellfish aquaculture crucial to the development of an industry that relies on the use of the marine common lands. Under grant funding from the Massachusetts Department of Food and Agriculture, the Martha's Vineyard Shellfish Group conducted a collaborative, multifaceted public relations project with the goals of showcasing local public and private aquaculture operations and extolling the environmental, economic, and social benefits of the shellfish aquaculture industry. We employed a multitude of communication outlets to spread the gospel of aquaculture. The project included aqua-tours of private shellfish farms, web site development, tastings of cultured shellfish, public access cable programs, posters, and the distribution of printed information.

With financial support from the National Fish and Wildlife Foundation, five growers cultured over a million seed oysters in tidal upweller nurseries. Some of the nurseries were modified with the addition of side vents. Although these "turbo-charged" nurseries experienced an improved flow rate, there appeared to be no improvement in oyster growth rate compared to nurseries without the added vents.

Both public and private oyster stocks were tested for disease. Private growers in Katama Bay were relieved to find that their cultured oysters, which were believed to be infected with MSX (*Haplosporidium nelsoni*) upon PCR analysis, were found to be infected with the less serious SSO (*Haplosporidium costale*). Oysters sampled for Dermo (*Perkinsus marinus*) from public beds in Tisbury Great Pond showed an increased infection from 8% in 1999 to over 50% in 2000.

We report the discovery of an unusual flattened form of *Mer-*

cenaria mercenaria from a sand bottom in Katama Bay. It measured 57.8 mm in length, 49.3 mm in height, and 19.5 mm in width.

SUMMER FLOUNDER (PARALICHTHYS DENTATUS) PRODUCTION AT GREATBAY AQUAFARMS, INC. Nick King, GreatBay Aquafarms, Inc., 153 Gosling Road, Portsmouth, NH 03801

Since 1996, GreatBay Aquafarms (GBA) has been producing summer flounder at its hatchery in Portsmouth, NH. Recently, GBA has sent its first major crop of flounder to market from its demonstration growout facility that utilizes re-circulation technology developed by the company. Survival of fish through the hatchery phase (6 mo) tends to be less than 30% and varies with production lot. Growth of individuals differentiates following metamorphosis, and by six months considerable variation in body size occurs around the mean size of 10 g. Size grading begins at 70 days (ph) and is necessary through the growing cycle to avoid nipping and to ensure proper feed management. Currently, fish reach an average size of 650 grams in two years from hatching, and our studies have shown that growth rates differ between the sexes during commercial ongrowing. Great strides toward improving production standards and improving the growth curve for summer flounder can be obtained through advances in husbandry, nutrition, fish health, and selective breeding.

THE ECONOMICS OF NEW ENGLAND FINFISH GROWOUT: AQUACULTURE AT AN OFFSHORE SITE. Hauke L. Kite-Powell and **Porter Hoagland,** Marine Policy Center, Woods Hole Oceanographic Institution, Woods Hole, MA 02543

We have developed a bioeconomic model of an open ocean finfish growout operation. The model optimizes stocking and harvesting schedules, and projects financial flows. It allows for comparison of alternate growout sites based on their physical characteristics (distance from shore, water temperature, water depth, etc.). The model takes into account seasonal variability in the price of fish landings as well as the effect of water temperature on fish growth rates. We have illustrated the use of the model by applying it to hypothetical growout operations for cod, salmon, and flounder off the coast of New England.

The model's optimization procedure assumes that the growout operation is to produce a fixed amount of fish (v_h, by weight) each month (or in specified months only). The model determines the optimal stocking time and number of fish for each harvest month. It also calculates expected financial flows and summary values such as project NPV and the amount of up-front investment required.

For each harvest month h (h = 1,2,3,...,12), the model uses a species-specific growth function to calculate the weight at harvest of an individual fish ($f_h(m)$) stocked as a fingerling in month m (m = h-23, h-22, h-21, ...). The model then calculates the number of fish at harvest $n_h(m) = v_h/f_h(m)$, and works backward, using the mortality function, to calculate the number of fingerlings to be stocked.

For each harvest month h, the model then identifies the stocking month m that results in the maximum net revenue (discounted difference between revenue and variable cost). Revenue is the product of harvest weight and price, which varies with fish size and time of year: $v_h * p(h, f_h(m))$. (Stocking months that result in sub-market-size fish result in zero revenue and are not considered.) Variable costs include the cost of fingerlings, feed and medication, and harvesting, including associated vessel costs. The maximum net revenue determines the optimal stocking month (and length of growout), as well as the number of fingerlings.

Once stocking decisions have been optimized, the model calculates the financial performance of the growout operation month-by-month over 15 years to determine projected cash flows, project NPV, and investment capital needed, as well as operational parameters such as vessel utilization and feed volume. The table below summarizes model results for three species.

TABLE 1.

	Cod	Salmon	Flounder
number of cages	72	72	6
fingerlings/year	1,788,000	532,000	261,000
tons of feed/year	5,416	5,281	474
boat days/year	81	77	14
average harvest weight, g	1,466	4,093	1,025
harvest, tons/month	175	151	125
NPV at 5% discount rate, $m	1.50	14.16	1.07
investment capital required, $m	8.61	9.24	1.17

THE ROLE OF APOPTOSIS IN THE PATHOGENESIS OF THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*. Jill LaBanca, Fairfield University, Fairfield, CT 06430; **Inke Sunila,** State of Connecticut, Department of Agriculture, Bureau of Aquaculture, P.O. Box 97, Milford, CT 06460

Apoptosis, programmed cell death, is an essential part of cell renewal and embryonic development. During apoptosis, cells undergo shrinkage and zeiosis, or blebbing. Endonucleases digest DNA into 200 base pair fragments. Later, the cell breaks into apoptotic bodies that are ingested by phagocytes. Apoptosis, or the lack of apoptosis, is also pivotal in the pathogenesis of several different diseases. *Perkinsus marinus* (Dermo), *Haplosporidium nelsoni* (MSX), and Juvenile Oyster Disease (JOD) are common diseases of the eastern oyster (*Crassostrea virginica*) along the New England shoreline. The complete pathogenesis of these diseases is still unknown. We studied the effects of apoptosis on the progression of these diseases.

Archived oyster tissues from the State of Connecticut's Bureau of Aquaculture were classified according to the type of infection

and five categories were created: oysters infected with only Dermo, oysters infected with only MSX, oysters infected with only JOD, mature oysters with no infections, and juvenile oysters with no infections. Ten oysters from each group underwent *in situ* hybridization to detect DNA fragments by end labeling. A 6 μm section from each oyster was deparaffinized and digested with proteinase K. A digoxigenin nucleotide probe was used to anneal to and label the 200 base pair fragment yielded by apoptosis. The probe was detected immunohistochemically using an antidigoxigenin peroxidase conjugate. The complex was stained with a peroxidase substrate and the slide was counter-stained with methyl green.

Apoptotic hemocytes were found to be present in the gill and stomach epithelia and surrounding connective tissue at a regular rate in both sets of healthy oysters. The oysters infected with Dermo had a reduced number of apoptotic hemocytes present in their tissues. These oysters had Dermo weighted prevalences from 0.5 to 4. The prevention of hemocyte apoptosis yields a greater number of hemocytes in which Dermo houses itself. Large numbers of Dermo cells in some infected oysters were eliminated via apoptosis in the stomach epithelia, disabling the spread of infectious particles through sea water. The oysters infected with MSX also had reduced numbers of apoptotic hemocytes. MSX appears to prevent hemocyte apoptosis. In some infected oysters large numbers of MSX-plasmodia were eliminated via apoptosis. Part of the vesicular connective tissue cells of MSX-infected oysters were apoptotic. Oysters infected with JOD had the presence of large, unidentified, apoptotic cells in the stomach epithelia whose role has not yet been determined.

Apoptosis enhances progression and prevents transmission of oyster diseases. The ability of oysters to eliminate parasites via apoptosis may establish the genetic basis of disease resistance.

EFFECTS OF NURSERY CULTURE TECHNIQUE ON THE MORPHOLOGY AND BURROWING CAPABILITY OF THE SOFTSHELL CLAM, *MYA ARENARIA*. Kenneth J. LaValley, Spinney Creek Shellfish, Inc., Eliot, ME 03903

In August of 1999 trials began to evaluate the benefits of a raceway nursery system compared to a Floating Upweller System (FLUPSY). Raceways are shallow rectangular trays into which water is introduced at one end, flows over the seed clams, and exits at the other end through a drain. During normal operation, silt from the estuarine waters and pseudofeces from shellfish produce a substrate. This substrate would be detrimental to other bivalve shellfish (oysters, quahogs) and would represent an intense maintenance problem. However, to the juvenile softshell clam the substrate represents an artificial mud flat.

It was initially hypothesized that the ability to burrow into a substrate would allow enhanced growth by reducing the physiological stress experienced while in an upweller system. The anterior and posterior adductor muscles, having evolved to suit a habitat several inches beneath the sediment, are unable to maintain a "normal" gape or closed position outside of sediment. This condition results in a physiological stress, which incurs abnormal growth. During initial FLUPSY trials a significant stress (reduced growth, shell deformities) was observed after juveniles had reached 15 mm.

To determine the effect of initial size and planting density, two size ranges of softshell clam seed, 6 and 9 mm, were planted at three densities (4, 8, and 16 clams/square inch) within the raceway. In order to compare the performance between the two nursery techniques both size ranges were stocked in the floating upweller system at a density of 8 clams per square inch. The weekly growth rates were consistently higher at the raceway than the floating upweller. The raceway clams grew at a rate of approximately 2 mm per week, while the upweller clams did so at a range of .75 to 1.0 mm per week. Stocking density did not significantly affect growth rate of raceway clams.

Following growth and density comparisons, culture observations were statistically evaluated by comparing "wild" softshell clam seed to cultured animals, as well as by comparing the morphology of market size "wild" softshell clams to cultured seed. We also determined and compared the burrowing capability of "wild" and cultured seed.

Softshell clams produced in the FLUPSY significantly differed in their morphology compared to clams cultured in the raceway or "wild" seed. Clams cultured in the FLUPSY also demonstrated a significant decrease in their ability to burrow compared to raceway or "wild" seed. The percentage of clams that successfully burrowed in a two hour period was proportionally lower in seed produced in the FLUPSY (65% compared to 80%).

Raceway seed did not significantly differ from "wild" seed or market size animals in their morphology or ability to burrow. In summary, nursery technique can significantly affect the morphology and behavior of cultured shellfish. These differences may significantly impact initial survival of softshell clam seed postplanting. For softshell clams, a sediment-filled culture environment appears to be the optimal nursery strategy.

THE RAZOR CLAM (*ENSIS DIRECTUS*) AS A CANDIDATE FOR CULTURE IN THE NORTHEAST: AN INTRODUCTION. Dale Leavitt and **William Burt,** Southeastern Massachusetts Aquaculture Center, Hurley Library, Mass. Maritime Academy, 101 Academy Dr., Buzzards Bay, MA 02532

There is an urgent need for the shellfish culture industry in the northeastern United States to expand their list of candidate species for culture and to diversify their crop. Reliance on two species of bivalve mollusk, given the historic and current prevalence of debilitating diseases, may result in lost opportunities to use sites for farming shellfish. By expanding the selection of candidate species, growers will have better success in conducting their business by providing alternate crops that may be appropriate for their specific growout situation.

The razor clam represents one candidate species that has a high

potential for commercialization. Market demand for the razor clam seems to be constant and can be expanded given the relative lack of awareness on the part of consumers regarding the acceptability of the product. Landed value is currently at a level that makes farming the razor clam economically attractive. The constraints at this point are focused on developing the appropriate technology for growing the razor clam to a market size.

The razor clam exhibits biological properties that suggest it is a reasonable candidate for culture. It undergoes a routine bivalve larval cycle that should adapt to hatchery conditions readily. It grows relatively quickly and has been successfully cultured as a by-product under quahog anti-predator netting, due to wild recruitment onto the site. It naturally inhabits intertidal and subtidal areas that are currently being used for quahog culture.

The razor clam, however, will present some challenges to development of it as a commercially viable farmed bivalve. These include:

1. Mobility
2. Over-winter survival
3. Predators & disease
4. Shelf-life
5. Overall lack of knowledge about the species.

To aid in diversifying the industry, the Northeast Regional Aquaculture Center (NRAC) has funded us to begin work on developing technology for razor clam growout. The overall objective of this project is to provide an opportunity for the current shellfish culture industry to investigate, develop, and optimize the growout technology for a cultured razor clam. An overview of the projected work and a solicitation for industry involvement is presented.

PRELIMINARY STUDIES ON OPTIMAL ROTIFER CULTURE DIETS AND ALTERNATIVE REPLACEMENT DIETS AND ENRICHMENTS FOR LARVAL BLACK SEA BASS (*CENTROPRISTIS STRIATA*). **Jennie M. Mandeville,** Middlebury College, MC Box 3365, Middlebury, VT 05753; **Mark T. Watson** and **Brandy M. Moran,** Massachusetts Institute of Technology Sea Grant College Program, MIT Bldg. E38–300, 292 Main St., Cambridge, MA 02139

Rotifers *(Brachionus plicatilis)* are excellent first-feed food for cultured larval fish as they are one of the fishes' naturally occurring food sources, small in size, mobile, and easily cultured. It is important that the rotifers are fed a healthy diet that promotes rapid growth in order to maintain a constant food source for the larvae. Several rotifer diets have been tested in the past; this study examines three new, as well as previously tested, diets for their effect on rotifer population growth. The diets were Instant Algae (Reed Mariculture, CA), consisting of *Nannochloropsis oculata* (Nanno), *Isochrysis galbana* (T-Iso), and *Pavlova sp.*, bakers yeast and Algamac 2000 (Aquafauna Bio-Marine, Inc., Hawthorne, CA). Fifteen combinations of these diets were evaluated for their performance. Nanno supported the highest maximum population growth rate, and was significantly higher than 8 other diets ($P < 0.05$). However, three other combinations of algae and yeast significantly ($P<0.05$) enhanced population growth rates as well. Food combinations including Algamac resulted in significantly ($P < 0.05$) poorer growth rates. While preliminary, these findings can be used to guide aquaculturists in their choice of rotifer diet, and also as a foundation on which to base future studies exploring the nutritional value that these diets confer to larval fish.

Advancements in culture methods of alternative marine finfish species, especially early life stages, are necessary in order to encourage commercial production. Alternative diets and more efficient live feed enrichments are two ways to enhance growth and survival of cultured fish. Black sea bass *(Centropristis striata)* eggs, spawned in captivity at the University of Rhode Island (Kingston, RI), were transported to the Massachusetts Institute of Technology Sea Grant College Marine Finfish Hatchery (Charlestown, MA). The eggs were incubated in filtered (1 µ, with UV) harbor water (22 °C, 28 ppt salinity), and 24 h photoperiod) until hatch and then transferred into nine 40 L tanks.

In preliminary studies we tested a live-feed replacement, Revolution (Salt Creek Inc., UT) liquid fish diet, and compared it to rotifers enriched with Instant Algae (Nanno and T-Iso). Newly hatched larval sea bass were fed three combinations of diets: (1) 100% Revolution diet, (2) 50% Revolution and 50% Rotifers, and (3) 100% rotifers. Results of growth and survival showed that there was no difference between diets #2 & #3; diet #1, however, resulted in 100% mortality after 10 days, demonstrating that the Revolution diet can be used as a supplement in larval fish cultures, but not as a substitute for rotifers. Recent studies have shown that larvae allowed to feed for several days on live feed prior to replacement diets show higher survival. This is thought to permit proper digestive tract development.

A second series of studies compared various enrichment media for rotifers and examined their effect on growth and survival of newly hatched black sea bass larvae. Three popular, commercially available enrichments were tested: Instant Algae (Nanno and T-Iso); Culture Selco (Inve Aquaculture Inc., Grantsville, UT); and Algamac 2000. Preliminary results showed that Algamac 2000 provided the highest growth and the most consistent survival (50%) as an enrichment. Research is continuing to compare the economic benefits of the various enrichments.

PREVALENCE OF *PERKINSUS MARINUS* IN THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*, IN RHODE ISLAND. **Karen Mareiro, Josefa Dougal, Meggan Dwyer, Kenneth Leonard III** and **Marta Gómez-Chiarri,** University of Rhode Island, Fisheries, Animal and Veterinary Science, Kingston, RI 02881; **Arthur Ganz,** Rhode Island Department of Environmental Management, Coastal Fisheries Laboratory, Wakefield, RI 02879

Populations of Eastern oyster, *Crassostrea virginica*, along the East Coast of the United States have been severely decimated by various diseases in recent years. One of the most common of those

diseases is Dermo disease, which is caused by the protozoan parasite *Perkinsus marinus*. Since 1998, our laboratory has been tracking the prevalence of this disease in oysters from several locations in Rhode Island. Thirty oysters were collected from 12 sites throughout Rhode Island waters, including aquaculture lease sites, in August and November of 1998–2000. The presence and intensity of Dermo disease was tested using the Ray's Fluid Thioglycollate Media (RFTM) method. Dermo infections were detected at most sites, with the highest intensity of infections being observed in Barrington River and Point Judith Pond (wild). Areas where prevalence of Dermo was low include Block Island and Prudence Island. In addition, Dermo prevalence was also low in oysters collected from aquaculture lease sites. Differences in prevalence of Dermo disease in these areas could be due to lower exposure to parasite, resistance to parasite, food availability, or abiotic factors including flushing rates, salinity, and temperature variability. Furthermore, in 1998 and 1999, intensity of infections was higher in August than in November. However, in 2000 the reverse was true. It is possible that the late peak in prevalence and intensity could be due to the cold weather of early 2000 winter. This research has been funded by the Rhode Island Department of Environmental Management, Division of Fish and Wildlife.

IS *SIROLPIDIUM ZOOPHTHORUM* THE ANIMAL EATER ITS NAME SUGGESTS? NEW EVIDENCE OF PARASITISM. Christopher Martin, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

A phycomycetous fungus has been observed repeatedly in larvae of the bay scallop, *Argopecten irradians*, at the Milford Laboratory. This microorganism has been tentatively identified as *Sirolpidium zoophthorum* Vishniac, first observed at this laboratory by V.L. Loosanoff almost fifty years ago. The morphology and development of the fungus have been previously described. While apparently enzootic in scallop cultures at our laboratory, *S. zoophthorum* has not been tied directly to mass mortalities of this species. Loosanoff regarded it as parasitic in the bay scallop and in the larvae and juveniles of other bivalves. However, his evidence was largely circumstantial, i.e., conspicuous presence of "infected" larvae in cultures suffering high mortality.

Using pure cultures of *S. zoophthorum*, freshly isolated from affected scallop larvae, it has been possible to demonstrate that this fungus is one likely cause of observed mortality. Exposure of 72 h scallop larvae to suspensions of recently emerged zoospores resulted in approximately 70% mortality in 4 days. Fungal thalli were detected in up to 88% of dead larvae. Untreated controls remained unaffected. *S. zoophthorum* was successfully re-isolated from parasitized larvae, thus satisfying Koch's Postulates.

POTENTIAL EFFECTS OF CONTAMINANT EXPOSURE ON CULTURED TAUTOG, *TAUTOGA ONITIS*. Brandy M. Moran, Mark T. Watson, and **Cliff A. Goudey,** Massachusetts Institute of Technology Sea Grant College Program, MIT Bldg. E38–300, 292 Main St., Cambridge, MA 02139

MIT Sea Grant College Program has been demonstrating aquaculture in recirculating systems in the Boston Harbor since May 1998. The hatchery is located in the inner harbor within the Charlestown Navy Yard, Charlestown, MA. The Navy Yard was in full commission from 1799 to 1975. Due to the shipbuilding, equipment facility, and cordage activities conducted at the yard and the overall industrial character of the port, the surrounding seafloor sediments are contaminated by waste products such as heavy metals. The contaminated sediments and other pollution sources in the harbor may influence the water quality used in the recirculating systems. Because there was a concern about contaminant accumulation in the fish reared at the hatchery, a monitoring program began. To establish an economical and commercial hatchery in Boston Harbor, the possibility of cultured fish accumulating harmful pollutants needed to be investigated.

Tautog exclusively raised in a recirculating system from egg, spawned in July 1998, are currently 2 ½ years. Collaborating with the Massachusetts Water Resource Authority, the muscle tissues of these fish were analyzed for heavy metals and contaminants in February 1999 (7 mo), November 1999 (16 mo) and June 2000 (23 mo). The data reveal traces of heavy metals and other contaminants in fish tissue, but all levels are below FDA regulations, action levels, and recommendation levels. This demonstrates that fish being held for long periods of time in Boston Harbor water are safe for human consumption under current regulations.

Additional unique findings in the reared tautog were observed during this study. In February 2000, when the tautog were 18 mo, fertilized and unfertilized eggs were found in the recirculating system. This spawning occurrence is early according to literature on tautog reproductive strategies. Tautog are known to mature sexually between 2 and 3 y. By June 2000, some of the tautog showed signs of an enlarged abdomen and unbalanced swimming behavior. The fish were sent for a full diagnostic analysis. The tautog with swollen abdomens were all females that were not successfully reabsorbing unspawned eggs. The tautog also had gill deformities consisting of migrating chloride cells to the tip of the lamellae, fusion of lamellae, and enlarged mucus cells. The water quality of the system was stable over the 2 ½ year time span except for the ammonia, which fluctuated between 0 ppm–5 ppm.

These abnormalities are potentially associated with water quality and/or low-level contaminants. The impact of the fluctuating ammonia may have caused a stress-induced acclimation to the gills to be able to tolerate its surroundings. It is also possible that exposure to low-level contaminants for an extended period of time could cause these gill deformations. Both the stress from the ammonia and contaminants may affect the female tautog ability to reabsorb eggs that were not spent. Although the tautog are edible

under the current FDA regulations, the exposure to these contaminants could be affecting the overall health of the fish. Further research is needed to determine tautog's exposure tolerance to metals, ammonia, and other critical environmental parameters. This information would aid in the siting and success of a commercial hatchery in industrial harbors.

BOTTOMS UP! AN INDUSTRY-LED PROJECT: BRINGING AN AQUACULTURE TECHNIQUE TO THE INSHORE SCALLOP FISHERY IN MAINE. Dana L. Morse, University of Maine, Darling Marine Center, 193 Clark's Cove Rd., Walpole, ME 04573

In May of 1999, a delegation from Maine traveled to Japan to learn about the scallop culture industry. Focusing on Aomori Prefecture, the group quickly realized that the Japanese industry relied on a successful spat collection program, and that elements of this program could yield benefits in Maine's wild fishery. The late summer and fall of 1999 saw many fishermen up and down the coast experimenting with spat collection gear, particularly in the port of Stonington.

Since the start, industry has had the leading voice in implementing and continuing this work, with strong collaborations with a wide variety of agencies and organizations. Catches of seed from the 1999 year class were spotty but encouraging, and preliminary assessments from the year 2000 set indicate that catches will be good.

Many obstacles exist for the continued development and acceptance of the program. However, the effort has yielded promising results thus far, and industry support has remained strong. Future work will rely on this continued support, and from the productive working relationships with other groups in the state.

EFFECTS OF FILTER-FEEDING OYSTERS ON SEDIMENTATION RATES AND PHYTOPLANKTON SPECIES COMPOSITION: PRELIMINARY RESULTS OF MESOCOSM EXPERIMENTS. Jennifer Mugg, Michael A. Rice, and Monique Perron, University of Rhode Island, Fisheries, Animal, and Veterinary Science, Kingston, RI 02881

Eutrophication is occurring in many coastal estuaries. A possible solution to this problem is to raise aquaculture oysters to improve water clarity and to help remove excess nitrogen. In order to determine what effects aquaculture oysters have on the environment, a mesocosm study was performed at the Marine Ecosystem Research Laboratory (MERL) from June to October 2000. The MERL facility is located adjacent to Narragansett Bay with thirteen 13,000 L mesocosm tanks that simulate the environmental conditions of the Bay. Two hundred oysters (≈35 mm in valve length; nominally filtering about 48 L da^{-1} ind^{-1}) were placed into three mesocosms, and three mesocosms were maintained without oysters as controls. Experiments were run with varying rates of water exchange in the tanks ranging from 0% to 100% per day (0–13,000 L da^{-1}). Several parameters were measured and compared between the two treatments, which included chlorophyll-a, particulate organic and inorganic matter, sedimentation rates, nitrate, ammonia, phytoplankton analysis and growth rates.

Preliminary results show that oysters have an effect on species composition of phytoplankton in the water column and induce increased rates of sedimentation to the benthos. Diatoms of the genus *Nitzschia* were predominant in mesocosms with oysters, and in the control tanks *Skeletonema* were dominant. Tanks with oysters consistently showed rates of sedimentation greater than twice the control tanks. We speculate that this increased organic sedimentation by actively filter feeding oysters may contribute to increased rates of sediment deposition leading to increased denitrification in natural systems. This is work from RI-AES Project H-886, and is publication number 3857 of the College of the Environment and Life Sciences, University of Rhode Island.

LABORATORY CULTURE OF LARVAL TAUTOG: RECENT UPDATES AND CHANGES. Dean M. Perry, David A. Nelson, and **Robin S. Katersky,** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Adult field-captured tautog, *Tautoga onitis,* were spawned in the laboratory. Larvae were cultured according to standard laboratory procedures developed at the Milford laboratory using a recirculating system containing six 1140 L conical rearing tanks. During the summer of 2000, the following changes were made to our protocol which increased larval survival. These changes included increasing live feed density in the rearing system, extending the duration of rotifer feeding, and decreasing the initial larval stocking density. Larvae were fed an average of 9×10^6 rotifers per day, which is double the amount fed in previous years. They were also fed rotifers for a 25 d period compared to 14 d in prior years. With this increased larval survival we are currently monitoring growth rates of these juveniles under laboratory conditions. From December 14, 2000 to February 2, 2001, total length (mm) and biomass were measured and recorded biweekly. Specific growth rate was 0.30 mm d^{-1} and biomass increased at an average of 0.04 g d^{-1}.

DEPARTMENT OF COMMERCE AQUACULTURE—AN UPDATE OF POLICIES, PLANS AND PROGRAMS. Edwin Rhodes, Aquaculture Coordinator, National Oceanic and Atmospheric Administration, National Marine Fisheries Service, 1315 East-West Highway, Silver Spring, MD 20910

The Department of Commerce Aquaculture Policy, signed in 1999, has created a renewed interest in aquaculture within the Department. Guidance to Commerce agencies concerning aqua-

culture has been developed that should insure that aquaculture is considered in all relevant Department programs. The chief funding increase for aquaculture came through an additional $3 million appropriation to the Office of Oceanic and Atmospheric Research that will result in a competitive distribution of $5 million in this fiscal year, and a similar amount next year. Funding from this program in the last cycle went primarily toward management and regulatory issues, but this year's priorities include a strong emphasis on research and encourages industry, government, and academic partnerships that will result in commercialization of aquaculture, and which also will contribute to the Commerce goal of a fivefold increase in U.S. aquaculture production by 2025.

Other NOAA programs that support the development of environmentally sound aquaculture include the in-house aquaculture R&D programs at our Northeast and Northwest Science Centers, and the Fisheries Finance Program that made significant loans to the aquaculture industry in 2000. NOAA has also drafted offshore aquaculture legislation that would authorize long term leases in the U.S. EEZ. Additionally, NOAA, along with other Federal partners and with stakeholder input, is developing a code of conduct for responsible aquaculture in the U.S. exclusive economic zone. NOAA is also providing some funding for offshore aquaculture development.

KEEPING GENTRIFICATION AT BAY: HOW A DEFUNCT SHELLFISH FACILITY WAS KEPT FROM THE DEVELOPERS. Gregg Rivara, Cornell Cooperative Extension of Suffolk County, Marine Environmental Learning Center, Southold, NY, 11971; **Timothy Caufield,** Peconic Land Trust, P.O. Box 1776, Southampton, NY 11969; and **Walter Smith,** P. O. Box 395, Orient, NY 11957

The loss of waterfront real estate to non-water dependent uses in the Northeast and elsewhere has made siting new shellfish mariculture operations expensive, if possible at all. The Shelter Island Oyster Company (SIOC) was formed in 1924 by Anna and John Plock Sr. By the 1960s the company had offices in Manhattan and Greenport, and a nursery/growout facility in Southold, New York. John Plock has been called a marketing genius— many types of SIOC marketing devices can today be found in online auctions. As a result of Plock's business sense, the company was well known, and plans to sell its "greenhouse" oysters by mail were featured in *National Fisherman* in the 1970's.

A number of unfortunate events led to the demise of the company in 1984. What remained of SIOC's holdings was the Southold location, a 22-acre site of buildings, artificial lagoons, tide gates, and decaying culture gear— all in all, a facility that could not be built with today's environmental regulations. After a series of failed development plans that would have precluded mariculture at the site, the Peconic Land Trust, a not-for-profit land conservation organization, and Cornell Cooperative Extension worked on a plan with the Plock family to save most of the area used for shellfish culture while limiting development to four two-acre lots.

Dedicated in 1996, the "Shellfisher Preserve" consists of 14 acres with structures and water access that are offered by the Trust as an incubator for shellfish mariculture firms. Currently there are two such tenants, both with hatchery and nursery operations in place or planned for 2001.

DEVELOPMENT OF THE NOANK AQUACULTURE COOPERATIVE IN CONNECTICUT. Karen Rivara, The Noank Aquaculture Cooperative, 100 Main St., Noank, CT 06340

The Noank Aquaculture Cooperative (NAC) is now a legal entity which will operate a commercial shellfish hatchery and nursery system. It will provide shellfish seed to our members to grow to market size. The market shellfish will then be sold through the Cooperative. In addition to operating a commercial hatchery, the Cooperative will have wet storage and a processing facility at the Noank site.

The Noank Aquaculture Cooperative (NAC) will coordinate with the Long Island Sound Regional Vocational Aquaculture School to provide hands-on learning experiences for their students. The Groton Shellfish Commission will be involved in our education outreach program. We will be working with researchers in Connecticut, both from the universities and the Bureau of Aquaculture, to develop disease resistant oysters. Future work with lobsters, finfish, and seaweeds is possible. The Groton Shellfish Commission (GSC) will be managing a portion of the shellfish seed provided by the Cooperative to the Town of Groton. This seed will be used for Recreational Shellfish Programs and for their Shellfish Restoration Programs. The GSC will most likely be helping the NAC with our public education outreach programs.

The Cooperative has received a lot of help and support from the Groton Shellfish Commission, the Noank Fire District, the Connecticut Department of Agriculture, Bureau of Aquaculture, and the USDA. With this support we should become an important asset to the Southeastern Connecticut Maritime Community and to the Connecticut Shellfish industry in general.

A COMPARISON OF THE GROWTH AND MORTALITY OF JUVENILE *ARGOPECTEN IRRADIANS* IN THE VARIOUS CULTURE METHODS EMPLOYED BY THE STUDENTS AT THE SOUND SCHOOL REGIONAL AQUACULTURE CENTER. John Roy, Amber L. Beitler, and **Kathryn R. Markey,** The Sound School, 60 South Water St., New Haven, CT 06519

In 1982, the Connecticut Department of Education contacted the University of Connecticut Sea Grant Program and the Connecticut Marine Trades Association in Essex regarding the creation

of a special curriculum for a new type of regional vocational agriculture center—one devoted to Aquaculture Science and Technology. Five sites were proposed that would cover the Connecticut coastline (no coastal towns would be excluded). The sites included Stamford for the western part of the state, then Bridgeport (Fairfield to Milford), then New Haven (West Haven to Guilford), Old Lyme (Clinton to East Lyme), and either Groton or New London for the eastern Connecticut towns. These new vocational aquaculture centers were designed not to compete with the existing agriculture centers, but to offer young people a new program based on the educated use and appreciation of the many marine business opportunities offered by the sea and coastal waters. It was supposed, at the time these schools were being conceptualized, that there would be a tremendous amount of interest from the shoreline communities. However, this has not proved to be the case. The limited inclination for communities to act as host district is perplexing.

To support the development of the program, a planning committee was created in 1983 to review site criteria and assemble a curriculum for these new "Aquaculture Centers." Vocational education was viewed as a long-term investment in young people. Economic impacts of these students would maximize 15 years after high school graduation. This had a tremendous impact on the curriculum that strived to educate both for current job titles and future aquacultural employment opportunities. The curriculum is not static. As advances in technology unfold and new scientific finds are realized, we as aquaculture teachers are challenged to upgrade and expand the curriculum.

Aquaculture as an applied science lends itself readily to the classroom. The senior science courses offered at the Sound School comply with the Vocational Agriculture Education Standard of offering students, in their fourth year at a VoAg Center, the option of continuing and concentrating their studies in the science portion of the school's curriculum. Students taking Special Topics have elected to participate in the science portion of the Aquaculture program for their entire senior year at the Sound School. As further dictated by VoAg standards, the curriculum of this class is determined by student-driven investigation. Each student who has chosen to participate in this class will select an area of interest, will create a specialized plan of study, and will pursue his or her chosen aspect of aquaculture through in-depth research.

Special Topics incorporates the Vocational Agriculture attitude of learning through doing. The students perform a variety of experiments each year. In October 2000, a study was begun with *ca* 10,000 juvenile *Argopecten irradians*. The bay scallops were purchased from Frank M. Flower and Sons Inc. of Long Island, New York. The guaranteed seed size was 25 mm. The scallops were placed in a variety of cages, open systems, and static culture. The students involved in the project have compared the effectiveness of the various methods of growout by monitoring growth and mortality.

FEDERAL CROP INSURANCE FOR QUOHOG FARMS. **John Sarkes,** Rural Community Insurance Services, P. O. Box 206, Harwichport, MA 02646

The second year of the cultivated clam pilot crop insurance program developed by the United States Department of Agriculture Risk Management Agency has begun. The pilot may run three to five years before expanding. The program is offered in 11 counties in the four states of Massachusetts, Virginia, South Carolina, and Florida. Insurance is available for *Mercenaria mercenaria* that are grown in grants located in these participating counties. Growers can check with the local Farm Service Agency office or county extension service to see if they are eligible.

A brief summary of the crop year and the overview of the program were presented. General information pertaining to insurability conditions, such as covering during the growout phase and size requirements for clams, was included. It was emphasized that mortality due to oxygen depletion, disease, freeze, hurricane, increase or decrease in salinity, tidal wave, storm surge, and windstorm are covered losses. Only losses that occurred during the insurance period are covered. It was further explained that it is the farmer's responsibility to follow good farming practices, the cultural practices generally in use in the county, and those recognized by the Cooperative State Research Education and Extension Service. A field representative explained what the loss adjuster's job is and some of the challenges encountered in the field.

AN INTRODUCTION TO THE S.P.A.T. (SPECIAL PROGRAMS IN AQUACULTURE TRAINING) INITIATIVE. **Kim W. Tetrault, Robert M. Patricio,** and **Rory MacNish,** Cornell Cooperative Extension of Suffolk County, Marine Environmental Learning Center, Southold, NY, 11971; and **Jonathan P. Polistena,** Mattituck High School, Mattituck, NY 11952

Cornell Cooperative Extension of Suffolk County, N.Y. has maintained and operated a shellfish hatchery on the North Fork of Long Island for the past decade. While the primary function of the hatchery has been to produce seed clams, scallops, and oysters for local town enhancement programs, the facility has been able to expand its goals to include a series of educational and training initiatives collectively referred to as S.P.A.T. (Special Programs in Aquaculture Training). The S.P.A.T. campaign, in its broadest interpretation, is a model that incorporates a community-based shellfish enhancement effort with intensive aquaculture training and information gathering. The principle components of the project include monthly public workshops pertaining to all aspects of shellfish aquaculture, extensive on-site test plots for nursery and growout of cultured seed products, a master shellfish gardener program, school outreach and teacher training opportunities, and a formalized internship program. An additional five-day summer program will also be available to ages 13–18, with overnight housing provided to non-residents. It is anticipated that these new pro-

grams will prove to be extremely popular and have, at this time, solicited over 100 responses.

BROODSTOCK CONDITIONING OF THE SEA SCALLOP, *PLACOPECTEN MAGELLANICUS*, WITH VARIOUS MICROALGAL DIETS. **Bethany A. Walton,** University of Maine, Marine BioResources Program, Rogers Hall, Orono, ME 04469 and Beals Island Regional Shellfish Hatchery, P.O. Box 83, Beals, ME 04611; and **Brian F. Beal,** University of Maine at Machias, 9 O'Brien Ave., Machias, ME 04654

One of the primary concerns of shellfish aquaculturists is to achieve maximum survival of larvae in culture. One possible way to achieve this goal is to obtain high quality eggs from broodstock. It has been well documented that conditioning broodstock may help to increase the number of high quality eggs released during spawning, thereby increasing larval viability. A laboratory study focusing on 40 adult sea scallops (*Placopecten magellanicus*) obtained from the Eastport, ME area was conducted between March and June of 2000. Sea scallops (mean size = 115.6 mm ± 8.85 mm SD) were placed individually into aerated buckets that held 12 L of filtered seawater. These 40 animals were examined nondestructively on a monthly basis for the condition of their gonads; gonad length and thickness were also measured. These were compared to a sample of animals obtained from the same location that were dissected to determine whether conditioning animals with microalgal diets had any effect on gonadal development. The following four microalgal treatments were used for the duration of the experiment and were fed at a rate of 55,000 c/ml per species for a total of 110,000 c/ml: (1) *Tetraselmis sp.* (MC:2) and *Tetraselmis chui*, (2) *Tetraselmis chui* and *Thallassiosira weissflogii*, (3) *Rhodomonas salina* and *Tetraselmis striata* and (4) *Tetraselmis* sp. (MC:2) and *Rhodomonas salina*. Initial temperature was maintained at 5°C ± 1°C, and slowly increased at intervals to a final temperature of 10°C ± 1°C. Preliminary results indicate that conditioning broodstock sea scallops with certain microalgal diets increases the gonad index.

REMOVAL OF BLUE MUSSELS, *MYTILUS EDULIS*, FROM MUDFLATS: DOES IT IMPROVE SOFTSHELL CLAM, *MYA ARENARIA*, HABITAT? **William C. Walton,** Beals Island Regional Shellfish Hatchery, PO Box 83, Beals, ME 04611

In response to apparent increasing abundance of the blue mussel, *Mytilus edulis*, on certain productive mudflats, municipal shellfish managers in Downeast Maine have become concerned about the effects of mussels upon clams. In Perry, ME, the shellfish committee enlisted local clam diggers to remove ~1 acre of mussels to reduce presumed negative effects upon softshell clams, *Mya arenaria*. To test both the effects of mussels and the efficacy of removal, we conducted a field-based experiment initiated on August 1st, 2000.

Sediment-filled, plastic flowerpots (~150 mm deep and ~150 mm in diameter) were each seeded with 10 juvenile clams, 14.3 ± 0.17 mm shell length. To test the effect of the presence of a mussel bed, 36 pots were then placed in either a bed of mussels (a patchwork of clumps of mussels) or on an adjacent mudflat in the lower intertidal of a cove in Perry. Within each of these two areas, pots were placed underneath a clump of mussels (>0.5 m in diameter), adjacent to a clump, or in an open area without mussels (>1 m from any mussels). Lastly, half of the pots were meshed to protect them from predation with flexible 6 mm meshing.

All pots were collected on September 28th, 2000, and surviving clams were counted and measured. Survival was significantly lower in unprotected pots ($P = 0.0001$) than protected pots, and was also low underneath mussels. More interestingly, among unprotected clams not under mussels, survival tended to be better in the mussel bed than on the flat (adjacent, $P = 0.0801$; open, $P = 0.0380$). In terms of growth, final shell length was lowest underneath clumps of mussels; among clams not underneath mussels (where survival was very low), growth tended to be better on the mudflat than in the mussel bed.

This result was greater for unprotected clams ($P \leq 0.1437$) than for protected clams ($P \geq 0.2803$), suggesting a possible interaction with predation. Thus, the presence of mussels has a mixture of effects upon clams, which need to be considered when contemplating removal.

NURTURING A SOFTSHELL CLAM PRIVATE/PUBLIC INITIATIVE ON MASSACHUSETTS' NORTH SHORE. **Scott Weston, Joseph Buttner,** and **Mark Fregeau,** Northeastern Massachusetts Aquaculture Center and Department of Biology, Salem State College, Salem, MA 01070

Commercial aquaculture is in its infancy on the North Shore of Massachusetts. Interest and support for aquaculture continue to grow as evidenced by an increasing number of restoration and enhancement initiatives that target the "Ipswich clam" (softshell clam, *Mya arenaria*). Many North Shore towns (e.g., Ipswich, Rowley, Gloucester and Essex) have sponsored public/private efforts involving shellfish wardens, advisory boards, shellfishers and the Merrimack Valley Planning Commission in innovative, volunteer projects to identify technologically effective and socially acceptable methods of seeding and managing local clam flats. The Department of Marine Fisheries and Department of Food and Agriculture (DFA) have provided permits and/or funding. Acknowledging the social and economic importance of a viable aquaculture industry on the North Shore and throughout Massachusetts, three regional centers have been created by legislative act and supported through the DFA. The Northeastern Massachusetts Aquaculture Center (NEMAC), housed at Salem State College, serves as a catalyst to forge the knowledge and experience gained through

independent efforts by North Shore communities into a regional, collaborative softshell clam initiative.

Since its official opening in April 1999, NEMAC's Cat Cove Marine Laboratory has made courses, reference materials, and outreach (extension) assistance available to aspiring/practicing aquaculturists. Perhaps the most significant contribution has been filling a void as a local supplier of clam seed. In its first year of operation, 30,000 softshell clams (3 mm) were acquired from the Beals Island Regional Shellfish Hatchery (ME) in October 1999, successfully raised by laboratory personnel and released as 10 mm spat in Ipswich in October 2000 by town officials, volunteers, and people from the MVPC and NEMAC. Currently, an estimated 500,000 softshell clams reside at NEMAC's Cat Cove Marine Laboratory. Most clams originated from the Beals Island Regional Shellfish Hatchery (300,000) or were collected from mud flats in Rowley by the shellfish warden and volunteer shellfishers (200,000). A modest number of clams (1,000–2,000) were spawned from local broodstock maintained in the Cat Cove Marine Laboratory (July 2000). As these clams attain an appropriate size they will be released onto the flats of Ipswich, Rowley, Gloucester, and Essex in the early summer and/or early fall 2001. Production and seeding of clams are expected to continue increasing as laboratory personnel gain experience and the facility becomes fully functional.

Through the input of varied stakeholders an economically feasible and environmentally sustainable aquaculture industry is gradually developing on Massachusetts's North Shore at a rate and in a manner consistent with the expectations of all collaborators, specifically through supplementing the traditional wild harvest with increasing numbers of cultured clams. Aquaculture is growing because local shellfishers and towns are supportive, technical expertise and an increasingly dependable source of seed exists, and state agencies are making significant financial and logistical commitments. The private/public approach to establish a sustainable aquaculture industry on Massachusetts' North Shore is working and could prove applicable elsewhere.

GROWTH AND SURVIVAL OF BAY SCALLOPS, *ARGOPECTEN IRRADIANS IRRADIANS*, FED *TETRASELMIS CHUI* BY TWO METHODS. James C. Widman Jr. and **David Veilleux,** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Tetraselmis chui was grown using two different methods, carboy vs. GRAMPS (Greenhouse Algal Mass Production System), and fed to bay scallops, *Argopecten irradians irradians*. Growth and survival were monitored. Algae grown by the traditional Milford carboy method utilize artificial light and artificial seawater with the addition of various nutrients, trace elements, and vitamins. GRAMPS-grown algae utilize sunlight and natural seawater from Milford CT harbor, which is UV treated and then enriched with a commercially available F/2 media. Current results indicate a slight growth advantage when using algae grown in the carboys. Increases in mean shell height ranged from 2.6–3.1 mm for scallops fed with GRAMPS-grown algae, while scallops fed carboy-grown algae increased 3.6–4.1 mm. Most surprising was the decrease in survival when scallops were fed *Tetraselmis* grown using the GRAMPS method. Survival of scallops on the GRAMPS-grown *Tetraselmis* averaged 64%, and scallops fed carboy *Tetraselmis* averaged 89%. Additional research is needed to determine the cause of the growth and survival discrepancies observed between the two growing methods.

EFFECT OF FEEDING RATION AND REGIME UPON GROWTH AND FOOD-CONVERSION OF JUVENILE QUAHOGS, *MERCENARIA MERCENARIA*, AND COMPARISON WITH BAY SCALLOPS AND EASTERN OYSTERS. Gary H. Wikfors, Jennifer H. Alix, Mark S. Dixon, and **Barry C. Smith.** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460

Our previous studies have demonstrated effects of both feeding ration (how much) and regime (how often) upon growth and feed-conversion efficiency of juvenile bay scallops, *Argopecten irradians*, and eastern oysters, *Crassostrea virginica*. As this information is useful in design and scaling of land-based hatchery and nursery processes, we conducted an experiment identical to those done previously with bay scallops and oysters, this time with juvenile (3mm) clams, *Mercenaria mercenaria* (*notata* variety, generously provided by the F.M. Flower Co., Oyster Bay, NY). The feeding experiment was a factorial design in which ration, at 1, 2, 5, or 10% of clam live weight in dry weight-equivalent algal feed per day, and regime, with the daily ration divided equally into 2, 4, or 16 daily feedings, were co-varied. Our computer-controlled molluscan rearing chambers were used to accomplish the multiple daily feedings of a 50:50 mix of two high-lipid *Tetraselmis* strains, PLY429 and PLAT-P, that were cultured free of bacteria in semi-continuous carboy assemblies. The 50 clams held in each chamber were removed weekly, and growth was monitored as live weight, volume displacement, and shell size. Rations were adjusted weekly to remain consistent with live-weight increases, and the same clams were returned to the chambers. Organic weight growth (ash-free) of clams was determined after six weeks of feeding and compared with organic weight of algae fed to calculate conversion efficiency (CE) as the percentage of algal mass converted to clam tissue mass. A multifactor Analysis of Variance (ANOVA) was used to analyze main and interactive effects of the independent variables ration and regime upon the dependent variables growth and CE.

Clam survival was near 100% during the experiment. Growth of clams was significantly affected by ration, but not regime. Growth was not significantly greater than zero on 1 and 2% rations, and increased exponentially at 5 and 10% rations. CE was

affected significantly by both ration and regime, as well as by the interaction of these two variables. CE was highest at the 10% ration given as 16 daily feedings, but was only slightly over 2%, i.e., it took 50 g of algal dry weight to produce 1 g of clam flesh. These results contrast sharply both qualitatively and quantitatively with findings for scallops and oysters, in which maximal growth occurred on 5% rations, and CE values were in the range of 20–25%. Possible reasons for this contrast may include lower nutritional value of the *Tetraselmis* strains for clams than for the other bivalves, differences in initial size of individuals in experiments with different shellfish, or the fact that ash-free dry weight was used for clams, whereas dry tissue weight was used previously. Nevertheless, it appears likely that northern quahogs are far less efficient at using low levels of algal food, and require more food than other bivalves and, thus, are poorer suited to land-based, controlled nursery culture.

ABSTRACTS OF TECHNICAL PAPERS

Presented at
AQUACULTURE '01*

Triennial Meeting of:

WORLD AQUACULTURE SOCIETY
NATIONAL SHELLFISHERIES ASSOCIATION
FISH CULTURE SECTION OF THE AMERICAN FISHERIES SOCIETY

Orlando, Florida

January 21–25, 2001

*__Editor's Note:__ Since this meeting was topic-oriented rather than society-oriented, papers presented here represent those whose author(s) signified membership in the National Shellfisheries Association.

CONTENTS

NORMAL AND ALTERED GAMETOGENESIS IN THE GREEN SEA URCHIN: IMPLICATIONS FOR AQUACULTURE.

During the annual reproductive cycle, gonads of both sexes of the green sea urchin pass through a characteristic series of structural changes. These changes can be classified according to the activities of the two major populations of cells that compose the germinal epithelium. These cellular populations are either: (1) germinal cells (oogonia → fully mature ova in the ovary or spermatogonia → fully differentiated spermatozoa in the testis); or (2) somatic cells called nutritive phagocytes (NP) and present in both sexes. In an effort to help others better understand normal gametogenesis in the green sea urchin, we present an accompanying web page, which provides a detailed catalog of the appearance and functions of these two populations of cells during the following stages:

1. intergametogenesis and NP phagocytosis;
2. pregametogenesis and NP renewal;
3. gametogenesis and NP utilization; and
4. end of gametogenesis, NP exhaustion, and spawning.

This web page: http://zoology.unh.edu/faculty/walker/urchin/gametogenesis.html also covers gamete structure, fertilization, and very early sea urchin development, gives an extensive bibliography, and will be amended as new information becomes available. We also encourage others with more extensive information than our own to help us to develop this web page. Intimate knowledge of these topics in the sea urchin is useful in aquaculture, if it does no more than enhance our abilities to manipulate reproduction and development. High-quality sea urchin gonads (often called roe) are distinguished by superior size, taste, color, texture, and firmness (= extended shelf life). Ovaries and testes containing fewer gametes relative to somatic cells (NP) are preferred in most cultures that eat sea urchin gonads. Gametogenesis usually has a negative influence on the quality of sea urchin gonads. This is particularly true near the conclusion of gametogenesis, when gonads are very fragile and contain mainly gametes. Rough handling of sea urchins during harvesting results in disintegration of the gonads. In the future, a more thorough understanding of the cell and molecular biology of sea urchin gametogenesis will permit us to manipulate the process at various stages to accomplish particular marketing goals. For example, it would be advantageous for aquaculturists to understand: (1) how to suppress gametogenesis to produce high-quality gonads for consumption; and (2) how to promote gametogenesis for the increased production of seed stock. The concept of producing "designer" urchins with gametogenesis customized to particular market needs is not beyond reach. Based on our current understanding of the normal process of gametogenesis in the green sea urchin, we present methods that can accomplish both of these very different goals within a land-based facility.

Supported by the University of New Hampshire Center for Marine Biology and by Sea Grant (R/FMD-146) to CWW and MPL of UNH, DOC SBIR to MD and CWW and Hatch Grant #353 to CWW and Dr. Larry G. Harris. We thank Elia Heath-Antonelli, Erin Zook, and Paula Rodgers for their efforts in preparing tissues for this study and Tanya Hakala for preparing the web site.

USING GIS, GPS, AND DIGITAL PHOTOGRAPHY IN SHELLFISH RESOURCE MANAGEMENT. William D. Anderson and **Guy M. Yianopoulos,** South Carolina Department of Natural Resources, Marine Resources Center, P.O. Box 12559, Charleston, SC 29422, USA. E-mail:andersonb@mrd.dnr.state.sc.us

Multiple data layers, consisting of intertidal oyster (*Crassostrea virginica*) spatial distributions, management categories, water quality, and boundary markers, all linked to attribute databases and digital photography, are used to characterize bivalve habitats and manage shellfish resources in coastal South Carolina. The three-dimensional intertidal oyster habitat, which serves as a critical nursery to resident and transient fish populations, is characterized as a keystone species in a geographic area devoid of submerged aquatic vegetation. Environmental perturbations, such as coastal development, boat wakes, nonpoint source runoff, and siltation, complicate resource conservation and management for a species chronically exploited by recreational and commercial harvesting.

This presentation describes how intertidal oyster resource assessments are conducted utilizing GIS, GPS, laser rangefinders, and digital photography. Color ArcView® maps are produced to delineate harvest areas for commercial fishermen; disseminated to recreational harvesters, and made available (in easily readable .PDF format) on the SC Department of Natural Resources' web page (www.dnr.state.sc.us/marine/regs/stateshell). Mariculture and wild stock shellfish permit interface with water bodies conditionally approved, restricted, and closed to harvest by coliform bacteria—dynamic and complex environment—its management facilitated by multiple GIS layers and linked attribute data. Digital maps depict oyster populations, water bodies closed by coliform bacteria, and shellfish management areas, all linked to commercial harvest and resource assessment data.

MOLECULAR ANALYSES OF A *PERKINSUS* SPECIES IN THE EUROPEAN FLAT OYSTER *OSTREA EDULIS*. Kathleen Apakupakul, Antonio Villalba, Sandra M. Casas, and Kimberly S. Reece, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062, USA. E-mail: kathleen@vims.edu

Members of the genus *Perkinsus* are protozoan parasites that have a subtropical distribution and infect a variety of shellfish host species. *Perkinsus* species have caused high mortality among the world's shellfish and are, therefore, the subject of intensive study to develop effective management strategies for the health of commercial shellfish fisheries. Currently, there are five recognized

species of *Perkinsus*. An infection of *Perkinsus* has been discovered in the tissues of the European flat oyster *Ostrea edulis*, a previously unreported host species.

To determine the species of parasites infecting the flat oyster, portions of the internal transcribed spacer (ITS) region and the small subunit ribosomal (SSU) RNA gene were sequenced and compared to the sequences of other *Perkinsus* species as well as to those of other protozoans. Based on these data, phylogenetic analyses showed that the parasites are a distinct sister clade to the *Perkinsus atlanticus/olseni* group. Whether or not these parasites comprise an entirely new species of *Perkinsus* or a strain of *P. atlanticus/olseni* has yet to be determined. *Perkinsus* species are known to have rather wide host selectivity. The sequences we obtained are different from any of those deposited in GenBank or published to date. If morphology data corroborate the differences seen in the molecular data, these parasites may be considered a new species of *Perkinsus*.

A *Perkinsus* genus-specific DNA probe was designed based on the alignments of the SSU rRNA sequences of all known *Perkinsus* species. In *in situ* hybridization protocols, this probe has been effective in labeling *P. marinus*, *P. atlanticus*, *P. olseni*, and *Perkinsus* species from *Chama pacificus*, *Ruditapes philappinarum*, *Macoma balthica*, and *Mya arenaria*. *In situ* hybridization was performed on histologically prepared infected *Ostrea edulis* tissue sections. We found that this probe also hybridizes to the parasites infecting *O. edulis*.

VARIATION IN SERINE PROTEASE GENE(S) AMONG *PERKINSUS MARINUS* ISOLATES. Gwynne D. Brown and **Kimberly S. Reece,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062, USA. E-mail: gbrown@vims.edu

Perkinsus marinus, the causative agent of dermo, is a major pathogen of the eastern oyster, *Crassostrea virginica* along the U.S. Atlantic and Gulf coasts. Although scientists have studied the organism for fifty years, little is known regarding the pathogenic mechanisms of the protozoan. Serine proteases present in cell-free supernatants of *P. marinus* cultures *in vitro* are currently under investigation as a putative virulence factor. Serine proteases have been found to play key roles in pathogenesis of several parasitic protozoans. In this study, we identified and sequenced a serine protease gene from *P. marinus*. We also examined variations in the identified gene among different isolates.

We first amplified a 475 bp subtilisin-like serine protease gene fragment from *P. marinus* using "universal" degenerate primers. The 475 bp fragment was then labeled with digoxigenin and used to screen a *P. marinus* λ phage genomic library. DNA from hybridizing phage was isolated and subjected to Southern blot analysis. Two different recombinant clones were identified. Clones were subcloned and sequenced using internal primers. Within one subclone, a 1,254 bp open reading frame was identified containing the probe sequence. BLAST analysis confirmed the similarity to subtilisin proteases, reporting an E value of 7e-40.

Genomic Southern blot analysis using the 475 bp digoxigenin-labeled probe showed that variations exist among different isolates of *P. marinus*. Two clonal isolates from Louisiana, LA 5-2 and LA 10-1, produced similar hybridization patterns with *Nci* I and *Sal* I; whereas, additional bands were detected in the isolates P-1 (York River, VA) and MA 2-11 (MA). These results suggest that either the P-1 and MA 2-11 genomes contain a second gene or that they possess an alternate allele of the same gene.

GENE TRANSFER IN CELL CULTURE OF THE EASTERN OYSTER *CRASSOSTREA VIRGINICA*. John T. Buchanan, Ta-Chi Cheng, S. Reyna Gonsalves, Jerome F. La Peyre, Richard K. Cooper, and **Terrence R. Tiersch,** Department of Veterinary Science, Louisiana State University Agricultural Center, Louisiana Agricultural Experiment Station, Baton Rouge, LA 70803, USA. E-mail: jbuchanan@agctr.lsu.edu

The eastern oyster *Crassostrea virginica* supports a valuable industry along the East and Gulf coasts of the United States. Recently the oyster industry has been injured by disease problems, especially infections of the protozoa *Perkinsus marinus* (causing dermo) and *Haplosporidium nelsoni* (causing MSX). Both protozoa have been significant factors in the decline of the oyster fishery in the Chesapeake Bay. Along with techniques such as selective breeding and ploidy manipulation, gene transfer may be an effective tool to combat these disease problems.

Cell culture serves as an effective model for *in vivo* work, and gene transfer in cell culture would be useful for screening promoters and genes for use *in vivo*. Because a cell line from bivalve mollusks has not been established, it is necessary to work with primary cultures of oyster cells. To this end, ventricle cells from *C. virginica* were isolated, and conditions for optimal gene transfer and gene expression were investigated. Cells were cultured in 96-well plates in 100 μL of medium LA-2 at 4×10^5 cells per well.

The transfection reagent Effectene® (Qiagen Inc., Valencia, CA) was used to deliver DNA to cells, and expression of the reporter gene luciferase was used to evaluate promoters suitable for use in oyster cells. One of the promoters tested, the heat shock promoter (HSP70) from the snail *Biomphalaria glabrata* was found to be inducible in oyster cells, with significantly higher levels of luciferase detected after transfection and heat shock ($P < 0.00001$). The optimal conditions for heat shock were 40°C for 1 h ($P < 0.05$). Gene expression varied over time, with highest levels of expression observed 16 to 24 h after heat shock ($P = 0.0001$). Various conditions for transfection with Effectene® were tested, and optimal conditions per well were 0.3 μg DNA mixed with 3 μL of Effectene® ($P < 0.05$). Although gene expression was de-

tected, we found significant toxicity associated with transfection with Effectene® ($P < 0.05$). Other transfection reagents may provide adequate levels of gene expression in oyster cell culture with less toxicity. We have also observed luciferase expression using the following promoters: *C. gigas* actin, *Drosophila melanogaster* actin, *D. melanogaster* heat shock, and human cytomegalovirus (CMV) immediate early promoter. Future work will involve characterization of gene expression with these promoters and identification of promoters suitable for constitutive and inducible gene expression *in vivo*.

THE INFLUENCE OF SUBSTRATES AND CULTURE MEDIA FORMULATIONS ON THE ATTACHMENT AND SPREADING OF EASTERN OYSTER CELLS IN PRIMARY CULTURES. John T. Buchanan, Y. Li, and **Jerome F. La Peyre,** Department of Oceanography and Coastal Sciences, Louisiana State University, Baton Rouge, Louisiana 70803, USA. E-mail: jbuchanan@agctr.lsu.edu

The utility of cell culture in research has long been recognized. However, cell lines from any bivalve mollusk have yet to be established. In addition, a lack of standard protocols for primary cell culture has hindered bivalve research. Improved media have been recently developed in our laboratory. Enhanced cell attachment and spreading in primary culture would improve protocols and may prove essential for the development of a bivalve cell line. To this end, ventricle cells from *Crassostrea virginica* were isolated and the attachment factors collagen I, collagen IV, fibronectin, laminin, and poly-D-lysine were tested for their ability to promote cell attachment and spreading in the media JL-ODRP-4, LA-2, and LA-5. Also tested were two commercially available uncoated tissue culture plates (Falcon, Inc. and Costar, Inc.). A spectrophotometric assay (MTS assay) based on the reduction of tetrazolium salts to a formazan dye by metabolically active cells was employed to estimate metabolic activity and cell numbers remaining in a well after washing. A fluorescent assay (CyQuant assay) measuring the amount of nucleic acid in a well was used to estimate cell number in wells after washing, cell survival, and RNA production on the various substrates. Cell response to each attachment factor was measured at 1.5 d, 3.5 d, and 6.5 d.

Measured with the MTS assay, cell attachment was significantly affected by length of culture, media, and substrate ($P < 0.0001$). Interaction between media and substrate was significant ($P < 0.0001$). At day 1.5, significantly greater attachment was detected in JL-ODRP-4 on poly-D-lysine ($P < 0.05$), in LA-2 on fibronectin, poly-D-lysine, and uncoated Falcon substrates ($P < 0.05$), and in LA-5 on fibronectin, poly-D-lysine, laminin, and uncoated Costar substrates. At day 3.5, significantly greater attachment was detected in JL-ODRP-4 on all substrates other than laminin ($P < 0.05$), in LA-2 on all substrates other than laminin ($P < 0.05$), and in LA-5 on all substrates other than collagen I. At day 6.5, significantly greater attachment was detected in JL-ODRP-4 on the uncoated Costar substrate, in LA-2 on poly-D-lysine, uncoated Falcon, and uncoated Costar substrate, and in LA-5 on the uncoated Costar substrate.

Measured with the CyQuant assay, cell attachment was significantly affected by length of culture, media, and substrate ($P < 0.0001$). Interaction between media and substrate was significant ($P < 0.0001$). Results were similar to results for attachment with the MTS assay. Cell survival and RNA production were significantly affected by length of culture, media, and substrate ($P < 0.0001$), with significant interaction between these three factors.

In summary, cell attachment, cell survival, and RNA production were all significantly affected by the media and the substrate cells were cultured with. Furthermore, the response of cells to the various substrates tested varied with the media used indicating potential interaction between media components and substrates.

OPTIMIZATION OF GENE DELIVERY FOR IMPROVED OYSTER HEALTH. John T. Buchanan, Jerome F. La Peyre, Terrence R. Tiersch, and **Richard K. Cooper,** Department of Veterinary Science, Louisiana State University Agricultural Center, Louisiana Agricultural Experiment Station, Baton Rouge, LA 70803. E-mail: jbuchanan@agctr.lsu.edu

In Louisiana, over 300,000 acres of bottom area are privately leased for production of the eastern oyster *Crassostrea virginica*. Recently, disease problems have plagued this industry, particularly the protozoan parasite *Perkinsus marinus* (causes dermo disease). The transfer of human pathogens (such as *Vibrio vulnificus*) from oysters to human consumers has become a serious concern for the industry as well. Research in disease resistance and microbial elimination in oysters is needed. Along with selective breeding and ploidy manipulation, gene transfer research may lead to advances in this area.

There are unique needs associated with culture of oysters in the laboratory, especially for transgenic research. Consideration must be given to experimental replication, avoidance of contamination, and containment of genetically modified organisms. With this in mind, all of our work is done with artificial seawater in recirculating systems over seventy miles from the nearest coastal area. We have developed techniques for reliable production of high-quality oyster gametes and larvae in these conditions.

We have successfully transferred genes to oyster gametes and embryos and have observed expression of the red-shifted green fluorescent protein gene (*rsGFP*) in the oyster larvae produced. We have also observed expression of *rsGFP* in the hemocytes of transfected adult oysters, although the levels of gene expression were low (~1% of cells). We are currently screening promoter elements to identify constitutive and inducible promoters useful for expression of disease resistance genes. Because cell culture is a useful model for *in vivo* research, we have developed conditions

for gene delivery and gene expression in primary cultures of oyster ventricle cells. Using this model, we are screening the following promoters for expression in oyster cells: *C. gigas* actin, *Drosophila melanogaster* actin, *D. melanogaster* heat shock, *Biomphalaria glabrata* heat shock, *Autographa californica* nuclear polyhedrosis virus immediate early, human cytomegalovirus (CMV) immediate early, and simian virus 40 immediate early promoter. With identification of suitable promoters, we will further optimize conditions for gene transfer to oysters and begin to screen disease resistance genes in oyster cells. Combined with ongoing research in cryopreservation of oyster gametes and larvae and production of sterile oysters, progress is continuing toward the production of transgenic eastern oysters with enhanced disease resistance.

TOWARD CREATION OF A CELL LINE IN *CRASSOSTREA VIRGINICA*. **Jane C. Burns, James D. Moore, Chisato Shimizu, Hiroko Shike,** and **Carolyn S. Friedman,** University of California San Diego, 9500 Gilman Dr.-0830, La Jolla, CA 92093-0830. E-mail: jcburns@ucsd.edu

Immortalized cell lines are important tools for the *in vitro* study of the cellular and molecular biology of an organism, for the assessment of environmental toxins, and for the growth and study of intracellular pathogens. Many vertebrate cell lines were created by the introduction of oncogenes whose products interact with cell cycle regulatory proteins. To assess the feasibility of this approach in oyster cells, we tested the ability of retroviral vectors with a substituted envelope glycoprotein to infect and express foreign genes in primary cultured cells from hearts of *C. virginica*. To provide nutritional support for the cultured cells, we analyzed components of *C. virginica* hemolymph and assessed DNA synthesis of cells cultured in different media and at different temperatures.

Previous promoter comparisons in *C. gigas* had demonstrated that the Moloney murine leukemia virus (MoMLV) long terminal repeat (LTR) mediated the highest levels of reporter gene expression in cultured oyster cells. Therefore, the vector LLRNL (LTR-luciferase-RSV LTR-neomycin phosphotransferase-LTR) was used for all experiments in *C. virginica*. Vectors lacking an envelope glycoprotein ("bald vectors") are noninfectious and were used as a negative control. Oncovectors were created that expressed either the SV40 large T antigen or h-ras from the MoMLV LTR. Hemolymph was analyzed for free amino acids, organic acids, carbohydrates, metals, electrolytes, pH and osmolality. DNA synthesis was assessed by ^{3}H-thymidine uptake.

Luciferase expression was detected in the cell lysates of 100% of cultures exposed to infectious LLRNL, but in none of the cultures exposed to bald LLRNL. Luciferase activity was proportional to the number of vector particles, was highest during the first week after initiation of cultures and declined thereafter. The polycation, polybrene, had no effect on infection efficiency. Attempts to use the green and red fluorescent proteins were hampered by a high background autofluorescence in dead or dying cells in the cultures.

Vectors expressing the SV40 large T antigen and h-ras from the MoMLV LTR were tested in mammalian cell lines. Immunofluorescent staining with monoclonal antibodies to these proteins confirmed expression in transduced cells. These vectors were used to infect primary cultured heart cells. No immortalized phenotype was seen after infection of approximately one hundred twenty-six cultures from eighty-nine oysters. Attempts to infect oyster embryos are in progress. Future experiments will be directed at verifying stable integration of the vector in the oyster genome, testing whether SV40 large T binds to homologs of p53 and Rb in oyster cells and exploring the use of other cell cycle regulatory proteins (e.g. cyclins) to force cultured cells back into the cell cycle. We will also continue ^{3}H-thymidine studies to optimize nutritional support for potentially transformed cells.

THE ECOLOGICAL STRUCTURE AND FUNCTION OF INTERTIDAL CREEK ECOSYSTEMS: HOW MUCH DO OYSTERS CONTROL? **David Bushek, Richard Dame, Dennis Allen, Alan Lewitus, Eric Koepfler,** and **Don Edwards,** Baruch Marine Field Laboratory, Baruch Institute for Marine Biology and Coastal Research, University of South Carolina, P.O. Box 1630, Georgetown, SC 29442, USA. E-mail:bushek@sc.edu

Along the southeast Atlantic coast of North America, oysters form extensive intertidal reefs that provide habitat for a variety of estuarine organisms (both resident and transient), passively and actively filter particulates from the water column and facilitate nutrient cycling. Recognizing these activities, restoration of oyster populations is being promoted to improve ecosystem health in addition to revitalizing oyster fisheries. Ecosystems include a complexity of organisms that interact through a multitude of processes in space and time. To examine the role of oysters in the structure and function of intertidal creek systems, we characterized eight small (100–400 m long) intertidal creeks within the pristine North Inlet Estuary, SC, then experimentally removed oyster reefs from four of the creeks and monitored changes through time.

Despite clearly important roles of oyster reefs, their removal did not significantly alter nutrient concentrations, over-all nekton utilization, or phytoplankton production. Slight increases in oyster growth and recruitment were observed and interpreted as indications that oyster populations were near carrying capacity. Remineralization of ammonium by oysters was insufficient to satisfy primary production, but remineralization by nekton, the microbial loop and sediments more than accounts for the deficit. This observation was interpreted as an indication of redundancy in the system. Results also indicated that the biomass of nekton utilizing the intertidal creeks during summer often exceeded oyster biomass, at times by 50-fold. A general shift in phytoplankton communities from flagellates in summer, a preferred food by oysters,

to diatoms in winter corresponded to the seasonal arrival and departure of nekton.

Healthy oyster reefs undoubtedly serve important roles in estuarine ecology. At the scale of intertidal creeks within a larger estuarine ecosystem; however, the effect of removing oyster reefs on nutrient concentration is compensated by other components within the system. Impacts may be quite different at larger scales. We argue that dense bivalve reefs and beds are indicative of intense positive feedback loops that make an ecosystem resilient to small-scale change, but fragile and susceptible to large-scale change. The response is not linear across scales. Such changes have not been reported for natural systems, but are found in systems influenced by over-fishing, nutrient loading, and pollution. Thus, the management of sustainable fisheries in coastal ecosystems requires an understanding of the ecosystem science and the realization that estuarine ecosystems exhibit complex responses that are not easily explained by linear dynamics.

DISEASE RESISTANCE AND POTENTIAL BIOCHEMICAL CORRELATES IN A SELECTIVELY BRED OYSTER STRAIN. Gustavo W. Calvo, Christopher G. Earnhart, and **Stephen L. Kaattari,** Department of Environmental Science, School of Marine Science, College of William and Mary, Gloucester Point, VA 23062, USA. E-mail: calvo@vims.edu

In recent years, DEBY oysters, a VIMS stock that has been selectively bred for five generations at a disease endemic site in the lower York River, Virginia, has consistently shown higher growth, survival, and disease resistance relative to other stocks. For example, F4 DEBY outperformed offspring from two putatively disease-resistant wild Chesapeake Bay brood stocks tested over a range of salinity at three sites during 1997–1999. To understand the mechanism of disease resistance in DEBY better, we recently started a comparative study in which susceptible (Rappahanock River = RR, Mobjack Bay = MB) and resistant (F5 DEBY and CROSSBreed = XB) oysters are being exposed to *P. marinus* and *H. nelsoni* at the York River site. Brood stocks were spawned in July 1999, and juvenile oysters (n = 1,000 of each group) were deployed in replicate floating mesh cages in October 1999. In May 2000, we started bimonthly sampling to assess survival, growth, disease status, plasma protein composition and concentration, plasma proteolytic activity, and plasma inhibitory activity against *P. marinus* extracellular proteases (ECP). We hypothesize that plasma factors enumerated above are related to disease resistance. Disease and plasma factors are being examined in samples (n = 20) of each group. *P. marinus* and *H. nelsoni* are being diagnosed, respectively, by the body burden assay and by paraffin histology. Protein content is being determined by the BCA assay. Proteolytic activity and inhibitory activity against *P. marinus* ECP are determined using Hyde Powder Azure methods.

By July 2000, mean cumulative mortality was high (52%) in susceptible RR and 16% in the other susceptible group (MB). In comparison, cumulative mortality was low (3%) in resistant groups (XB and DB). Growth rate was low in RR relative to that of the other three groups. No *P. marinus* and presence of *H. nelsoni* were similarly observed in all groups in May. By July 2000, *H. nelsoni* infections were very high (96% prevalence with mostly high intensity infections) in RR. At that time, initial *P. marinus* infections of light intensity (<10 cells/g) were observed in all groups. Mean protein concentration decreased in all groups, from 13.4–16.3 mg/mL in May to 2.1–9.1 mg/mL in July, with RR exhibiting the highest decline. Mean proteolytic activity decreased, particularly in RR, during the same time interval. Inhibitory activity against *P. marinus* ECP was extremely variable (SD > mean) in all groups. These preliminary observations suggest that *H. nelsoni* has an adverse effect on protein content and proteolytic activity in susceptible oyster stocks.

A MODEL OF WITHIN-HOST POPULATION DYNAMICS OF THE OYSTER PARASITE *PERKINSUS MARINUS*: SIMULATED EFFECTS OF TEMPERATURE AND SALINITY. Lisa M. Ragone Calvo and **Eugene M. Burreson,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, Virginia 23062. E-mail: ragone@vims.edu

A computer model was developed to investigate the population dynamics of the protistan parasite, *Perkinsus marinus*, within its host, the eastern oyster, *Crassostrea virginica*. The individual-based model, which is driven by temperature and salinity, tracks average within-host parasite density in oysters, age one year and older. The model was validated using parasite abundance and environmental time series from three oyster populations located along a salinity gradient in the James River, VA. Predicted parasite abundance exhibited a dynamic steady state and significantly correlated with actual observed densities at all three locations (Fig. 1). The simulations accurately captured the distinct seasonal periodicity of *P. marinus* and the relative differences in abundance that typically occur along a salinity gradient.

We are presently using the model to examine the interaction of temperature and salinity in controlling the initiation and termination of *P. marinus* epizootics. In preliminary experimental simulations, parasite extinction occurred in up-river oyster populations following a single year of "normal," long-term average, salinity, and temperature conditions, when no new infections were acquired. In contrast the parasite persisted at a down-river location for the entire ten-year simulation period, despite the fact that no new infections were acquired and that temperature and salinity were consistently "normal." This suggests that a single transmission event may be sufficient for *P. marinus* to become enzootic in specific year classes of oysters located in moderate-to-high salinity areas, whereas, periodic transmission events are required for the parasite to persist in lower salinity areas.

Simulation results indicate that fairly accurate quantitative predictions of *P. marinus* abundance can be made using *in situ* tem-

perature and salinity data and a relatively simple model. An improved understanding of *P. marinus*–environment interactions will aid oyster management and rehabilitation efforts.

DETECTION OF THE FLAT OYSTER (*OSTREA EDULIS*) PARASITE *BONAMIA OSTREAE* BY FLUORESCENT *IN SITU* HYBRIDIZATION. **Ryan B. Carnegie,[1] Bruce J. Barber,[1]** and **Daniel L. Distel[1,2],** [1]School of Marine Sciences and [2]Department of Biochemistry, Microbiology, and Molecular Biology, University of Maine, Orono, ME 04469, USA. E-mail: ryan.carnegie@umit.maine.edu

Reliable and sensitive detection of parasites is essential for prevention and management of disease in shellfish aquaculture. Of the two common molecular diagnostic techniques complementing standard histopathology, *in situ* hybridization (ISH) assays hold the advantages over polymerase chain reaction (PCR) assays of providing a morphological validation and a physical context; that is, a tissue location, for a positive signal. The development of an ISH assay using fluorescently labeled DNA probes for the flat oyster parasite *Bonamia ostreae* was the objective of this project.

Three fluorescein-labeled, *Bonamia ostreae*-specific oligonucleotides, when hybridized in repeated single reactions to paraffin-embedded *Ostrea edulis* sections, reacted specifically with *B. ostreae* ribosomal RNA. Nonspecific hybridization to *O. edulis* cells or tissues was never observed.

A fluorescent *in situ* assay for *Bonamia ostreae* has several advantages over a nonfluorescent analog. An epifluorescence microscope is necessary to view the slides, but otherwise FISH is faster and less expensive than ISH with digoxigenin-labeled or biotinylated probes, which require additional treatments for visualization. Most significant will be the ability to employ multiple stains. Fluorescent probes specific to different symbionts or parasites, or different strains or subspecies of the same parasite, may be distinguished on a single tissue section when hybridized simultaneously. Such fluorescent assays will, thus, be powerful tools for the diagnosis of shellfish parasites and for studies of the epizootiology of these organisms.

SUMMER MORTALITY OF THE PACIFIC OYSTER *CRASSOSTREA GIGAS*: INFLUENCES OF CULTURE METHODS, SITE CONDITIONS, AND STOCK SELECTION. **Daniel Cheney, Ralph Elston, Brian MacDonald, Kendra Kinnan,** and **Andy Suhrbier,** Pacific Shellfish Institute, 120 State Ave NE #142, Olympia, WA 98501, USA. E-mail: psi@pacshell.org

During the late summer to early fall period, Pacific oysters cultured on the West Coast of the United States and elsewhere may experience high levels of mortality. In the 1960s to the 1980s, this condition was subject to intensive investigation focusing on broad areas of disease pathology, genetics, physiology, and the environment. Results of these studies were largely inconclusive, or pointed to a poorly defined etiology. Although several factors, such as a bacterial and herpes-like virus infections could be linked to certain mortality events, no clear picture emerged.

Recent studies in Puget Sound, Washington, USA and Tomales Bay, California, USA center on the influence of multiple stressors and their effects on oyster survival, physiology, and pathology. The goal of this research is to identify possible modifications in culture practices, brood stock selection, or grow-out location to increase survival of Pacific oysters.

Field observations indicate oysters are subject to extreme variations in a number of parameters during intertidal cycles. Annual or seasonal variations in those parameters and differing culture practices likely play major roles in oyster survival. An increased rate of oyster mortality and modified physiological response seems to be strongly correlated with both elevated temperatures and extended periods of depressed dissolved oxygen (DO). A long period of neap tides with low and slack water during the evening was observed to result in daily and successive reductions in DO to levels, ranging from 0.5 and 2 mg/L. The DO reductions are sometimes coupled with heavy macroalgae blooms and high phytoplankton densities. This and other work also indicate oyster summer mortality rates are strongly influenced by ploidy and broodstock origin/stock selection. These observations have renewed interest in testing stocks selected for reduced rates of summer mortality and that retain desirable characteristics of good growth and meat yield.

This research is supported by Grant numbers NA86RG0015 and NA96RG0488 from the National Sea Grant College Oyster Disease Research Program and matching contributions from West Coast shellfish farmers.

***DE NOVO* FATTY ACID SYNTHESIS IN *IN VITRO PERKINSUS MARINUS* MERONTS: AN IMPLICATION OF BITROPHIC METABOLIC PATHWAYS IN MERONT STAGE.** **Fu-Lin E. Chu, Philippe Soudant,** and **Eric Lund,** Virginia Institute of Marine Science, School of Marine Science, College of William and Mary, P.O. Box 1346, 1208 Greate Road, Gloucester Point, VA 23062, USA. E-mail: chu@vims.edu

Perkinsus marinus is a protozoan parasite of the Eastern oyster, *Crassostrea virginica*. Meront stage *P. marinus* isolated from infected oysters have a fatty acid composition similar to the host. They are both rich in n-3 polyunsaturated fatty acids (PUFAs) as is typical of marine organisms. However, when meronts are cultured in a host-free media containing n-3 PUFAs they contain low levels of n-3 fatty acids and high levels of n-6 fatty acids which are characteristic of terrestrial origins. These results suggest that *P. marinus* meronts may have bitrophic metabolic pathways: utilizing host lipids when host-associated, but synthesizing their own lipids when they are not host-associated. To test whether *P. marinus* meronts are capable of synthesizing fatty acids *de novo*, we incubated meronts for 48 h in seawater containing acetate labeled with

deuterium and ^{13}C, or deuterium-labeled palmitic acid (16:0). GC/MS analysis of fatty acid methyl esters (FAMEs) from meronts incubated for 48 h with acetate revealed isotope incorporation in palmitic acid, 16:0. Molecules of 16:0 contained up to 62% labeled C and H originating in acetate. Analysis of samples incubated with deuterium labeled 16:0 found isotope incorporated in 18:0, and 18:1(*n*-9). This provides evidence that *P. marinus* meronts are capable of *de novo* synthesis, elongation, and desaturation of fatty acids. The results suggest that host-free *P. marinus* meronts are capable of synthesizing a range of fatty acids from dissolved organic matter. This capacity may play a role in the survival of *P. marinus* outside the host and the parasite's ability to use the water column as a transmission vector for colonizing new oyster populations.

TABLE 1.

Evidence of fatty acid synthesis, elongation, and desaturation by *Perkinsus marinus* from stable isotope metabolism.

Substrate	Product	MW-Labeled FAME*	MW-non-labeled FAME
Sodium acetate 1,2-$^{13}C_2$;D_3	16:0	300	270
Palmitic acid D_{31}	18:0	329	298
Palmitic acid D_{31}	18:1	325	296

* Molecular weights (MW) of fatty acid methyl esters (FAME) from *P. marinus* cells incubated in York River water (28 ppt) with stable isotope substrates for 48 h. Products were identified and their masses determined by GC/MS.

This research was funded by NSF (MCB9728284).

PRODUCTION AND BINDING SPECIFICITIES OF MONOCLONAL ANTIBODIES TO *PERKINSUS MARINUS* CELLULAR ANTIGENS. Christopher F. Dungan and **Rosalee M. Hamilton,** Cooperative Oxford Laboratory, Maryland Department of Natural Resources, 904 S. Morris Street, Oxford, MD 21654, USA. E-mail: cdungan@dnr.state.md.us

Availability of polyclonal antibodies labeling *Perkinsus marinus* cells and secretory products fostered development of several novel and rapid immunoassays for sensitive detection of this lethal oyster pathogen in oyster tissues, tissue extracts, and environmental waters. Although differentiation of species within the protozoan genus *Perkinsus* remains equivocal, rabbit polyclonal antibodies to *P. marinus* werealso found to label all described *Perkinsus* species as well as several tested dinoflagellates. Production of monoclonal antibodies (MAB) with narrowed specificity for *P. marinus* was conducted to produce unlimited quantities of diagnostic antibodies for monospecific detection and identification of this important oyster pathogen.

Soluble cytoplasmic, detergent-extracted, and whole cell immunogens from *in vitro P. marinus* cells were used to hyperimmunize donor mice to produce B-lymphocytes employed in cell fusions for production and cloning of immortal hybridoma cell lines secreting MABs to *P. marinus* cellular epitopes. Resulting hybridomas were screened by enzyme-linked immunosorbent assays (ELISAs) for secretion of specific IgG isotype immunoglobulins, using solubilized parasite proteins immobilized on polystyrene microtiter plates, and positive cell populations were cloned at least three times by limiting dilution plating. Of twelve different hybridomas cloned and cryopreserved, ten secrete monoclonal IgG_1 antibodies, and two secrete IgM.

IgG_1 MABs were produced *in vitro* for isolation from tissue culture medium by ultrafiltration and thiophilic gel chromatography. Binding specificities of purified MABs determined by Western blot analyses of reduced and native proteins indicate that a variety of different molecular weight epitopes are recognized by several MABs, but that the epitopes recognized by most are labile under reducing PAGE conditions. Similarly, MAB immunostaining of fixed parasite cells in histological sections was variable, suggesting that some MAB binding epitopes may be corrupted by formalin fixation or histological processing. Diagnostic specificity and sensitivity testing of IgG_1 MABs to *P. marinus* are ongoing.

PHYSIOLOGICAL CONDITION AND ENERGY RESERVES IN "NATURAL DERMO RESISTANT" OYSTER STOCKS. Vincent G. Encomio, Shawn Stickler, and **Fu-Lin Chu,**Virginia Institute of Marine Science, School of Marine Sciences, College of William and Mary, Gloucester Point, VA 23062, USA. E-mail: vge@vims.edu

The objective of our study is to use physiological and biochemical indices of condition to compare performance in putative "dermo resistant and nonresistant" oysters (*Crassostrea virginica*). We compare the effects of parasitic stress (*Perkinsus marinus*) on physiological condition and energy reserves between F1 progeny from presumably genetically distinct oyster populations. These oysters represent geographically disparate populations (three Gulf of Mexico and three Chesapeake Bay populations and one hatchery strain) exhibiting variation in tolerance to the protozoan parasite *P. marinus*. These oysters were deployed in the fall of 1999 at two sites within the Chesapeake Bay, (Port Kinsale,Wicomico River; Regent Point, Rappahannock River) in areas where dermo disease is known to occur, but not MSX. Energy reserves (glycogen, lipids, protein contents) are quantified and evaluated for their contribution to over-all physiological condition. Initial analysis on all the deployed stocks showed that the Rappahannock River stock have the fastest growth. Tissue dry weights of this stock increased significantly over time at both locations, but most significantly at Regent Point. Glycogen and protein content [mg/g dry weight (dw)] increased significantly over periodic samplings, but site-specific differences were not significant. Total lipid content (mg/g dw) also increased with growth, but not significantly. However, lipid class analysis showed a significant decrease in triacylglycerol (TAG) content from May/June to July, possibly indicating a spawning event occurring before sampling. Our study provides

information on the variation in growth and condition between sites and tests interactions of environmental factors with disease progression and intensity. Biochemical data from individual oysters are correlated with changes in shell height, condition index, and *P. marinus* infection. In addition, interaction of seasonal variation in physiological condition (because of changes in temperature, salinity, and gametogenic processes) with onset and increasing prevalence and intensity of disease are examined. Biochemical analysis on other oyster stocks is currently in progress. This research was funded by the NOAA-Virginia Sea Grant–Oyster Disease Research Program.

CAN BIVALVES BE USEFUL INDICATORS OF ECOSYSTEM CONDITION? **William S. Fisher,** U.S. Environmental Protection Agency, ORD/NHEERL, Gulf Ecology Division, 1 Sabine Island Drive, Gulf Breeze FL 32561, USA. E-mail: fisher.william@epa.gov

Numerous management decisions are made to sustain multiple, and often competing, products and services from coastal ecosystems. Scientific support for these decisions emanate from environmental indicators or selected measurements used in a monitoring program. Indicators are surrogates, estimates, or representations of conditions that are otherwise too numerous or complex to measure. One of the major challenges for indicator development is to identify those measurable environmental characteristics that are essential to the integrity of valued resources.

Integrity and sustainability of ecosystem condition are important societal values that can be broadly interpreted because of the multiple products and services derived. Even scientific descriptions of ecosystem condition vary, but generally include *vigor* (function, activity, metabolism, primary production), *organization* (biodiversity, trophic structure, degree of specialization), and *resilience* (ability to resist or recuperate from stress). Indicators of ecosystem condition must reflect these qualities. Measurements on bivalves are reasonable indicator candidates, because bivalves contribute significantly in these critical ecological areas. Water filtration for feeding is requisite for metabolic activity and also generates nutrient cycling that stimulates primary production (vigor). Accumulation (and possible deactivation) of toxins, contaminants, and pathogens without adverse effects is a byproduct of water filtration and may contribute to ecosystem resilience. Bivalve shell and reef structure provide habitat for both micro- and macrofauna and flora, drawing foragers and predators into a reef-based community (organization). Also, organization is served when bivalve reef structures alter hydrology to create and/or protect habitat diversity.

It follows that the critical ecological aspects of bivalves are water filtration capacity and reef structure, characteristics that should be reflected if measurements on bivalves are to be useful indicators of ecosystem condition. A possible strategy would be to estimate gross water filtration by monitoring every (5–10 years) the number of living bivalves on a target reef, their size, and filtration rate. Reef structure might be characterized using size, shape, and biodiversity measures. Annual measurements, such as mortality rates, disease prevalence, defense activities, recruitment, or shell growth could be used as "early warning" indicators of change in the health of the population. However, physiological measurements of bivalves include a high degree of variability because of season, reproductive status, salinity, temperature, and geographic (genetic) stock. This variability can be reduced by monitoring of individual reefs (rather than across regions) and by monitoring during winter when organisms exhibit a more stable physiological condition and have lower disease intensity.

SPECIES DESIGNATION AMONG SYMPATRIC OYSTERS *CRASSOSTREA ARIAKENSIS*, *C. GIGAS* AND *C. SIKAMEA*. **Elizabeth A. Francis, Patrick M. Gaffney, Standish K. Allen,** and **Kimberly S. Reece,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062. E-mail: lizbeth@vims.edu

Despite the recent interest in marketing non-native oysters, little has been published about the distribution or population genetic structure of the Asian oyster *Crassostrea ariakensis*. Furthermore, morphological plasticity and hybridization with congeneric species *C. sikamea* and *C. gigas* make identifying this species difficult. Previously developed molecular typing keys produced conflicting results when typing individuals collected from sites in Japan and The Peoples Republic of China (PRC). The objectives of this project are to: (1) develop a reliable molecular typing key for distinguishing between sympatric Asian oysters; and (2) uncover the population structure of *C. ariakensis*.

Development of a molecular key distinguishing these species is underway using restriction length polymorphism analysis (RFLP) for both nuclear and mitochondrial loci. The ability of this key to distinguish between putative species is corroborated by the phylogenies produced from sequence data collected from both the nuclear ITS-1 locus and a fragment amplified from the mitochondrial CO1 locus. PCR products were amplified, cloned, and sequenced from at least two individuals of putative *C. ariakensis* representing each sampling site as well as individuals of *C. gigas*, *C. sikamea*, *C. belcheri*, and *C. virginica*. Phylogenetic analysis distinguished two closely related clades representing possibly two subspecies of *C. ariakensis*. One clade included the putative *C. ariakensis* individuals from Japan, northern China, and hatchery stocks; whereas, another group included most of the other samples from PRC. Individuals collected from Yangjiang County, Guangdong Province, PRC as putative *C. ariakensis* grouped with the *C. sikamea*. Phylogenetic results suggest that there is intraspecific variation within *C. ariakensis* that was not detected when the previous keys were developed. Sequence data were used to perform virtual digests from which to base the development of the key. Variation could be present in restriction sites thought to be

diagnostic for a particular species. This indicates the importance of determining the level of variation present within *C. ariakensis*.

Additional putative *C. ariakensis* samples and sympatric oyster species are being collected and analyzed from India and Vietnam. A genetic population survey shall be carried out for all individuals typing as *C. ariakensis*. Individuals (approximately fifty/site) will be subjected to PCR amplification of multiple markers, which will be digested with restriction enzymes cutting at polymorphic sites. Population genetic structure will be estimated by calculating genotypic and allelic frequencies.

IN SITU MONITORING OF PUMPING RATES IN THE OYSTER *CRASSOSTREA VIRGINICA* TO INVESTIGATE RESPONSE TO ENVIRONMENTAL CHANGE. Dana M. Frank and **J. Evan Ward,** University of Connecticut, Department of Marine Sciences, 1084 Shennecossett Road, Groton, CT 06340, USA.

One primary goal toward understanding compensatory responses of bivalve mollusks to environmental change is to obtain *in situ* measurements of physiologically relevant parameters. Feeding activity and its constituent components (e.g., pumping and clearance rates) are prime indicators of physiological response to environmental change. Although previous researchers have attempted to obtain field measurements since the late 1950s, at this time, no convenient method exists for the continuous monitoring of feeding activity of individual bivalves. Although controlled experimental manipulations have yielded valuable results, it is difficult to reproduce in the laboratory all the complex changes in environmental conditions to which animals are subjected in their natural habitats.

We have developed an optical biomonitor for recording *in situ* measurements of pumping pressures, rates, and valve gape in bivalves. Fiber optic sensors are used to measure alterations in both pressure and valve gape. The pressure sensor is situated in the suprabranchial chamber of the oyster. The valve gape sensor is attached to the right valve during experimental trials. With this arrangement, we can examine the relationship between valve gape and changes in pumping pressures to explore more thoroughly the mechanisms available to the bivalve for altering pumping rates. Results of preliminary laboratory trials have established the value of this system for recording changes in oyster pumping and valve gape continuously, both in the laboratory and *in situ*. By monitoring changes in activities over time, we hope to expand the scope of our understanding about the physiological responses of bivalves to changes in environmental parameters, such as temperature, dissolved oxygen concentrations, current velocity, and food availability.

TRIPLOID GIGANTISM IN MOLLUSKS AND POSSIBLE EXPLANATIONS. Ximing Guo, Zhaoping Wang, Standish K. Allen, Jr., and **Brenda J. Landau,** Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349, USA. E-mail: xguo@hsrl.rutgers.edu

Triploids are organisms with three sets of chromosomes instead of two sets in normal diploids. During the past two decades, triploids have been studied in over 20 species of mollusks. A review of available data indicates that superior growth or increased body size is a general feature of triploid mollusks. Triploids are significantly larger than diploids in almost all species studied so far. Triploids are observed to be larger than diploids by 12 to 30% in *Crassostrea virginica*, 25 to 51% in *Crassostrea gigas*, 42 to 52% in *Crassostrea dalienwhanensis*, 60% in *Ostrea edulis*, 41% in *Saccostrea commercialis*, 72% in *Mulinia lateralis*, 27 to 58% in *Pinctada martensii*, 36% in *Argopecten irradians*, 32 to 59% in *Chlamys nobilis*, and 81% in *Chlamys farreri*. Adductor muscles of triploid scallops are larger that that of diploids, by 73% in *A. irradians*, 44 to 96% in *C. farreri*, and 167% in *Argopecten ventricosus*. Guo and Allen (*Genetics* 1994, 138:1199–1206) proposed the concept of "polyploid gigantism" and attributed the increased body size in triploids as a function of increased cell size. Two other hypotheses have also been used in discussions on triploid mollusks: (1) the heterozygosity hypothesis that attributes the superior growth to increased heterozygosity in triploids; and (2) the sterility hypothesis that views that sterility in triploids results in energy relocation from reproduction to somatic growth. We considered all three hypotheses in an analysis of growth and genetics data from several types of triploids. Our analysis suggests that increased cell size is the fundamental cause for triploid gigantism in mollusks. The expression of triploid gigantism in meiosis II triploids may be limited by genetic problems from the retention of polar body II. Increased heterozygosity in mated (and sometimes meiosis I) triploids corrects genetic problems and permits efficient expression of triploid gigantism. Sterility or energy relocation helps to accelerate the expression of triploid gigantism in old animals. Triploid gigantism is manifest in certain organs, such as the adductor muscles of scallops and oysters. Triploid gigantism may not be expression in nutrient-limiting environments.

CONSUMER ATTITUDES AND PREFERENCES FOR OYSTERS: GULF OYSTER INDUSTRY PROGRAM. Terrill R. Hanson, Lisa O. House, and **Benedict Posadas,** Mississippi State University, Department of Agricultural Economics, P.O. Box 5187, Mississippi State, MS 39762. E-mail: hanson@agecon.msstate.edu

Although Gulf of Mexico oyster landings have remained fairly constant at 17.3 million pounds during the 1980s and 18.0 million pounds during the 1990s, average landings for the United States have decreased. There has been an 11.1 million pound decrease in

total U.S. oyster landings between the two decades with most of the decrease having occurred in eastern U.S. landings. To maintain or increase consumption of Gulf oysters, it is essential to determine consumer and nonconsumer preferences and consumption patterns, which will be important in strengthening the Gulf oyster industry. This project will determine oyster consumer demographics, consumption patterns, attitudes, and preferences allowing market segments to be identified and strategies to reach these audiences.

Specific objectives of this project are to: investigate the characteristics that influence regional variations in the consumption of oysters; evaluate the effects of oyster supply upon consumption; evaluate the effects of hazard analysis critical control point (HACCP)-based seafood inspection on oyster consumption; develop criteria for potential market segments; and disseminate information obtained from this research to appropriate processors, associations, and other audiences through publications and meetings.

Questionnaire development is centered on measuring consumers' preferences and attitudes about oyster purchase and consumption and developing demographics profiles for use in future marketing plans. Because many seafood consumers do not eat oysters, both consumers and nonconsumers of oysters will be surveyed. The specific configuration of the survey will be developed through exploratory research based on focus group methods. However, to obtain quantitative estimates, a "double hurdle" econometric model will be used. First, factors that affect the decision to consume oysters will be modeled. The results from this section will be important in determining the market segments that can be successfully targeted. Second, factors that affect the decision as to the quantity of oysters consumed will be studied. This will only apply to the subgroup of respondents that do consume oysters. Consumer attitudes toward food safety, perceptions of food safety for various oyster product forms compared with other meats, and consumer awareness of HACCP will be important explanatory variables. The marginal effects of these variables will allow the researchers to estimate the change in the probability of consumption of oysters because of HACCP programs.

Results from the survey and model will be used to estimate the effect of socioeconomic characteristics of consumers on demand for oysters. This information will then be used to determine viable market segments and to determine the best marketing efforts to reach those segments successfully.

MOLECULAR DIAGNOSTICS FOR THE PARASITIC DINOFLAGELLATE *HEMATODINIUM PEREZI*. **Karen L. Hudson, Jeffrey D. Shields,** and **Kimberly S. Reece,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062, USA. E-mail: khudson@vims.edu

Hematodinium species are parasitic dinoflagellates that infect a variety of marine crustaceans including crabs, lobsters, and amphipods. Outbreaks of this parasite proliferate in the hemolymph and cause excessive host mortalities. Species of *Hematodinium* and *Hematodinium*-like parasites have impacted commercial fisheries around the world. *Hematodinium perezi* has caused a decline in the commercially important blue crab (*Callinectes sapidus*) fishery in U.S. coastal areas from Delaware to Florida. Our primary goal in this study was to develop species-specific PCR primers and DNA probes to detect *Hematodinium perezi* infections.

To assess intraspecific DNA sequence variation within *H. perezi* strains we amplified and sequenced the internal transcribed spacer region (ITS) from two heavily infected crabs. Sequence data were then compared to previously published sequences. Although DNA clones from the heavily infected samples had insert sequences that showed high similarity to published *H. perezi* ITS sequences, several polymorphic nucleotide sites were identified.

To specifically amplify *H. perezi* small subunit (SSU) ribosomal RNA gene from host tissue, we utilized two sets of primers. The first set of primers was constructed from a conserved region of the SSU gene and from a previously published *H. perezi* partial SSU sequence. A reverse complement of the later primer was used in conjunction with a primer we designed from the ITS sequence regions exhibiting *H. perezi* specificity. We then aligned the SSU gene sequence of *H. perezi* with that of other dinoflagellates, host species, ciliates, and apicomplexans. Based on sequence comparisons we have designed several potential DNA probes for *in situ* hybridization of paraffin embedded infected host tissue sections. We are testing the probes against infected *C. sapidus*, *Necora puber* (velvet crab), *Chionoecetes bairdi* (tanner crab), and *Nephrops norvegicus* (Norway lobster), in hopes of identifying both species- and genus-specific DNA probes. We are also using the SSU sequence data to elucidate the taxonomic relations within the genus.

A SYSTEMATIC APPROACH TO DEVELOP AN OYSTER CELL LINE. **Jerome La Peyre, Yanli Li, John Buchanan, Philip Cheng, Richard Cooper,** and **Terrence Tiersch,** Department of Veterinary Science, Louisiana State University, Baton Rouge, LA, 70803, USA. E-mail: jlapeyre@agctr.lsu.edu

No oyster cell line has been developed despite numerous attempts over the last fifty years. A major difficulty is that the proliferation of oyster cells cannot be maintained *in vitro*. Moreover, although numerous procedures have been used to prepare primary oyster cell cultures, the viability and survival time of oyster cells obtained from dissociated tissues have been disappointing.

Our working hypothesis is that the lack of proliferation is mainly attributable to suboptimal techniques and conditions that have been used to establish and maintain oyster cells in culture. Therefore, a systematic approach is needed, not only to optimize procedures to establish primary cultures, but also to optimize culture media and physical conditions to maintain viable oyster cells

over an extended period of time (i.e., weeks, months) a prerequisite to developing a cell line.

During the past several years, we have optimized techniques to decontaminate and dissociate tissues of the eastern oyster *Crassostrea virginica* and to cryopreserve oyster cells. A culture medium was formulated and optimized. Attachment factors to improve cell adherence and spreading were also tested. As a result, cell survival was significantly increased by optimization of these procedures. In this presentation, we review some of the problems encountered in the culture of eastern oyster cells and discuss additional strategies that are being used to develop an oyster cell line.

FORMULATION AND OPTIMIZATION OF A CULTURE MEDIUM FOR CELLS OF THE EASTERN OYSTER *CRASSOSTREA VIRGINICA*. **Jerome La Peyre, Yanli Li,** and **John Buchanan,** Department of Veterinary Science, Louisiana State University, Baton Rouge, LA 70803, USA. E-mail: jlapeyre@agctr.lsu.edu

The optimization of a culture medium for oyster cells may be a critical factor for the development of a cell line. A variety of commercial culture media supplemented with fetal bovine serum have been used to maintain oyster cells in primary cultures. Although certain ingredients found in oyster plasma are often added to these commercial media, there have been limited attempts to evaluate the benefits of these ingredients to oyster cells and to optimize their concentrations. Moreover, no culture medium has yet been formulated specifically for cells of oysters or other bivalve mollusks. Therefore, a strategy was adopted to develop a culture medium for oyster cells methodically.

A basal medium composed of a mixture of inorganic salts, buffers, amino acids, carbohydrates, and vitamins that resembled the known composition of oyster plasma was initially prepared. The concentrations of each mixture were optimized by comparing the metabolic (dehydrogenase) activity of heart cells, as measured by the reduction of tetrazolium salts to formazan, and by observing the morphology and contractility of heart cells in culture. Our basal medium, designated LA-1, was found to be superior to L-15 medium, a commercial medium that has most often been used for oyster cells.

Using our basal medium LA-1, the effects of more than 30 ingredients on primary heart cell cultures were then evaluated individually over a broad range of concentrations and in combination using a statistical optimization approach based on a Plackett–Burmann design. A defined medium, designated LA-2, was formulated by supplementing our basal medium with all beneficial ingredients. LA-2 was far better than L-15 supplemented with fetal bovine serum (FBS) for maintaining oyster cells in primary cultures. Moreover, addition of low concentrations of FBS (i.e., 2 and 4%) to LA-2 did not benefit oyster heart cells; whereas, the addition of higher concentrations of FBS (i.e., 6 and 8%) to LA-2 was detrimental.

Finally, we tested a number of undefined medium supplements (e.g., lactalbumin hydrolysate, egg yolk) reported to be beneficial to oyster cells as well as sera from a variety of animals (e.g., goat, chicken, fish). Their effects on oyster heart cells maintained in LA-2 were determined individually and in combination to select beneficial supplements. The culture medium developed greatly increased the survival and metabolic activity of oyster cells *in vitro* as compared to L-15. This medium will be used to stimulate cell proliferation with known mitogens in future studies.

EFFECTS OF OYSTER REEFS ON MICROBIAL COMMUNITY STRUCTURE AND PRODUCTION. **Alan J. Lewitus, Michael S. Wetz, Eric T. Koepfler, Kenneth C. Hayes,** and **Richard F. Dame,** Baruch Marine Field Laboratory, Baruch Institute, University of South Carolina, P.O. Box 1630, Georgetown, SC 29442, USA. E-mail: Lewitus@belle.baruch.sc.edu

Oyster reefs can influence microbial communities through grazing and nutrient regenerative activities. Each process can be selective. Therefore, the net effect of oyster reefs on microbial food webs is a function of the combined influences of oyster reef feeding preference and microbial uptake ability for regenerated nutrients (e.g., NH_4). We compared: (1) microbial community composition and biomass in intertidal creeks with (+Oys) and without (−Oys) oyster reefs; (2) the potential for nutrient or grazing limitation of phytoplankton from those creeks using bioassays; and (3) changes in microbial communities in water flowing across oysters in linear flumes. When comparing all +Oys to −Oys creeks, no significant differences in NH_4 or chlorophyll *a* (chl) were found, nor did the responses of chl to nutrient additions or reduced grazing pressure differ in bioassays. However, when geomorphologically similar +Oys and −Oys creeks were paired, differences in NH_4, chl, and bioassay responses were evident, suggesting that the influence of oyster reefs on phytoplankton growth and nutrient availability depends on creek geomorphology. A consistent effect of oyster reefs on phytoplankton composition was seen in summer, when +Oys creeks contained significantly fewer phototrophic flagellates, but not heterotrophic flagellates, ciliates, bacteria, cyanobacteria, or diatoms. Flume experiments demonstrated preferential removal of phototrophic flagellates, but not other groups, by live oysters but not dead oyster shells. Thus, oyster reefs can exert control over microbial food web structure, but their impact on microbial community production apparently depends on tidal creek morphology and hydrography. When examined across a range of creek types, the influence of oyster reefs on microbial community composition and nutrient availability did not affect over-all nutrient concentration or phytoplankton biomass, suggesting that other grazers (e.g., zooplankton, nekton) or nutrient sources (e.g., zooplankton, nekton, groundwater) may override or compensate for the effects of oyster reefs.

EVALUATING POTENTIAL COMPETITIVE INTERACTIONS BETWEEN *CRASSOSTREA VIRGINICA* AND NONINDIGENOUS OYSTER SPECIES IN THE CHESAPEAKE BAY. **Mark W. Luckenbach,** and **Albert G. Curry, Jr.,** Virginia Institute of Marine Science, College of William and Mary, Wachapreague, VA, 23480, USA. E-mail: luck@vims.edu

Declines in standing stocks of native oysters, *Crassostrea virginica*, throughout the mid-Atlantic coast of the United States has focused attention on management options for using nonindigenous species for the purposes of enhancing wild fisheries, reestablishing ecosystem services, and promoting aquaculture development. Recently, small-scale commercial trials using triploids of the exotic oyster species *Crassostrea ariakensis* have been permitted in Virginia. Despite the sterility of triploids, this practice presents some risk of unintended reproduction and, thus, introduction of the exotic species. To evaluate both the utility of nonindigenous species for these purposes and the risks posed by their introduction, we have conducted a series of quarantined laboratory and field experiments using sterile triploids of the Pacific oyster species *C. gigas* and *C. ariakensis*.

Among the issues of concern posed by any such introduction is the outcome of potential competition between native and nonnative species. In a series of quarantined, flow-through laboratory flume experiments, we have investigated competitive interactions between *C. virginica* and either *C. gigas* or *C. ariakensis*. Replicate treatments consisting of the native and one non-native oyster species in five proportions (100:0, 90:10, 50:50, 10:90, 0:100) were established with newly settled juvenile oysters onto ceramic tile plates. These plates were photographed, and the location of each individual of each species was mapped with an image analysis system. Plates were then placed individually in an array of flow-through pipe flumes. Effluent from the flumes was filtered through a series of sand filters before discharge. On a weekly basis for 10 to 12 weeks the plates were removed, gently rinsed, and photographed in a standard orientation. Image analysis was used to track growth, survival, and the outcome of intra- and interspecific interactions. The results indicate complex patterns of species interactions dependent in part upon the relative orientations of individuals. Moreover, they point to the uncertainty associated with predicting the ecological risks associated with the introduction of a non-native oyster and provide a cautionary note to fisheries managers considering such an option.

PHOSPHOLIPID SYNTHESIS IN PERKINSUS MARINUS: A PRELIMINARY INVESTIGATION OF FACTORS LIMITING CELL REPLICATION. **Eric Lund, Philippe Soudant,** and **Fu-Lin E. Chu,** Virginia Institute of Marine Science, School of Marine Science, College of William and Mary, P.O. Box 1346, 1208 Greate Road, Gloucester Point, VA 23062, USA. E-mail: lund@vims.edu

Perkinsus marinus is a protozoan parasite that causes high mortality rates in its commercially important host, the eastern oyster *Crassostrea virginica*. Previous studies in our laboratory and elsewhere have shown that amino acids in the media were almost completely depleted when meront cultures of *P. marinus* reached stationary phase. We hypothesize that the termination of cell proliferation may be due to the depletion of polar headgroups in the media, not the ability of the parasite to synthesize polar lipids *de novo*. To determine the phospholipid nutritional requirements of *P. marinus*, we investigated the ability of this parasite to synthesize phospholipids from various polar headgroup precursors. Pulse/chase experiments using precursors of polar lipid headgroups revealed that *P. marinus* meronts rapidly utilized exogenous amino acids and sugars for incorporation in a wide variety of polar lipids (Table 1). Specifically, serine was incorporated into phosphatidylserine (PS), phosphatidylethanolamine (PE), phosphatidylcholine (PC), and ceramide (CER). Ethanolamine was incorporated into PE and PS. Choline was incorporated into PC. Inositol was incorporated into phosphatidylinositol (PI) and other glycolipids. Preliminary experiments also revealed that cell replication occurred in lipid-free media containing amino acid mixtures and other nutrients. Cell numbers increased from 0.8×10^6 cells mL^{-1} to 1.59×10^6 cells mL^{-1} in seven days. These results suggest that *P. marinus* may not require intact polar lipids from its host for membrane synthesis and proliferation.

TABLE 1.

Activity recovered (nCi) in HPTLC scrapings of extracted culture lipids after incubation of 2×10^6 *P. marinus* meronts with 15 µCi of a single radiolabeled headgroup in 5 ml 0.22 µm filtered York River water (28 ppt) containing 10 µg ml^{-1} cod liver oil for 2 hr.

Headgroup	PC	PS and PI	PE*	CER and unknown polar lipids
^{14}C choline	40.65	0.45	0.08	0.18
^{14}C ethanolamine	0.03	0.10	1.29	0.55
^{3}H serine	8.65	17.44	39.95	27.17
^{3}H myo-inositol	0.10	2.56	1.90	1.23

* This fraction may also contain unidentified glycolipids.

This research was funded by NSF (MCB9728284).

ALTERED *PERKINSUS MARINUS* PROTEASE PROFILES UPON EXPOSURE TO SELECTED OYSTER TISSUE HOMOGENATES. **Alanna MacIntyre** and **Stephen Kaattari,** Department of Environmental Sciences, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA, USA. E-mail: alanna@vims.edu

Utilizing *in vitro* culture methodologies for the growth of *P. marinus*, we have examined the possible role of oyster tissue factors in the modification and/or regulation of parasitic secretory products. Various concentrations of oyster tissue homogenates were used to supplement a defined culture medium. The growth

rate and protease expression with the various supplements was then determined. It was found that although the growth rate of the *P. marinus* cells is relatively unchanged upon exposure to the homogenates of various oyster species, a distinctly different array of proteases, as determined by gelatin-gel electrophoresis were observed with *Crassostrea virginica* homogenates, but not with *Crassostrea ariakensis*. Typically at least five proteases within the molecular weight range of 65–135 kDa can be observed in bovine serum albumin (BSA)-free medium or BSA-free medium supplemented with *C. ariakensis* or homogenates. However addition of *C. virginica* homogenates reveals the presence of five additional protease bands in the 10–50 kDa molecular weight range. This is of particular interest, because *C. virginica* is the most susceptible oyster species to *P. marinus* infection. This research was funded by the NOAA–Virginia Sea Grant Association, Oyster Disease Research Program.

TEMPORAL VARIATION IN THE GAMETOGENIC CYCLE OF MARINE MUSSELS, *MYTILUS EDULIS* AND *MYTILUS TROSSULUS*, IN COBSCOOK BAY, MAINE. **Aaron Maloy, Bruce J. Barber,** and **Paul D. Rawson,** University of Maine, School of Marine Science, 5735 Hitchner Hall, Orono, ME 04469-0001. E-mail: aaron.maloy@umit.maine.edu

Culture of the edible blue mussel, *Mytilus edulis*, is expanding in the state of Maine to meet a growing demand. Current practice involves the dredging of juveniles from natural seed beds for placement on bottom leases or collection of seed on ropes for suspension from rafts. It has recently been discovered that a second species of mussel, *Mytilus trossulus*, occurs sympatrically with *M. edulis* in eastern Maine. Future economic viability of the industry is dependent on the ability of growers to collect the more valuable *M. edulis* seed preferentially. A lack of natural hybridization between the two species and observations of two distinctive spat settlements in the region suggests there may be a temporal difference in spawning that could be utilized for preferential collection of *M. edulis* seed. This study was undertaken to compare the gametogenic cycles of *M. edulis* and *M. trossulus* from a single population from Cobscook Bay, Maine.

Throughout 2000, one hundred to one hundred thirty mussels were sampled from a low intertidal site at monthly to bimonthly intervals. Three-polymerase chain reaction (PCR)-based nuclear markers and one ribosomal marker were used to differentiate between mussels species. Histologically based quantitative assessments of gametogenesis were carried out using image analysis software. The gametic volume fraction (GVF) for twenty individuals of each species was obtained from each sample and used to make assessments concerning gametogenic development and timing of the spawning events. Preliminary analysis indicates that *M. trossulus* initiates gametogenesis earlier than *M. edulis*.

MASS MORTALITIES OF SOFT-SHELL CLAMS (*MYA ARENARIA*) IN ATLANTIC CANADA ASSOCIATED WITH UNPRECEDENTED LEVELS OF HEMIC NEOPLASIA. **Sharon E. McGladdery,[1] Gregory S. MacCallum,[2] Neil G. MacNair,[3]** and **Jeffrey T. Davidson[2],** [1]Department of Fisheries and Oceans, Canada, Gulf Fisheries Centre, Moncton, NB, Canada, E-mail: mcgladderys@dfo-mpo.gc.ca; [2]Atlantic Veterinary College, UPEI, Charlottetown, PEI, Canada; and [3]PEI Department of Fisheries and Environment, Charlottetown, PEI, Canada.

In July, 1999, a soft-shell clam (*Mya arenaria*) farmer reported heavy losses that seemed to be increasing in severity. A sample of moribund and neighboring, apparently healthy, clams showed levels of hemic neoplasia >95%. Low prevalences (<13%) of hemic neoplasia has been reported previously from soft-shell clams in Atlantic Canada (Morrison *et al.* 1993) and over 2,000 soft-shell clams sampled between 1990 and 1999 revealed equally low sporadic prevalences (<11%, unpublished data). This is the first case of mortalities being associated with the condition in Atlantic Canada.

Repeat samples of different size groups in August found 20 to 60% in one- to five-year-old specimens. Archived samples from reproductive studies by the Department of Fisheries and oceans (DFO) St. Andrews in the Bay of Fundy, showed prevalences <10% between 1989 and 1991. Similar samples held at the Atlantic Veterinary College showed prevalences of 0 to 20% in 1997. In 1998, samples from a neighboring site showed an over-all prevalence of 5%. This site showed an increase to 8% in June 1999 and 80% in August, with associated mortalities.

A broad-scale survey of PEI clam beds revealed negative and positive sites with linkages to seed collection and transfers, as well as in close proximity to agriculture activity; thus, the cause of the neoplasia increase is not clearly evident. Interestingly, an independent submission from New Brunswick revealed a similar high prevalence of neoplasia in weak and dying clams (34%), indicating a possibility that this may be wider spread than in PEI. It also suggests that warm, shallow Gulf of St. Lawrence waters may be a contributing factor.

To date, only soft-shell clams are affected, which is consistent with similar mortalities reported from the eastern United States (Barber 1990, Farley et al. 1991). Transmission experiments are currently underway to determine whether or not this is a transmissible condition or more closely related to environmental triggers.

THE USE OF *CRASSOSTREA VIRGINICA* CULTCH TO STABILIZE AND ENHANCE CREATED *SPARTINA ALTERNIFORA* MARSH. David L. Meyer, NOAA Beaufort Laboratory,101 Pivers Island Road, Beaufort, NC 28516, USA. E-mail: dave.meyer@noaa.gov

In 1987, three dredge material sites were sculpted and planted with *Spartina alterniflora*. By spring 1992, the plantings had completely colonized the sites. These sites were modified in 1992 by the addition of *Crassostrea virginica* cultch to the lower intertidal fringe of select portions of the created marshes. Twelve 5-m wide plots were established at each site, six randomly selected plots remained unaltered (noncultched), and six plots were modified by addition of 1.5-m wide, 4.5-m long, and 0.25-m deep band of cultch (cultched). This was performed to examine: (1) the cultch additions potential to stabilize marsh vegetation and sediment; (2) cultch use by oyster reef fauna; and (3) the effect of increased marsh habitat heterogeneity, via cultch addition, on nekton.

Marsh edge vegetation stability and sediment erosion was measured for each plot from September 1992 to April 1994. A significant difference ($P < 0.05$) in marsh edge vegetation change was detected at the only south facing site after a major southwester storm. Significantly different rates of sediment erosion (noncultched plots lost 3.2 cm) and accretion (cultched plots accreted 6.3 cm) also occurred. A second site, with a northern orientation, also experienced differential sediment accretion and erosion between plot type. Here, the results were in response to boat wakes that were magnified by the abutment of a dredge effluent pipe across the front of the site. During this time period, we observed sediment accretion in the cultched plots of 2.9 cm and erosion in the noncultched plots of 1.3 cm.

Cultch plots supported numerous oyster reef associated fauna at densities equivalent to nearby natural reefs. Two years after placement, harvestable sized *C. virginica* (> 75 mm) were present within the cultch. Cultched plots also contained a higher number of oyster-associated species than natural reefs and noncultched plots. After two years, densities within the cultched plots for the most abundant species including *C. virginica, Balanus amphitrite, Panopeus herbstii,* and *Eurypanopeus depressus* were equivalent to natural reefs. These species were not present within the noncultched plots. In addition, the fringe of oyster cultch seemed to enhance marsh use by some marsh resident nekton species and those known to have an affinity for oyster substrate, including *Cyprinodon variegatus, Fundulus heteroclitus, Gobionellus boleosoma, Gobiosoma bosci,* and *Palaemonetes* spp. The cultch may, however, serve as a barrier for species that move onto the marsh early in the tidal cycle including *Leiostomus xanthurus* and *Callinectes sapidus.*

Cultch placement at the lower fringe of created salt marsh can reduce marsh sediment erosion and vegetation loss in areas prone to storm-related wave activity. The addition of cultch to the lower marsh fringe may promote resident marsh nekton use beyond that of noncultched marsh. Furthermore, cultch additions can provide quality habitat for oyster reef fauna.

***IN VITRO* STUDIES OF DISSEMINATED NEOPLASMS OF *MYTILUS TROSSULUS*. James D. Moore, Hiroko Shike, Chisato Shimizu, Ralph A. Elston,** and **Jane C. Burns,** U.C. Davis Bodega Marine Laboratory, 2009 Westside Road, Bodega Bay, CA 94923, USA. E-mail: jimmoore@ucdavis.edu

Establishment of a cell line requires immortalized or transformed cells that divide continuously in culture. Naturally occurring neoplasms provide a source of highly concentrated, rapidly proliferating, transformed cells. The only impediment to establishing a cell line from this material is to identify culture conditions that will support long-term growth. We are exploring the *in vitro* culture of disseminated neoplasms of mussels, *Mytilus trossulus* from Puget Sound, Washington, U.S.A. Approximately 0.5–1% of mussels in these populations contain advanced neoplasms in which more than 90% of the cells in the hemolymph are rapidly cycling, transformed cells with altered DNA content.

We assessed the cycling activity of normal and neoplastic cells *in vitro* by tritiated thymidine incorporation. Cells from a mussel with an advanced neoplasm showed different levels of DNA synthesis in different media, thus demonstrating the utility of this assay for optimizing culture conditions.

To study the transmissibility of the neoplasms, we sought a method to mark the cells genetically. Neoplastic cells were exposed *in vitro* to pantropic retroviral vectors that contain a substituted envelope protein that permits infection of invertebrate cells. The vector, LLRNL (Moloney murine leukemia virus long terminal repeat (LTR) (L)-firefly luciferase (L)-Rous sarcoma virus LTR (R)-neomycin phosphotransferase (N)-MoMLV LTR), was used to infect cells. Transduction of cells was stable over a six-day period, was independent of polybrene, and was proportional to number of vector particles. These results suggest that pantropic vectors can be used to mark genetically neoplastic cells *ex vivo*, which can then be transplanted into healthy mussels to study transmission and provide a continuous source of neoplastic cells for *in vitro* experiments.

OPTIMIZING CULTURE CONDITIONS FOR CREATION OF AN OYSTER CELL LINE. James D. Moore, Viviane Boulo, Chisato Shimizu, Hiroko Shike, Carolyn S. Friedman, and **Jane C. Burns,** U.C. Davis Bodega Marine Laboratory, 2099 Westside Road, Bodega Bay, CA 94923, USA. E-mail: jimmoore@ucdavis.edu

To aid in the formulation of media to support oyster cells nutritionally in culture, we analyzed the hemolymph components from *Crassostrea virginica* and *C. gigas*. We measured DNA synthesis in primary cultures incubated in different media and at different temperatures to optimize culture conditions.

Pooled hemolymph (two to three oysters/pool) was obtained by cardiac puncture. Hemocytes were removed by centrifugation (1,000 × g) and the supernatants stored at −70°C. Analysis of hemolymph components included free amino acids, organic acids, carbohydrates, metals, electrolytes, pH, and osmolality. Cultures of heart and embryos were established according to published methods (Boulo et al. 1996, 2000). DNA synthesis in cultured cells was assessed by ^{3}H-thymidine uptake.

Two media formulations based on published data were compared: (1) KS medium (based on Kleinschuster and Swink 1993): L-15 adjusted to 750 mOsm with synthetic sea salts, and supplemented with amino acids, lipids, carbohydrates, vitamins, 10% fetal calf serum (FCS), and 10% *C. virginica* hemolymph; (2) 2X L-15 (Boulo et al. 1996) adjusted to 750 mOsm with NaCl plus 10% FCS.

Selected components that were lower in the media than in the pooled hemolymph samples are shown below (mean values ± SD; NA = not available)

Component	*C. virginica* hemolymph	KS medium	2X L-15 medium/10% FBS
Taurine	195.9 ± 12.1mg/L	51.9	NA
Proline	90.5 ± 3.7	34.2	NA
Calcium	40.7 ± 6.2	19.8	9.3
Strontium	4.7 ± 0.9	3.0	0.1
Boron	4.4 ± 0.7	NA	0.1
Zinc	1.3 ± 1.3	NA	0.1

pH ranged from 6.4–6.9.

Preliminary comparison of ^{3}H-thymidine uptake by primary *C. gigas* heart cells cultured in different media at different temperatures revealed that DNA synthesis occurred between 48 and 72 h postinitiation of the cultures under all conditions. In contrast, dissociated embryo cells had maximal DNA synthesis during the first 24-h period in culture and 2X L-15 at 23°C supported the highest level of DNA synthesis. Additional comparisons will guide formulation of media to nutritionally support primary cultured oyster cells. Supported in part by California Sea Grant NA86RG0073 Project No. R/A-110B and the California Department of Fish and Game.

REVIEW OF GULF OYSTER INDUSTRY PROGRAM GRANT PROJECTS: LOUISIANA OYSTER LEASES VERSUS COASTAL RESTORATION AND CLEAN-UP OF CONTAMINATED OYSTER BEDS. Erinn W. Neyrey, Joe Stevenson, and **Michelle Marney,** LSU Sea Grant Legal Program, LSU Law Center, Rm. 170, Baton Rouge, LA 70803, USA. E-mail: eneyrey@lsu.edu

Louisiana oyster leases versus coastal restoration: Louisiana's coastal wetlands account for more than 25% of all wetlands found within the United States; however, this important ecosystem is disappearing at an astonishing rate. To counter coastal erosion, Louisiana has developed an extensive plan consisting of numerous restoration projects. One of the major components of the plan is the construction of freshwater diversion projects. The diversion of sediment-rich river water is designed to mimic the natural flood cycle and allow the river's sediments and nutrients to be deposited in the coastal zone. Oyster farmers in the restoration areas have experienced negative impacts on their over-all productivity caused by the changes in salinity. These impacts have led to lawsuits being filed by the oyster farmers against the state for damages. In response, Louisiana has passed legislation creating the Oyster Lease Relocation Program (OLRP). The OLRP is designed to offer alternatives to the oyster farmers who find themselves in a restoration area. Although this program may not provide a cure for all of the problems that may arise, it does provide an extrajudicial means to resolve many of the disputes between oyster farmers and the state resulting from coastal restoration projects.

Clean-up of contaminated oyster beds: Louisiana is the top processor of oysters within the Gulf region, which produces nearly 60% of the nation's oysters, and is home to nine hundred oyster farmers. Successful business planning by members of this significant industry benefits not only those in the industry, but the state as well. Relocation of leases because of fouled oyster beds effects not only the livelihood of an oyster farmer, but lifestyle as well. Both the Clean Water Act and Louisiana's Water Control Law clearly prohibit the discharge of pollutants into waters; however, these laws do little to address the actual clean-up of polluted water bodies. Therefore, solutions to the water pollution problems are turning increasingly on interpretive regulation and policy of the U.S. Environmental Protection Agency and the private citizen actions that seek alternatives to the imposition of civil penalties. Supplement environmental projects offer a potential flexibility that traditional enforcement actions do not.

A REVIEW OF ORGANISMS ASSOCIATED WITH OYSTERS CULTURED IN FLOATING SYSTEMS. F. X. O'Beirn, P. G. Ross, and **M. W. Luckenbach,** Virginia Institute of Marine Science. E-mail: francis@vims.edu

Given the increase in oyster (*Crassostrea virginica*) aquaculture on the eastern seaboard of the United States, an issue to be considered is the influence of these intensive operations on faunal assemblages found adjacent to and among the oysters themselves. In fact, little is known concerning the organisms associated with such aquaculture operations. Using oysters in a typical culture scenario, we assessed the number of macrofaunal species associated with floating culture systems and the number of organisms within broad taxonomic groups. Within each floating structure (2 ft × 8 ft × 1 ft) oyster numbers ranged from 488 to 1,381. Overall, forty-four species of macrofauna were recorded from the floating structures. The species richness within each float ranged from twenty-four tothirty-six. Abundances ranged from 12,746 to 92,602 individuals per float. In an attempt to determine if the organisms were influenced directly by live oysters or the structure

provided by oyster shell, we evaluated communities associated with live oysters, oyster shell, and empty floats (culture systems). Preliminary results indicate that the live oyster and oyster shell have similar abundance and biomass of individuals, but the composition of individuals is different. These results suggest that structure of any sort is important to certain species (e.g., grass shrimp), but the presence of live oysters influences the presence of other species (e.g., anemones, blue mussels). Given the ephemeral nature of these communities (mediated by harvest and handling schedules), many organisms within these floating communities may not actually mature to reproduce, and these systems may be sink populations. Certain associated species may actually compete with the oysters for food resources (e.g., blue mussels) and increase the organic loading emanating from the culture systems. In addition, altering the habitat type in a particular area may change the constituent organisms of a community and species interactions within a system. For example, fishes nesting or taking refuge in the cages may reduce grazer abundances (e.g., amphipods); thereby, affecting macroalgal abundances. As the scale of aquaculture operations increase, it will be increasingly important to further elucidate these and other ecological interactions.

SPATIAL AND INTERANNUAL OCCURRENCE OF A BROWN SHELL CONDITION IN NEWFOUNDLAND FARMED BLUE MUSSELS (*MYTILUS* SPP.) G. Jay Parsons, Kelly Moret, Cyr Couturier, and **Miranda Pryor,** Centre for Aquaculture & Seafood Development, Marine Institute, Memorial University, P. O. Box 4920, St. Johns, NF, Canada A1C 5R3. E-mail: Jay.Parsons@mi.mun.ca

The appearance of a brown coloration on the surface of blue mussels in Newfoundland prompted an investigation into the extent, potential impact on mussels, and factors influencing its occurrence throughout the province. In severe infections, this brown shell condition results in the loss of the periostracum and has been described as the "mycotic periostractal sloughing" (MPS) disorder. The etiological agent is a fungus yet to be identified (T. J. Davidson, pers. comm.); however, similar mycotic infections are common in cultured mussels worldwide. The mode of transmission is unknown, but studies on PEI mussels suggest that initial infection occurs in early fall in mussels that are more than a year old (T. J. Davidson, pers. comm.). The objectives of this study were to determine the spatial distribution of the fungal shell infections (FSI) (resulting in the brown shell condition) throughout Newfoundland, determine the interannual variability, and determine if progression is size related.

The shells of mussels were examined from twenty-one culture sites throughout the province in 1998 and twenty-two sites in 1999. There were about sixty mussels sampled from each site. Mussels ranged in size from about 35 to 85 mm shell length. Mussels were examined for the occurrence of FSI on the surface of the exterior shell using a dissecting microscope to observe the occurrence of brown foci. On mussels with FSI present, the percentage coverage (to the nearest 5%) was recorded. Data on the occurrence and percent coverage were summarized by farm site and geographic zone.

The occurrence of FSI in both years ranged from 0 to 100% of mussels at sites around Newfoundland. At sites where the brown shell condition was recorded, the percentage coverage ranged from 1 to 93% and 1 to 99% for 1998 and 1999, respectively. When the farms were grouped by zones, the most northern sites had the lowest occurrence of FSI and the lowest percentage coverage. Sites in central Newfoundland had a higher rate of occurrence but a low percentage coverage. Sites on the south coast had both a high rate of occurrence and a high percentage coverage of FSI. A similar pattern occurred in both years of the study. There were, however, no consistent differences in the occurrence or percentage coverage of FSI on individual sites from 1998 to 1999. Some sites had a lower rate of occurrence of FSI in 1998 as compared to 1999, but other sites had a higher rate in 1998 as compared to 1999. Percentage coverage was significantly, but weakly, correlated to mussel shell length for both 1998 and 1999. There was no apparent decrease in condition or health in mussels with the brown shell condition.

Mussels with FSI were found throughout Newfoundland; however, the condition known as MPS was rarely observed even in larger, older mussels. Although there were distinct geographic differences in the rate of occurrence and percentage coverage, we have not yet been able to relate these differences to specific environmental parameters or husbandry conditions, except that it seems size/age, temperature, and husbandry practices may influence the extent of coverage.

INDUCTION OF TRIPLOIDY IN THE AMERICAN OYSTER *CRASSOSTREA VIRGINICA*: A RE-EVALUATION OF POLAR BODY I INHIBITION. Stefano Peruzzi and **Ximing Guo,** Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349, USA. E-mail: speruzzi@hsrl.rutgers.edu

In mollusks, triploidy can be induced by inhibiting either polar body 1 (PB1) or polar body 2 (PB2). It has been shown in the Pacific oyster that PB1 inhibition results in primarily aneuploids and heavy larval mortality. In the American oyster, an early study has shown that PB1 triploids grow faster than diploids and PB2 triploids, possibly because PB1 triploids are more heterozygous. The objective of this study is to re-evaluate if PB1 inhibition is a valid method for triploid induction and if PB1 triploids grow significantly faster than diploids and PB2 triploids in New Jersey. Growth performance of triploids is known to vary among different environments.

In this work, three experimental groups were produced: a normal diploid control, a PB1 triploid group, and a PB2 triploid group. Cytochalasin B (0.75 mg/L) was used as the induction agent. The

experiments were replicated four times using a total of twenty-five females and fifteen males oysters. Both methods were effective in generating variable levels of triploidy (41 to 100%). Viability of PB1 triploids was actually higher than PB2 triploids over the first two months of life. Oysters will be deployed at two sites in NJ. Oysters will be sampled at regular intervals for ploidy determination and growth measurements. Genomic heterozygosity of experimental oysters will be determined using allozyme markers. Sampling and analyses are currently underway and will be reported at the meeting.

REDUCTION OF RED TIDE TOXIN IN CLAMS BY OZONE PURIFICATION AND RELAYING. **Richard Pierce, Michael Henry,** and **Gary E. Rodrick,** University of Florida, Department of Food Science and Human Nutrition, Gainesville, FL, USA. E-mail: GER@GNV.IFAS.UFL.EDU

A study of the accumulation and purification of harmful algal biotoxins in the clam, *Mercenaria mercenaria* was initiated to investigate the use of ozone as a means to enhance the natural purification of toxins. Clams were exposed to viable cells of the Florida red tide organism, *Gymnodinium breve* (5 × 106 cells/clam/day) for nine days. Following exposure, the clams were divided into groups for natural relay versus ozone purification. The concentration of brevetoxins (PbTx-2 and PbTx-3) in the exposure water and clam tissue was monitored by high-power liquid chromatography–ultraviolet (HPLC–UV) analysis and by receptor-binding assay. The amount of total PbTx-2 and PbTx-3 in the original culture before dilution for clam exposure and brevetoxin concentration in the effluent water after exposure clams show that the clams were exposed to appropriate levels during the study. These results show the presence of brevetoxins in the spiked samples and a definite accumulation of active toxins after ten days of exposure. After three days of ozone purification, the treated clams exhibited a 50% drop in the brevetoxin activity level; whereas, the nonozone-treated clams exhibited a 38% drop in the ten-day exposure level. Relaying the red tide contaminated clams to a clean seawater area for fifteen days removed (100%) toxin activity when compared to nonrelayed controls.

OYSTERS REEFS AS HABITAT FOR FISH AND DECAPODS: SPECIES AND LANDSCAPE CONSIDERATIONS. **Martin H. Posey, Troy D. Alphin,** and **Thomas K. Frazer,** Center for Marine Science and Department of Biological Sciences, University of North Carolina at Wilmington, One Marvin K. Moss Lane, Wilmington, NC 28409, USA. E-mail: Poseym@uncwil.edu

Structural habitats have long been recognized as important nursery areas for juvenile fish and decapods, as indicated by work in seagrass and marsh habitats. Recent interest has focused on the potential importance of oyster reefs as a refuge habitat. Along much of the southeastern coast of the United States and in some areas of the Gulf of Mexico, seagrasses are largely absent, and oyster reefs may provide the primary structural habitat in low to shallow subtidal areas. However, use of these oyster reefs may vary among species and may depend on the occurrence of other habitat types.

We have examined abundances of decapods and fish in oyster and marsh edge/sand habitats in two regions of North Carolina—one that has seagrasses (New River) and one that completely lacks seagrass beds (Hewletts Creek). In the absence of seagrass beds, grass shrimp and certain fish were more abundant within oyster beds during peak periods of abundance in winter and spring (Fig. 1). However, other decapods may not show this pattern. In the New River, where seagrasses provide an alternative habitat, there were low abundances of all groups sampled within oyster beds (Fig. 2). Abundances were somewhat higher in sand/marsh edge habitats and were much higher for most groups within seagrass beds. In all cases, there are strong seasonal effects on use of oyster beds, including shifts in the major species present.

Our results emphasize the potential importance of oyster reefs as habitat for certain fish and decapods. However, the patterns of use varied between locations (especially with the presence of alternative habitats), varied between taxa, and varied seasonally.

DERMOWATCH: A WEB-BASED APPROACH FOR MANAGING *PERKINSUS MARINUS* DISEASE OF OYSTERS. **Sammy M. Ray, Thomas M. Soniat,** and **Enrique V. Kortright,** Department of Biological Sciences, Nicholls State University, Thibodaux, LA 70310, USA. E-mail: biol-tms@mail.nich.edu

A web site called DermoWatch (www.blueblee.com/dermo) has been established to help manage *Perkinsus marinus* (= *Dermocystidium marinum*) disease of eastern oysters, *Crassostrea virginica*. The main page provides the most recent data for nine stations in Galveston Bay, Texas. Data include water temperature (T) and salinity (S), weighted incidence (WI) and percentage infection, and estimated time to a critical level of disease (t_{Crit}). Archived historical data for each site is available from the main page and via a map of the bay. With a utility called the Dermo Calculator, the web site is useful wherever dermo disease is found. The Dermo Calculator allows anyone with information on water T and S, oyster length (L), and initial WI of disease to calculate a t_{Crit}. A prototype utility has also been developed that uses real-time values for water T and S from a fixed monitoring station. The utility requires input of the time period of interest and L; it returns, in graphical form, a time course of T, S and t_{Crit}. More frequent

values of T and S permit more frequent estimates of t_{Crit} and should increase the reliability of the model.

INTER- AND INTRA-SPECIFIC GENETIC VARIATION AMONG *PERKINSUS* SPECIES: IMPLICATIONS FOR SPECIES IDENTIFICATION AND DEVELOPMENT OF MOLECULAR DIAGNOSTICS. **Kimberly S. Reece, Gwynne D. Brown, Karen L. Hudson,** and **Kathleen Apakupakul,** Virginia Institute of Marine Science, The College of William and Mary, Gloucester Point, VA 23062, USA.

Perkinsus species are protozoan parasites of marine and estuarine mollusks. Globally, these pathogens have had devastating effects on wild and cultured host populations. There is considerable interest in developing efficient, sensitive, and accurate means of identifying marine pathogens to facilitate monitoring and development of appropriate management practices. The traditional methods for detection of *Perkinsus* species, histological analysis, and the fluid thioglycollate medium (FTM) assay, is time consuming and does not distinguish among recognized *Perkinsus* species. Molecular diagnostic techniques have the potential to improve on the speed and sensitivity of more traditional diagnostic methods. Unfortunately, molecular protocols often prove to be too expensive and technically cumbersome to be practical for routine monitoring purposes. In addition, unless molecular sequence data are available for many strains of a particular species and for closely related species, there is the chance that a molecular diagnostic may give false-negative or false-positive results.

To design genus- and species-specific molecular diagnostics appropriately it is best to obtain DNA sequence information from as many different strains of a particular species and as many species within the genus as possible. We have been examining the DNA sequences for the ribosomal RNA small subunit gene, the internal transcribed spacer (ITS) region, and an anonymous locus from genetic strains of *P. marinus* and from other species of *Perkinsus*. Examination of intra- and interspecific DNA sequence variation, as well as alignments to DNA sequences of other alveolates, has allowed development of *Perkinsus* probes for *in situ* hybridization and primers for use in polymerase chain reaction (PCR).

We have a genus-specific DNA probe that hybridizes to *Perkinsus* species (except *P. qugwadi*) infecting tissues from a variety of hosts. *Perkinsus* cells have been detected in host tissue samples from Asia, New Zealand, Australia, North America, and Europe. PCR primers have been designed based on sequence analysis of the ITS region that specifically amplify *Perkinsus* species DNA from host tissue. In addition, DNA sequencing of the amplified ITS region has allowed identification of *Perkinsus* species. We also have species-specific PCR primers designed from DNA sequence of other areas of the genome to amplify only *P. marinus*. We are testing and optimizing a quick, inexpensive, and sensitive PCR assay for detection of *Perkinsus* species.

HSP70 RESPONSE IN OYSTER *CRASSOSTREA VIRGINICA* EXPOSED TO CD^{2+} AND PAHs SORBED TO ARTIFICIAL SEDIMENTS. **Luis A. Cruz-Rodríguez** and **Fu-Lin E. Chu,** Virginia Institute of Marine Sciences, School of Marine Sciences, College of William and Mary, Gloucester Point, VA 23062, USA. E-mail: lcruz@vims.edu

The induction of Hsp70 has been used as a marker of exposure to pollutants. Ongoing studies are determining if changes in Hsp70 levels could be used as indicators of environmental quality. Our previous studies showed a general increase of total Hsp70 in oysters exposed to field-contaminated sediments containing a mixture of PAHs, heavy metals, and PCBs. To analyze further which contaminants are responsible for the response, we exposed oysters to a heavy metal (Cd^{+2}) or PAHs sorbed to artificial sediments. Oysters were exposed to 15 ppb or 25 ppb Cd^{+2} sorbed to 1 g or 2 g, respectively, artificial sediments, and to 40 µg, 200 µg or 400 µg PAHs sorbed to 1 g, 1.5 g, or 2 g, respectively, artificial sediments daily for 40 days. Concomitantly, to determine the effect of sediments alone, oysters were exposed to 0 g, 1 g, 1.5 g, or 2 g sediments for forty days.

Oysters exposed to 1 g, 1.5 g, or 2 g sediments showed no statistically significant difference in Hsp70 levels compared to the 0 g oysters after forty days (Fig. 1A). Oysters exposed to PAHs-sorbed to the sediments showed a significant increase in the Hsp70 response compared to those exposed to sediments only, but no dose dependency was observed. Oysters exposed to 15 ppb or 25 ppb Cd^{+2} did not show a statistically significant effect as compared to those exposed to sediments only, although the oysters exposed to the highest dose (25 ppb) showed an increase in the Hsp70 levels (Fig. 1B). In a separate study, however, Cd^{+2} sorbed to algae induced a statistically significant Hsp70 response as compared to controls (data not shown). PAHs seem to be more available and/or have a greater exchange between the sediments and the oyster gills than the heavy metal. In summary, based on the above results, Hsp70 potentially could be used as an indicator of exposure to contaminants (PAH and Cd^{+2}) in aquatic environments. This research was funded by the EPA.

COMPARISON OF OYSTER (*CRASSOSTREA VIRGINICA*) CULTURE NURSERY AND GROW-OUT TECHNIQUES. **P. G. Ross, F. X. O'Beirn,** and **M. W. Luckenbach.** E-mail: pg@vims.edu

Along the mid-Atlantic coast, decline of wild eastern oyster (*Crassostrea virginica*) stocks, combined with collateral declines of other fisheries, has prompted development of alternative sources of income from nearshore waters. As a result, interest in oyster aquaculture in the region has increased. Initially, natural reefs were enhanced to take advantage of natural spawning and subsequent settlement and growth of wild oysters. However, the current trend is toward culture of hatchery-spawned oysters. Currently, most commercial oyster aquaculture focuses on three phases: hatchery,

nursery (~3 to 25 mm shell height) and grow-out (~>25 mm shell height-market size). Different techniques are being utilized in each phase. Much research has focused on the hatchery phase with different nursery and grow-out techniques being utilized based on anecdotal comparisons. To further a technical comparison of post-hatchery culture, we evaluated growth and mortality of two nursery and several grow-out techniques. Two nursery techniques were evaluated and compared: (1) fine mesh bags (1/16-in mesh) suspended in the water column via polyvinylchloride (PVC) floats and 1-in × 1-in wire mesh cages, which relies on natural water flow; (2) a forced upweller system (flupsy) utilizing a pump and suspending oysters in the water column via square plastic "silos" with mesh bottoms, which enhances water flow mechanically. Oysters entered both systems at the same size ($\bar{x}$ = 3.08 mm shell height, SD = 0.36) and density (~2,500 oysters). After sixty-three days (April 5 to June 7) oysters had grown to 20.99 mm (SD = 3.02) in the "flupsy" and 18.87 mm (SD = 4.27) in the bag/float system. Low mortality (≤ 1%) was observed for both culture techniques. Although there was a slight growth differential and similar mortality, the most striking difference between these two techniques is their size variation. Variable sizes at the end of the nursery phase can lead to increased handling and sorting, leading to higher costs. In addition, two densities of oysters were compared within the "flupsy" system. Oysters were stocked at ~2,500 oysters and ~120,000 and, after sixty-three days, had grown to 20.99 mm (SD = 3.02) and 18.51 mm (SD = 2.98), respectively. Mortality was similar at both densities (≤ 1%). With similar mortality and size variance, the most important density effect within the "flupsy" system seems to be on growth. Cost comparisons are currently being analyzed for both techniques. Three grow-out techniques are currently being evaluated: (1) mesh bags (3/8-in mesh) in PVC/wire mesh floats (subtidal system); (2) mesh bags in intertidal 1-in × 1-in wire mesh trays with legs that keep oysters ~4 to 6 in off the bottom; and (3) mesh bags placed directly on intertidal shell bottom. Growth, mortality, and costs will be compared between these techniques. It is expected that the advantages conveyed by subtidal growth will be offset by reduced biofouling intertidally.

IMPACT OF WATERFLOW ALTERATION UPON OYSTER GROWTH AND DISTRIBUTION WITHIN ESTUARIES OF SOUTHWEST FLORIDA: IMPLICATIONS FOR MANAGEMENT AND RESTORATION. **Michael Savarese** and **Aswani K. Volety,** Florida Gulf Coast University, 10501 FGCU Boulevard South, Fort Myers, FL 33965, USA. E-mail: msavares@fgcu.edu

Water management practices within the fast growing coastal regions of Southwest Florida have drastically altered natural water quality conditions within estuaries. Two of the more profound changes have been to salinity and nutrient influx. Storm water management has caused some estuaries to receive excessive freshwater; whereas, others receive less because of interruption of sheet flow; and runoff from suburban and agricultural lands delivers higher nutrient loads to some estuaries. Many of these estuaries are targeted for restoration; however, our knowledge of the prealteration conditions is limited. This research employs the eastern oyster, *Crassostrea virginica*, as an indicator species of ecosystem health. The patterns of reef distribution, oyster productivity, and living density compared among pristine and altered estuaries with historically similar hydrologic conditions are used to establish target water quality conditions for restoration efforts. A "spatial homologue" approach is employed, whereby conditions are compared at sites with similar geomorphologies and geographic positions along the estuarine axis.

In the Faka-Union estuary, a system that receives excessive freshwater during the rainy season, the distribution of reefs, the regions of maximum living density, and the foci of maximum oyster productivity are displaced seaward relative to pristine estuaries. Henderson Creek, an estuary receiving greater input of nutrients, has oyster populations with higher mean productivities and higher living densities. Two demographic patterns of oyster productivity are consistently discernable in all estuaries: one of greater variance in biomass, indicating a wider age distribution; and a second skewed heavily toward smaller individuals, indicating greater levels of juvenile mortality. The first pattern persists at sites that experience pulsed release or protracted inundation of freshwater. Faka-Union, because its watershed area has increased significantly because of management practices, exhibits the "freshwater demographic signal" at all but the most downstream spatial homologue. Here, freshwater inundates the estuarine bays for five to six months of the year. The upstream homologues within the estuary below Henderson Creek's weir, whose simplistic design releases pulses of freshwater, exhibit the same freshwater demographic signal. The alternative, "marine demographic pattern" dominates in natural waterflow settings and at the downstream homologues in Henderson. The persistence of small-sized oysters with few older, large individuals, seen in the marine demographic pattern, may be related to the greater occurrence of the disease-causing protozoan *Perkinsus* within environments of higher salinity. Both Henderson Creek and Faka-Union are scheduled for watershed restoration. These patterns of oyster distribution will help establish target environmental conditions.

LABORATORY-BASED TRANSMISSION STUDIES OF QUAHOG PARASITE UNKNOWN (QPX) IN *MERCENARIA MERCENARIA*. **Roxanna Smolowitz, Dale Leavitt, Bruce Lancaster, Ernie Marks, Rhea Hanselmann,** and **Christine Brothers,** Marine Biological Laboratory, 7 MBL St., Woods Hole, MA 02543, USA. E-mail: rsmol@mbl.edu

Disease caused by the protistan QPX has caused severe mortality in aquacultured clams stocks in Massachusetts in the past few years. Before 1995, it had only been identified in Canada, but

had been responsible for mortality in hard clams there. In Massachusetts, up to 44% of clams sampled from a group of severely infected submarket sized clams have shown swellings and nodules in the mantles. Often these lesions are located at the mantle edge, close to, or directly adjacent to the siphon or adductor muscle. Mortality is usually the most severe in the spring and summer months and is associated with the appearance of the gross lesions in the mantle.

The QPX organism has been identified as an unusual member of the phylum Labyrinthulomycota, probably in the family Thraustochytriidae. As QPX proliferates in culture media, it produces abundant mucoid material that binds the individual organisms together. This mucoid material, which is also produced as QPX grows in clam tissues, may prevent phagocytosis and, thus, act as a pathogenic mechanism in the clam tissues. Cultured QPX proliferates best, and produces abundant mucus, at 22 °C.

The method of infection of clams by QPX is unknown. To study the pathogenesis of QPX infection and resultant disease in hard clams, we designed methods for the study of QPX transmission in the laboratory by exposing naive clams to QPX. Methods used involved injecting clams with cultured QPX (with and without the associated mucoid material) in the mantle and pericardial sac, exposing clams to cultured QPX added to the water column and exposing clams to infected clams harvested from severely infected leases. In one set of experiments, clams were placed in a raceway and exposed to filtered seawater at two temperatures and fed two different levels of prepared algae preparations. In the second set of experiments, animals were housed in aquaria at room temperature in the laboratory. Clams used in these experiments were approximately one-year-old.

Interestingly, results to date show that QPX is a directly infective organism. Naive clams, exposed over a twelve-month period to infected clams, developed mild focal QPX infections after three months of exposure, which progressed to severe infections and associated mortality at the end of the experiment. In contrast to the identification of the mantle as the primary location in submarket-sized aquacultured clams, the one-year-old clams first developed infections in the open vascular spaces at the base of the siphon. Clam injected with QPX washed of the mucus coat or exposed to washed QPX in the water column did not develop infections or disease. Studies of clams exposed to mucoid enveloped QPX are ongoing.

FATTY ACID COMPOSITION AND SYNTHESIS OF *PERKINSUS MARINUS* MERONTS AND PREZOOSPORANGIA. Philippe Soudant, Fu-Lin E. Chu, Eric Lund, Jerome La Peyre, and **Aswini Volety,** Laboratoire de Physiologie des Invertebres, Centre IFREMER de Brest BP 70, 29280 Plouzane, France, E-mail: Philippe.Soudan@ifremer.fr

Although parasitic protozoa generally require exogenous sources of essential fatty acids to support their growth and life cycle completion, some are capable of modifying exogenous fatty acids (FAs). Thus, their fatty acid profiles could differ from their culture media and their hosts. To investigate whether *P. marinus* maintains its characteristic fatty acid profile when cultured outside its host, meronts of this parasite were cultivated in two media with different lipids: (1) medium with lipids derived from bovine fetal serum (terrestrial characteristic lipids); and (2) medium with cod liver oil extract (marine characteristic lipids). Results revealed that despite the difference in lipid sources in the two media, FA composition of *P. marinus* meronts cultivated in these two media were similar and were dominated by 14:0, 16:0, 18:0, 18:1(*n*-9), 20:1(*n*-9), 18:2(*n*-6), and 20:4(*n*-6) (Fig. 1) Also, the FA quantity in meronts increased significantly as compared with amounts contained in their media. This suggests that *P. marinus* is able to *de novo* synthesize fatty acids during proliferation. The FA profile of prezoosporangia developed from tissue-associated meronts (PDFTAM) cultivated in fluid thioglycollate medium (FTM), which is deficient in 20:4(*n*-6) and low in 20: 5(*n*-3) (1.4%) and 22:6(*n*-3) (0.6%) resembled its host, although it contained a higher weight percentage of 20:4(*n*-6) (Fig. 2). Surprisingly, the prezoosporangia developed from tissue-free meronts (PDFTFM) cultivated in alternate FTM supplemented with cod liver oil had very high levels of 18:1(*n*-9) and very low levels of 20:5(*n*-3) and 22:6(*n*-3). This research was funded by NSF (MCB9728284).

DEFENSE-RELATED ACTIVITIES IN "NATURAL DERMO RESISTANT" OYSTER STOCKS. Shawn Stickler, Vincent Encomio, Luttrell Tadlock, Jerome LaPeyre, Standish K. Allen, Jr., and **Fu-Lin E. Chu,** Virginia Institute of Marine Science, College of William and Mary, P.O. Box 1346, Gloucester Point, VA 23062, USA. E-mail: stick@vims.edu

The restoration of eastern oyster (*Crassostrea virginica*) populations can be accelerated with the development of strains resistant to dermo disease, caused by the protozoan parasite, *Perkinsus marinus*. To date, this has meant the slow, methodical approach of selectively breeding oysters that have survived repeated exposure to the parasite. The identification of natural "dermo-resistant" wild stocks and related defense activities can benefit selection efforts. Our goals were to identify wild populations with natural dermo resistance or tolerance (NDR) in a common garden experiment and to identify effective defense activities in surviving individuals or populations for use as breeding markers. We collected and spawned oyster from putative resistant and susceptible control stocks from Louisiana (LGT, LHB, LOB) and the Chesapeake Bay (CCR, CRB, CTS), and a hatchery strain (XB). The progeny were deployed in December 1999 at two dermo-enzootic bay sites, Kinsale and Regent for grow-out. Growth and mortality have been

recorded monthly and samples analyzed for dermo prevalence and intensity. As of July 2000, the CRB stock has grown significantly faster at both sites. Mortality levels, unrelated to *Perkinsus* infection, were low in all stocks, and lower in Louisiana (L) than Chesapeake (C) stocks (Fig 1). Infection prevalence and intensity were minimal in all stocks. In July, we collected hemolymph samples to assay hemocyte counts, and we measured plasma protein and lysozyme levels. Protein levels were significantly different between stocks, but lysozyme levels were not (Fig. 2). Future hemolymph samples will also be assayed for *P. marinus* killing by hemocytes, and plasma protease inhibition activity. This research was funded by the NOAA-Virginia Sea Grant-Oyster Disease Research Program.

NATURAL DERMO RESISTANCE AND ITS ROLE IN THE DEVELOPMENT OF HATCHERIES FOR THE GULF OF MEXICO. Shawn M. Stickler, Eric Wagner, Vincent G. Encomio, Standish K. Allen, Jr., and **Jerome F. LaPeyre,** Aquaculture Genetics and Breeding Technology Center (ABC), Virginia Institute of Marine Science (VIMS), P.O. Box 1346, Gloucester Point, VA 23062, USA. E-mail: stick@vims.edu

The value of developing selectively bred dermo-resistant oyster seed for aquaculture and perhaps stock enhancement is obvious. An important step in developing such a value-added product is identifying wild stocks that may have acquired resistance as a result of natural selection. Our goal was to provide clear evidence for the existence of "naturally resistant populations" of eastern oysters *Crassostrea virginica* by using putatively dermo-resistant brood stock from both the Gulf of Mexico and the Chesapeake Bay and determining the inherent resistance of their progeny to dermo disease in a common garden experiment.

We identified and collected putative resistant and susceptible control stocks from both the Gulf (HAB, GTR, OYS) and the Chesapeake Bay (RPP, TSO, COK, XXB) that were spawned at the ABC Gloucester Point hatchery in the summer of 1999. Seed were deployed that fall in Taylor floats at two dermo-enzootic Gulf sites, Grand Isle and Grand Terre. Growth and mortality were recorded monthly, and samples were analyzed for dermo prevalence and intensity using a modified body burden assay.

As of July 2000, dermo prevalence was similar for all stocks; whereas intensity levels in non-Louisiana stock were considerably higher than in Louisiana stocks (Fig. 1). Mortality levels correlated with disease prevalence. Louisiana stocks showed little mortality attributed to disease, whereas, imported stocks experienced high mortality levels. Although there are differences between LA and CB stocks, there is little difference between the two putatively resistant populations from LA and their susceptible control HAB (Fig. 2).

VALIDATION OF DNA-BASED MOLECULAR DIAGNOSTICS FOR THE HARD CLAM PARASITE QPX (QUAHOG PARASITE UNKNOWN) AND THE OYSTER PARASITE SSO (*HAPLOSPORIDIUM COSTALE*). Nancy A. Stokes, Lisa M. Ragone Calvo, Kathleen Apakupakul, Eugene M. Burreson, Inke Sunila, and **Roxanna Smolowitz,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062, USA. E-mail: stokes@vims.edu

Traditionally, the diagnosis of parasitic diseases of bivalve mollusks has primarily relied on standard histological techniques. In recent years, DNA-based molecular diagnostics have been developed for a suite of bivalve parasites; however, for the most part, the utility of these novel tools for shellfish health certification, routine disease monitoring, and basic epizootiological research has yet to be determined and is dependent upon validation with standard diagnostic techniques.

DNA-based molecular diagnostics, DNA probes, and polymerase chain reaction (PCR) assays, were recently developed in our lab for two protistan parasites of bivalve mollusks, QPX (Quahog Parasite Unknown) and *Haplosporidium costale* (Seaside Organism or SSO). QPX is a parasite of hard clams, *Mercenaria mercenaria,* that has been found in cultured hard-clam populations in New Brunswick and Prince Edward Island, Canada and in Massachusetts, New Jersey, and Virginia, U.S.A. The disease has spread south to the United States in the last decade, causing significant clam mortalities in some areas. SSO is a parasite of eastern oysters, *Crassostrea virginica.* The parasite has been reported in oysters on the Atlantic Coast of the United States from Virginia to New Jersey, and organisms histologically similar to SSO have been noted in the northeast up to Maine. Studies using DNA probes recently confirmed the presence of SSO in Connecticut and Massachusetts. Historically, oyster mortalities attributed to SSO were confined to Virginia and Maryland; however, in 1998, the parasite was associated with oyster mortalities in Massachusetts.

The novel molecular diagnostic tools for QPX and SSO have been shown to be sensitive and specific. We are presently conducting studies to validate QPX and SSO PCR assays with the standard histological diagnostic method. Cultured hard clams are being sampled bimonthly from a Virginia coastal embayment and diagnosed for QPX by histological examination and PCR of tissue DNA. Oysters from Virginia, Connecticut, and Massachusetts are being sampled monthly and diagnosed for SSO and *Haplosporidium nelsoni* (MSX) by histological examination and by PCR of hemolymph DNA and tissue DNA. Both studies began in spring 2000 and will continue at least one year. To date diagnostic results between methods have been comparable for QPX; whereas, PCR has resulted in detection of more SSO infections than histological examination.

LOUISIANA'S DERMO ADVISORY PROGRAM: INCIDENCE AND PREVALENCE OF *PERKINSUS MARINUS* ON LOUISIANA'S PUBLIC OYSTER GROUNDS. **John Supan, Ron Dugas, Tom Soniat, Jerome Lapeyre, Ron Thune, John Hawke,** and **Al Camus,** Office of Sea Grant Development, Louisiana State University, Baton Rouge, LA 70803, USA. E-mail: jsupan@lsu.edu

Seed (25 to 75 mm) and market oysters (>75 mm) were collected along coastal Louisiana and analyzed for *Perkinsus marinus* during the summer, 1997 to 1999. The sampling program is funded by the Louisiana Oyster Task Force in response to industry observations of high oyster mortality on the state's public oyster grounds. Sampling locations included Cabbage, Three-Mile Bay, Mozambique Pt., Black Bay, Telegraph Pt., Bay Crabe, Bay Gardene, Lonesome Island, Hackberry Bay, Sister Lake, Bay Junope, Vermillion Bay, and Calcasieu Lake oyster reefs. The assay utilized rectal tissue in Ray's Fluid Thioglycollate Media, using the Mackin scale for qualification. The sampling program is the basis for the state's Dermo Advisory, printed annually in the task force's newsletter to assist industry in the management of private oyster leases. State fisheries managers also use the data to manage the public oyster grounds.

Perkinsus intensity varied annually at each site and oyster category and was greater during 1997 than subsequent years. On the prime grounds in the eastern portion of the coast, seed oysters ranged from 0.1–1.9 weighted incidence, with eight out of nine stations >1.0; prevalence ranged from 16–100%, with six stations >90%. Market oysters ranged from 0.6–2.0 and 59–100%, respectively. Vermillion Bay was the lowest site during all three years. Incidence and prevalence has declined during 1998 to 1999 at most stations; whereas, Hackberry Bay, in the central portion of the coast, had the highest infection levels for market oysters during 1999. High market oyster mortality and heavy spatfall have been prevalent during these latter years.

Sampling for 2000 is underway and will be incorporated in the annual Dermo Advisory. Preliminary stock assessments indicate greater mortality in market oysters a most stations. Higher levels of *Perkinsus* are expected because of severe drought. The advisory will soon utilize the new DermoWatch program now online, funded by the Gulf Oyster Industry Program.

DISEASE STATUS AND PHYSIOLOGICAL RESPONSES OF OYSTERS AS INDICATORS OF WATERSHED ALTERATION EFFECTS IN SOUTHWEST FLORIDA ESTUARIES. **Aswani K. Volety, Michael Savarese,** and **S. Gregory Tolley,** Florida Gulf Coast University, 10501 FGCU Boulevard South, Fort Myers, FL 33965, USA. E-mail: avolety@fgcu.edu

Southwest Florida possesses one of the country's fastest growing populations. Consequently, watersheds are heavily managed to accommodate development. Studies on the effects of watershed alterations involving valued ecosystem components, such as oysters, are lacking, but clearly necessary. Using the oyster, *Crassostrea virginica*, as an indicator species, we are investigating ecosystem-wide health effects of watershed management practices in altered (Faka-Union, Henderson Creek, and Caloosahatchee River) and pristine (Blackwater River) estuaries. Currently, watershed management involves the simple opening and closing of weirs in the estuaries, thus delivering pulses of freshwater during rainy season and decreasing freshwater input into the estuaries during the dry season. This results in the estuaries being mostly freshwater when the weirs are open and mostly higher salinity water when the weirs are closed. Measurements of disease prevalence of *Perkinsus marinus*, condition index, and substrate suitability of healthy oyster reefs as essential fish habitat are underway using a "spatial homolog approach" (comparing conditions among hydrologically and geomorphically similar points between estuaries) along salinity gradients. Preliminary results indicate that in summer months, mean prevalence of *P. marinus* infection in oysters varied between 33–73% depending on the location; mean condition index varied between 2.4 to 4.7 during July 2000, although lower disease prevalence was noted in oysters from homologs 2 and 3 in Faka-Union and is likely attributable to the greater freshwater input into the estuary, homolog 1 (upriver) was devoid of oysters because of freshwater-induced mortality. The lower disease prevalence in homologs 3–5 (down river) in Blackwater River and Henderson Creek may be attributable to the disease-induced mortality of these heavily infected oysters during the summer months. This project represents the first study of watershed alteration on oysters in Southwest Florida and will help provide target environmental conditions for restoration efforts.

PARTIAL PURIFICATION AND CHARACTERIZATION OF LYSOZYME-LIKE PROTEINS FROM THE PLASMA OF THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*. **Aswani K. Volety, Fu-Lin E. Chu,** and **Luis Cruz-Rodríguez,** Florida Gulf Coast University, College of Arts and Science, 10501 FGCU Boulevard South, Ft. Myers, FL 33912, USA.

Lysozyme(s) (and lysozyme-like proteins) are shown to be involved in a broad battery of such defense mechanisms as bacteriolysis and opsonization in both vertebrates and invertebrates. The action of the enzyme on microorganisms is mediated by the hydrolysis of β-(1-4)-glycosidic linkages between *N*-acetylmuramic acid and *N*-acetylglucosamine in bacterial cell walls. Our previous work showed that lysozyme activity in oysters, although positively correlated with low temperatures and salinities, was negatively correlated with *Perkinsus marinus* infections in oysters. Conditions of temperature below 10°C and salinity below 10‰ are not favorable to the parasite. This suggests that lysozyme may be involved in imparting a protective role in oysters against *P. marinus* infections. As a first step in elucidating the role of lysozyme in oysters' defense, we have partially purified lysozyme-like enzyme(s) from the plasma of oysters, *Crassostrea virginica*.

Lysozyme-like proteins were purified by cation-exchange chromatography using carboxymethyl cellulose, followed by concentration, desalting, and separation of proteins using Centricon 3 and Centricon 30 filtration. The proteins were eluted using a step gradient acetate buffer (0.01 M) with 0–0.8 M NaCl. Lysozyme activity was measured spectrophotometrically at 450 nm by the lysis of *Micrococcus lysodeikticus* suspension in phosphate buffer. Preliminary analysis using SDS-PAGE revealed the presence of two lyzozyme-like proteins with apparent molecular weight of 18.2 KDa and 38.8 Kda, respectively (Fig. 1). The separated proteins based on molecular weight cut-offs show the ability to lyse the bacterium *Micrococcus lysodeikticus*. We hypothesize the 38 KDa protein to be a dimer of the 19 KDa protein. Currently, we are investigating the effects of the separated proteins on *P. marinus* and various bacterial species. This research was funded by the NOAA-Virginia Sea Grant-Oyster Disease Research Program.

SUSCEPTIBILITY OF CULTURED *PERKINSUS MARINUS* AND *VIBRIO PARAHAEMOLYTICUS* CELLS TO HEMOCYTES OF EASTERN OYSTER, *CRASSOSTREA VIRGINICA*. **Aswani K. Volety,** Florida Gulf Coast University, College of Arts and Sciences, 10501 FGCU Boulevard South, Fort Myers, FL 33965, USA.

Oysters possess a very effective defense system comprising cellular and humoral defenses. Various measurements of the ability of oysters to generate a defense response against pathogenic and nonself particles have been developed. However, the relationship of these measurements to the actual defense of the organisms is unclear. Therefore, a colorimetric assay was developed to assess the ability of oyster hemocytes to kill *Vibrio parahaemolyticus, in vitro*. This assay was subsequently modified to investigate the ability of oyster hemocytes to the kill cultured *Perkinsus marinus* isolated from various geographical locations.

Hemocytes from Rhode Island and Florida oysters were used to assess their ability to kill *P. marinus* isolates from Connecticut, Delaware, Maryland, Virginia, Louisiana, and Texas. In addition, seasonal influences on the ability of hemocytes to kill *P. marinus* and *Vibrio parahaemolyticus* was examined by monthly sampling of Florida oysters. Hemocytes from both stocks of oysters were able to reduce viability of *P. marinus* cells by 25–90% depending on the isolate. *P. marinus* isolate from Virginia was the most susceptible; whereas, isolates from Louisiana, New Jersey, and Connecticut were less susceptible to hemocyte killing. Variation in the results seemed to result from differences in the susceptibility of the isolates rather than the ability of hemocytes from two oyster stocks. Killing of *P. marinus* by oyster hemocytes was lowest during peak summer months (July–August) and increased through the winter months. This trend contrasted with low winter and high summer bactericidal activity of hemocytes against *Vibrio parahaemolyticus*. The differences in the susceptibility may indicate different killing mechanisms for bacteria and *P. marinus*.

The assays developed for assessing killing of bacteria and *P. marinus* are relatively simple, inexpensive, reproducible, and enable numerous replications owing to the low numbers of hemocytes required to carry out the assays. These techniques could be used in investigating the role of environmental factors, mechanisms of action, and contaminant stress on host–parasite interactions.

EFFECT OF PERKINSOSIS ON THE ENERGETIC PHYSIOLOGY OF THE CLAM *RUDITAPES DECUSSATUS*. **Antonio Villalba** and **Sandra M. Casas,** Centro de Investigacións Mariñas, Xunta de Galicia, Aptdo. 13, Vilanova de Arousa 36620, Spain. E-mail: villalba@cimacoron.org

Perkinsosis has been considered a threat for Galician clam industry since its detection in late 1980s. A program is being developed to evaluate the potential effect of the disease in clam *Ruditapes decussatus* populations of the Galician coast. One of the approaches is estimating the effects of parasitization by *Perkinsus atlanticus* on clam energetic physiology. In a first experiment, fifty clams (40 to 50 mm in length) were taken from a natural bed (Ría de Arousa, Galicia, NW Spain) with high prevalence of this parasite. Clams were allowed to acclimatize for two weeks to laboratory conditions (15°C and 35 ppt) and fed with cultured phytoplankton. Temperature value of 15°C was chosen as a midvalue of the range in Galician Rías (10 to 20°C). Respiration and clearance rates of each clam were estimated. Then, each clam was processed for disease diagnosis. The intensity of infection by *Perkinsus atlanticus* was estimated both through histological techniques and incubation of a gill lamella in fluid thioglycollate medium. Both physiological rates showed a decreasing tendency as infection intensity increased. Nevertheless, differences between infection intensity categories were not statistically significant, with either diagnostic method.

In a second experiment, sixty clams (42 to 47 mm long) from the same bed were allowed to acclimatize for six days to laboratory conditions. Water (15°C and 33 ppt) was continuously pumped from the Ría de Arousa into the acclimatization tanks. In this occasion, respiration, clearance and excretion rates, and absorption efficiency of each clam were estimated. The total *Perkinsus atlanticus* body burden was calculated in addition to the two previous diagnostic methods. No significant effect of either infection intensity or *P. atlanticus* body burden on any of the physiological parameters was found. Those results support that perkinsosis does not broadly affect clam scope for growth, at least at 15°C. Nevertheless, in a previous study, a statistically significant decrease (up to 25%) of clam condition index was detected only when infection intensity was heavy.

Concurrent results allow rejecting that perkinsosis is responsible for clam mortality in the study bed, which is one of the most heavily affected by *P. atlanticus* in Galicia. Clam mortalities associated with perkinsosis have been described in warmer European

areas. New experiments will be performed at 20°C in September 2000, when seawater temperature in the clam bed is around that value to test if seawater temperature modulates the effect of perkinsosis on host energetic physiology.

GROWTH, GONAD DEVELOPMENT, AND MORTALITY OF GAMMA-IRRADIATED JUVENILE EASTERN OYSTERS. **Eric Wagner, Jerome La Peyre, John Buchanan, John Supan,** and **Terrence Tiersch,** Department of Veterinary Science, Louisiana State University, 111 Dalrymple Building, Baton Rouge, LA 70803, USA. E-mail: eric.wagner@mindspring.com

Gamma irradiation has been shown to cause sterility and to increase growth in a variety of organisms, possibly because of partial or complete blockage of gametogenesis and reallocation of energy to somatic tissues. Sterilization of oysters would be advantageous, because meat quality and yield would be improved during spawning season. Moreover, an increase in growth rate may allow oysters to reach market size before succumbing to diseases. The development of a sterilization method will also be essential for use of transgenic oysters. The objective of this study was, therefore, to determine the effect of gamma irradiation on the growth, gonadal development, and mortality of juvenile oysters.

Juvenile oysters were exposed to 5 and 10 krad of cobalt-60 gamma rays using a Sheperd irradiator at a rate of 1353 rad/min. Three groups of four hundred oysters were irradiated separately at each dose. Control oysters were handled similarly to the irradiated oysters, except they were not exposed to gamma rays. Each group of oysters were placed in Taylor floats (2-in × 3-in) and grown for one year at Grand Isle, Louisiana. The number of dead oysters in each of the nine floats and the size of fifty oysters per float were determined monthly. The gonadal development of irradiated and control oysters (fifteen per dose) was also evaluated every month from March to June.

The oysters receiving 10-krad of radiation experienced significantly greater mortality than either the 5-krad or control oysters during nine months of grow-out. Significant differences in growth occurred between the control oysters (63 ± 1 mm), 5-krad oysters (54 ± 5 mm) and the 10-krad oysters (42 ± 1 mm). Significant differences in mean gametic stage among the three treatments were detected for the oysters sampled in April ($P = 0.0066$) and May ($P = 0.0032$). In each month, oysters irradiated at 10-krad had significantly lower gametic stages than did control oysters ($P < 0.05$). No differences among treatments were detected for oysters sampled in June ($P = 0.6940$). Irradiation affected sex ratio among treatments as well. Control oysters were 68% female and 32% male; 5-krad oysters were 45% female, 45% male, 2% hermaphrodite, and 6% undifferentiated; 10-krad oysters were 20% female, 60% male, 2% hermaphrodite, and 18% undifferentiated. These data indicate no production advantage to irradiation of juvenile oysters at 5 or 10 krad, but provides insight into possible effects on sex ratio and gonadal development.

EXPERIMENTS IN DETERMINING OPTIMUM SIZE FOR PLANTING HATCHERY PRODUCED OYSTER *CRASSOSTREA VIRGINICA* SEED. **Richard K. Wallace, David B. Rouse, F. Scott Rikard, Jeffrey C. Howe, Blan A. Page, Donald B. Gruber,** and **John K. Dunne,** Auburn University Marine Extension & Research Center, 4170 Commanders Dr., Mobile, AL 36615, USA. E-mail: rwallace@acesag.auburn.edu

Hatchery-produced oyster seed has been available in the Gulf of Mexico region for several years. However, the oyster industry has been reluctant to invest in seed without more information on the relationship between cost of seed and survival. We investigated the survival of different size (≤5 mm, 6–10 mm, 11–15 mm, and 16–20 mm) remote set (on, shell) and cultchless oyster seed planted in replicated units at two sites (low salinity: 10–30 ppt and high salinity: 19–29 ppt) in Mobile Bay, Alabama. Water quality (temperature, salinity, and oxygen) was monitored continuously at the sites, and laboratory experiments were performed to examine survival under anoxic conditions.

Mean survival after thirty-two weeks for remote set seed at the low salinity site ranged from 43% for 11–15 mm seed to 51% for 16–20 mm seed (Fig. 1). There was no significant difference in survival among the four size groups. Cultchless seed at both sites and remote set seed planted at the high salinity site did not survive the first two-week sampling period. Predation seemed to be the cause of mortality.

Mean height of seed after thirty-two weeks varied from 48 mm (range = 23–63 mm) for the ≤5 mm group to 55 mm (range = 37–75 mm) for the 16–20 mm group. There was no significant difference in height among the three larger seed sizes, but the ≤5 mm group was significantly smaller than the other three seed sizes. Very low dissolved oxygen (<1 ppm) occurred at the low salinity site with varying durations (0.5–19.5 h). Preliminary laboratory studies indicated that the LT-50s for anoxic conditions (at 30°C and 15 ppt) ranged from 94 to 98 h, and there was no relationship between the LT-50s and size of seed.

EVALUATION OF A MARSHLAND UPWELLING SYSTEM FOR THE TREATMENT OF RAW DOMESTIC WASTEWATER FROM COASTAL DWELLINGS. **Robert E. Watson, Jr., Kelly A. Rusch,** and **Tingzong Guo,** Louisiana State University, Department of Civil and Environmental Engineering, Engineering Lab Annex Building, Baton Rouge, LA 70808, USA. E-mail: rwatson@unix1.sncc.lsu.edu

The oyster industry depends on a healthy water environment. Waters with fecal coliform bacteria concentrations in excess of the National Shellfish Sanitation Program standard of 14 MPN $^{FC}/_{100\ mL}$ are closed to harvesting. Improperly treated sewage from coastal dwellings is a major source of bacterial contamination. Conventional wastewater treatment strategies are not viable options for many of these dwellings because of their remote locations, sporadic usage, and proximity to water tables that are typi-

TABLE 1.

Fecal coliform removal under employed injection rates (Q = 0.25, 0.5, 1.0 gpm).

Flowrate	Influent fecal coliform concentration	Effluent fecal coliform concentration	Required vector feet of travel	Exceedance probability (≥ 14 $^{FC}/_{100\ mL}$)
0.25 gpm	326,700 $^{FC}/_{100\ mL}$	2.14 $^{FC}/_{100\ mL}$	8.8 ft	11%
0.5 gpm	930,400 $^{FC}/_{100\ mL}$	3.08 $^{FC}/_{100\ mL}$	10.3 ft	5%
1.0 gpm	559,200 $^{FC}/_{100\ mL}$	7.25 $^{FC}/_{100\ mL}$	11.7 ft	23%

cally at or above the ground surface. Thus increased efforts are being focused upon developing innovative methods to treat domestic wastewater effectively in poorly sewered coastal areas. The primary objective of this research was to evaluate the efficacy of a marshland upwelling system in removing fecal pathogens from raw domestic wastewater.

Wastewater was injected intermittently down a 15-foot deep well under three flowrates. Density gradients created between the wastewater and relatively dense native saline groundwater confined the injectant within a limited area and forced it vertically toward the ground surface, allowing the natural soil matrix to function as an upflow sand filter removing fecal pathogens. Concentrations in the 5-ft monitoring wells were used as a conservative estimate of effluent counts. Fecal coliform removal was assumed to follow first-order decay, allowing the required travel distance for influent concentrations to fall below the 14 MPN standard to be calculated. Best-fit probability density functions were determined for effluent fecal coliform concentrations under each flowrate and used to predict the probability of effluent counts exceeding the 14 MPN standard (see Table 1).

Two types of failure are believed to exist: (1) isolated failure created by accelerated intermittent injection flowrates, that may cause localized pressures to build and create transient episodes of channelization; and (2) catastrophic failure induced by excessive hydraulic loading rates that cause global increases in fecal concentrations because of reduced hydraulic retention times and the corresponding widespread declines in pathogen removal. Although treatment efficacy did vary with injection flowrate, and isolated instances of abnormally high fecal counts were observed under the 1.0 gpm flowrate, the MUS never experienced a catastrophic failure during the thirteen-month evaluation period.

MHACS: MARINE HABITAT ACOUSTIC CHARACTERIZATION SYSTEM. A PROGRAM FOR THE ACQUISITION AND INTERPRETATION OF DIGITAL ACOUSTICS TO CHARACTERIZE OYSTER HABITAT. Charles A. Wilson and **Harry H. Roberts,** Coastal Fisheries Institute, Department of Oceanography and Coastal Sciences, CCEER, Louisiana State University, Baton Rouge, LA 70803, USA.

Coastal Louisiana, like many deltaic land masses, faces continued landscape alteration from natural processes and anthropogenic impacts that affect estuarine habitat. Steps are being taken at both state and federal levels to slow/mitigate these changes. Most promising of these strategies is river diversions that introduce freshwater and sediment to river-flanking environments (lakes, bays, and associated marshlands). Two such diversion projects (Caenarvon and Davis Pond), planned by Louisiana and the U.S. Army Corps of Engineers, are designed to nourish marshes with water and sediment as well as to help establish ideal salinities over historic oyster grounds. Critical to the success of these programs is a rapid and accurate means to qualify and quantify changes in oyster habitat.

Digital high-resolution acoustic instrumentation linked to state-of-the-art data acquisition, and processing software was used to build a baseline of information for evaluating future changes in shallow and shelf water bottoms with special emphasis on oyster habitats. Application of digital side-scan sonar (100 and 500 kHz), a broad-spectrum sub-bottom profiler (4–24 kHz) for rapidly acquiring water column, surficial and shallow subsurface data has now been accomplished. In our most recent study, geo-referenced side-scan sonar mosaics of a Louisiana estuary were incorporated into a GIS data base. These datasets "calibrated" with surface sampling, coring, and other "ground truthing" have established that numerically indexed acoustic reflectance intensities correlate closely with surface shell and oyster reef density. With image-processing techniques to analyze mosaic reflectance patterns, we estimated the percentage and total acreage of several bottom types. Results were calibrated with field collected ground truth measurements.

PRODUCTION AND EVALUATION OF MEIOSIS I AND II TRIPLOIDS IN THE HARD CLAM, *MERCENARIA MERCENARIA*. Huiping Yang, Jian Wang, and **Ximing Guo,** Haskin Shellfish Research Laboratory, Institute of Marine Coastal Science, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349, USA. E-mail: hyang@hsrl.rutgers.edu

Triploid mollusks grow significantly faster than normal diploids in most species studied so far. Results from clams are mixed. Triploid dwarf-surf clams grow 72% faster than normal diploids; whereas, triploid soft-shell clams had the same or slower growth rate than diploids. In the hard clam, *Mercenaria mercenaria*, previous studies show that triploids grow faster than diploids at four years of age, but not during the first two years. Triploids may perform differently under different environments, and triploid hard

clams have not been evaluated in New Jersey. Different types of triploids, such as meiosis I triploids, meiosis II triploids, and mated triploids, also differ in growth performance. The objective of this study is to produce two types of triploids by inhibiting polar body 1 (PB1) and polar body 2 (PB2), respectively, and evaluate their growth performance in New Jersey.

Three experimental groups were produced: a diploid control, a PB1 triploid group, and a PB2 triploid group. Cytochalasin B (CB, 1.0 mg/L) was used as the induction agent. Four replicates were produced using different sets of brood stock. Ploidy was determined by counting chromosome number at two- to four-cell stage and by flow cytometry (FCM) at D-stage and beyond. High levels of triploids were produced with both methods, ranging from 62 to 83% in PB1 inhibition groups and from 82 to 100% in PB2 inhibition groups. Tetraploids and aneuploids were also produced in PB1 groups, but became undetectable at late larval stages by FCM. Survival of larvae in PB1 groups was lower than that in PB2 groups. Experimental clams will be deployed at two sites in New Jersey and sampled at regular intervals for ploidy determination and growth measurements. Data from the first two sampling dates, three and six months of age, are presented.

A STUDY OF THE EFFECT OF DERMO DISEASE *PERKINSUS MARINUS* ON EASTERN OYSTERS *CRASSOSTREA VIRGINICA* IN THE PATUXENT RIVER, MARYLAND WITH THE HELP OF COMMUNITY VOLUNTEERS. George R. Abbe, Brian W. Albright, Erin S. Woodrow, and **Shannon B. Campbell,** Academy of Natural Sciences, Estuarine Research Center, 10545 Mackall Road, St. Leonard, Maryland 20685, USA. E-mail: abbe@acnatsci.org

In studies of natural oyster populations affected by dermo disease in the Patuxent River Maryland, we have examined live oysters and boxes from dredged samples over time to gain some understanding of mortalities associated with disease. Not knowing the accuracy of the box- to-live ratio, we suspended three trays of one hundred oysters each from piers along a 33-km salinity gradient in the Patuxent in January 1997 and measured growth and survival monthly during the year. After a year, it was evident that oyster mortalities were highly correlated with salinity and dermo infection.

We thought that by increasing the number of sites along this salinity gradient we could gain a better understanding of oyster–salinity–disease interactions but lacked the resources and time to do so. With the help of community volunteers who donated piers and/or time and effort, we were able to conduct a similar study during 1998 at twenty sites along the Patuxent River. Each tray was stocked with one hundred oysters from the nearest natural oyster bed. By January 1999, it was evident that oyster mortalities decreased in an upriver direction with decreasing salinity as did the prevalence and intensity of dermo as measured by an infection index. Dermo levels in tray-held oysters were highly correlated with disease levels on nearby natural bars, and mortalities in trays were also highly correlated with estimated mortalities from dredged samples based on box-to-live oyster ratios. One of the most valuable results of this study was the increased awareness of the participants of environmental issues in their own communities. They learned to collect data year round at the same time each month and how their efforts fit into the larger riverwide picture.

Relationship of dermo infection index to oyster mortalities in trays as compared to those salinity in the Patuxent in September 1998, estimated from natural beds during 1998.

IMPROVING ACCURACY IN THE DETERMINATION OF MEAT CONDITION INDEX FOR THE EASTERN OYSTER *CRASSOSTREA VIRGINICA*. Brian W. Albright and **George R. Abbe,** Academy of Natural Sciences, Estuarine Research Center, 10545 Mackall Road St., Leonard, MD 20685, USA. E-mail: Albright@acnatsci.org

The meat condition index (MCI) of a bivalve is a numerical representation of the quality of its soft tissue. Based on the percentage of the internal shell volume occupied by an oyster's soft body tissue, enumeration of a quantitative index is possible. Older methods sought to measure shell cavity volume volumetrically; however, this is not practical. In 1982, Lawrence and Scott developed a method to determine MCI gravimetrically, where shell cavity capacity is determined by the difference between whole oyster weight and empty shell weight after drying for 24 h.

After using this method for more than fifteen years, we questioned its accuracy. Because any water contained in the shell itself (not between the valves) was included in the whole oyster weight, it seemed this should be included in the weight of the empty shells as well. Drying shells for 24 h could make the shell cavity appear larger than it really was, resulting in a reduced meat condition.

To determine the significance of weighing shells at 0 h verses 24 h of drying, meat condition indices were first determined based on true cavity volume using a moldable material of known density and then compared to the two methods. Weighing shells immediately after processing was determined to more accurately estimate cavity capacity whenever shells lost more than 3% of their weight because of drying.

Because oyster shells are highly variable with respect to porosity, we set out to determine the average weight loss of the valves after 24-h drying time. Over a 3-y period, monthly collections from many oyster bars in the Patuxent River resulted in the examination of 1,749 oysters, of which 74.3% lost more than 3% shell weight. Several other sites in the Chesapeake Bay were also examined yielding similar results.

Weighing shells at 0 h increased accuracy for most of the oysters we examined and also saved time and space, because shells do not need to be held for an additional 24 h for weighing. To date, this method has neither been tried for other species nor over the entire range of *C. virginica*. Differences in shell morphology and fouling communities may influence shell porosity, favoring one technique over the other.

ACKNOWLEDGMENT OF REVIEWERS

THANK YOU . . .

In addition to the editorial board, many individuals have contributed their time and efforts to the review process. Without the continued efforts of such individuals, the *Journal of Shellfish Research* could not maintain its standards of publication. It is a pleasure to thank the following individuals who have reviewed manuscripts over the past three years:

THE NATIONAL SHELLFISHERIES ASSOCIATION

The National Shellfisheries Association (NSA) is an international organization of scientists, management officials and members of industry that is deeply concerned and dedicated to the formulation of ideas and promotion of knowledge pertinent to the biology, ecology, production, economics and management of shellfish resources. The Association has a membership of more than 1000 from all parts of the USA, Canada and 18 other nations; the Association strongly encourages graduate students' membership and participation.

WHAT DOES IT DO?

—Sponsors an annual scientific conference.
—Publishes the peer-reviewed *Journal of Shellfish Research.*
—Produces a Quarterly Newsletter.
—Interacts with other associations and industry.

WHAT CAN IT DO FOR YOU?

—You will meet kindred scientists, managers and industry officials at annual meetings.
—You will get peer review through presentation of papers at the annual meeting.
—If you are young, you will benefit from the experience of your elders.
—If you are an elder, you will be rejuvenated by the fresh ideas of youth.
—If you are a student, you will make useful contacts for your job search.
—If you are a potential employer, you will meet promising young people.
—You will receive a scientific journal containing important research articles.
—You will receive a Quarterly Newsletter providing information on the Association and its activities, a book review section, information on other societies and their meetings, a job placement section, etc.

HOW TO JOIN

—Fill out and mail a copy of the application blank below. The dues are 65 US $ per year ($35 for students) and that includes the *Journal* and the Newsletter!

NATIONAL SHELLFISHERIES ASSOCIATION—APPLICATION FOR MEMBERSHIP
(NEW MEMBERS ONLY)

Name: _____ For the calendar year: ____ Date: _____
Mailing address: _____

Institutional affiliation, if any: _____
Shellfishery interests: _____

Regular or student membership: _____
Student members only—advisor's signature REQUIRED: _____

Make checks (*MUST* be drawn on a US bank), international postal money orders or VISA for $65 ($35 for students with advisor's signature) payable to the National Shellfisheries Association and send to Nancy Lewis, Bookkeeper, PO Box 350, V.I.M.S. Eastern Shore Lab, Wachapreague, VA 23480, USA.

INFORMATION FOR CONTRIBUTORS TO THE *JOURNAL OF SHELLFISH RESEARCH*

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the editors or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17: *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans,* or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual,* distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").
- Figures must not be embedded in a word-processor or spreadsheet document: the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.
- Resolution: *line shots:* 1000 dpi; *halftones/grayscales:* 300 dpi if no lettering, 500 dpi if figure contains lettering.
- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements a B/W, above.

Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations,* available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. PROCEEDINGS

4th International Symposium on Abalone Biology, Fisheries, and Culture

University of Cape Town
Cape Town, South Africa

February 6–11, 2000

Guest Editor:

Peter A. Cook
Zoology Department
University of Cape Town
Rondebosch, South Africa

PREFACE

The 4th International Symposium on Abalone Biology, Fisheries, and Culture was held at the University of Cape Town, South Africa from 6th to 11th February, 2000. The conference attracted about 250 delegates from at least 15 different countries, and was successful in bringing together scientists, entrepreneurs, divers, aquaculturists, and government representatives. This Special Issue of the *Journal of Shellfish Research* contains many of the contributions presented at the conference.

The Cape Town Abalone Symposium was the fourth in a series that started in La Paz, Mexico in 1989. The second was held in Hobart, Tasmania in 1994 and the third in Monterey, California in 1997. It was decided, at the Monterey symposium, that a three-year interval between symposia was appropriate in view of the rapid changes that were occurring worldwide in abalone fisheries and in farming techniques. The large quantity of new information presented at the Cape Town conference proved this decision to be correct.

The choice of Cape Town as the venue for the 4th International Abalone symposium was appropriate due to the fact that the South African abalone fishery is, perhaps, one of the most over-exploited in the world, principally because of illegal exploitation by poachers. The occasion of the symposium was used to highlight this problem, and extensive media coverage provided a platform for scientists to sound alarm bells about the state of the fishery. In addition, the south-western region of the country has developed as the center of South Africa's abalone farming industry and conference delegates were able to benefit from visits to local farming enterprises.

The symposium was opened with an interesting and thought-provoking review of the international supply, markets, and pricing of abalone products. The rest of the symposium was divided into a number of sections including abalone aquaculture, nutrition, genetics, diseases, stock assessment, and fisheries management. This volume contains a selection of the papers from each section and all papers have been through the usual stringent refereeing and review process applied by this journal. I wish to thank the authors who submitted manuscripts for publication in this volume and, in particular, I also wish to thank the numerous referees who contributed their time to review the papers.

The 5th International Abalone Symposium will be held in China in 2003.

Peter Cook
Editor

DEDICATION

This volume is dedicated to the memory of Mia Tegner, whose work on abalone contributed enormously to our understanding of the biology of this unique creature.

WORLD ABALONE SUPPLY, MARKETS AND PRICING: HISTORICAL, CURRENT AND FUTURE

H. ROY GORDON[1,*] AND PETER A. COOK[2,a]

[1]*Fishtech Inc, Box 6886, San Rafael, California 94903*

[2]*Zoology Department, University of Cape Town, Rondebosch, 7700, South Africa*

ABSTRACT The world supplies of wild-caught and cultured abalone are considered with implications of the past, present and future. Much of the data available in recent years, from various government sources, and even FAO, have often been inadvertently misleading. Reporting has often combined a number of dissimilar abalone products (fresh in shell, frozen meat, canned, dried, etc) resulting in misleading results. Surprising numbers result when an effort is made to standardize production and export information for both the commercial catch and cultured product. Factors affecting abalone FOB and CNF prices are discussed. Different market forms (live, fresh, frozen, canned, dried) affect pricing, and price is also influenced by processing and packaging as well as economic conditions. Suggestions are made for value added abalone products and the challenges of sustaining world demand at premium prices are discussed.

KEY WORDS: abalone, abalone market, abalone prices, abalone process and packaging, abalone future

INTRODUCTION

World abalone supply statistics have not all been accurate over the past 30 years. In a reexamination of the statistics the industry has used for many years, a need for some substantial adjustments in both the fisheries and the cultured sectors has been found. Annual data for some countries has substantial gaps in reporting. Whilst some countries have reported tonnage as "in shell", others report "meat only". This distinction alone can distort the comparative total production of an individual country by two to three hundred percent. To complicate the analysis further, export and import data often combine a number of dissimilar abalone products (fresh in shell, frozen meat, canned, dried etc) into a single number for tonnage and value. In an attempt to standardize the reporting of the world abalone supply, the following definitions are applied:

Abalone fisheries: The total allowable annual commercial landing quota (country by country) expressed in terms of "in shell" weight. This category would include the planting of seeds in large areas of the sea (e.g. in Japan) wherein the sea bottom has not been prepared with man-placed rocks or structures. This definition does not include the legal sport catch or any illegal catch worldwide.

Cultured abalone: (expressed in terms of "in shell" weight) includes both the farming of abalone on land or in the sea—contained in man-made tanks, nets or structures (Intensive culture) and sea planting of abalone seeds in artificially arranged substrate or structures, with or without added food (Extensive culture).

The illegal catch: Any harvest of abalone beyond the total allowable annual landing quota. To discuss the topic of world supply without consideration of the illegal catch would be grossly misleading (Murphy 1999).

TEN-YEAR FISHERIES COMPARISON

In order to compare the abalone fisheries and cultured totals on an "apples with apples" basis, we must apply a standard "in shell" weight. Retroactive reporting (in particular China, but other countries as well) dramatically changes the cultured abalone totals (New 1999). We now know that the FAO Yearbook of Fisheries Statistics had been reporting China's production of several groups of cultured mollusks, including abalone, as shelled or shucked weight, instead of their "in shell" live weight equivalent, which should be normal practice in submitting statistics to FAO. This has grossly underestimated both cultured abalone production and abalone fisheries. Adjustments must, therefore, be made to previous reporting over this 10-year timeframe.

Figure 1a shows that the worldwide catch from abalone fisheries has declined by about 30% over the past 10 years. In 1989 worldwide abalone catch was reported as 12,995 mt but, based on the assumptions given earlier concerning incorrect reporting, this has been adjusted to 14,830 mt. It is estimated that the catch in 1999 was 10,150 mt.

From Figure 1b it can be seen that Australia is the only country where abalone fisheries have increased over the past 10 years. Significant declines have occurred in countries such as Mexico, the U.S.A., and Japan.

TEN-YEAR COMPARISON OF CULTURED ABALONE

The situation with regard to cultured abalone is completely different (Figures 2a and 2b). Over the ten year period from 1989 to 1999, whilst abalone fisheries declined by about 30%, the production of cultured abalone increased by over 600%. In 1989 cultured abalone production was reported as 689 mt (adjusted to 1,220 mt), whilst in 1999, it is estimated that production was 7,775 mt. Of the total estimated 1998 cultured abalone world production of 7,165 mt, Asia accounted for 5,500 mt or 75% of that total. Within Asia, the vast majority of the cultured abalone production is from China and Taiwan.

ABALONE PRICING

With regard to the price of abalone products, it is interesting that the F.O.B. and C.N.F. prices for similar species and sizes tend to equate worldwide. Abalone is marketed in many different forms, each of which is priced differently. Figure 3 illustrates, diagrammatically, a range of prices that are quoted for different forms of abalone, but the examples given below will show that, when processing and marketing costs are taken into account, these prices tend to revert back to a similar "in shell" price of about US$32/kilo.

Example one: cultured Red abalone in the 90-mm-size range. (The principle is the same with other species when adjusted for the size/weight ratio of that species.) Many of the Asian traditional recipes call for dried abalone as their preparations began thousands

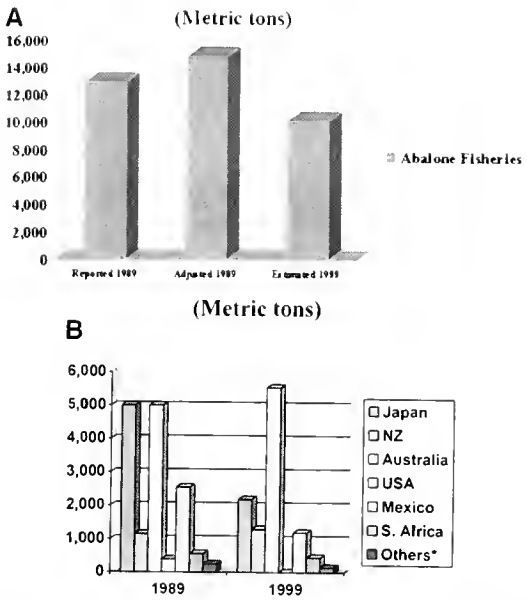

Figure 1. (A) Worldwide abalone fisheries: ten-year comparison; (B) Abalone fisheries country by country: ten-year comparison.

of years before refrigeration. There are a few special (often secret) processing methods creating a dried product which sells for a minimum of US$700 per kilo and as much as $12,000 per kilo or more. This dried abalone is not to be confused with the "standard" sun dried product that sells at a lower price. The preparation of this specialty-dried abalone is almost ceremonial, often prepared with unique coals and slow cooking in ceramic cooking utensils. Only about 10% of the "in shell" weight remains in the dried product. The preparation process is highly labor-intensive and takes months to complete. If the processor pays US$32/kilo "in shell", and sells the premium product for US$700/kilo, he is making only a reasonable profit for the effort.

Example two: a live 90-mm abalone at the Japanese wholesale

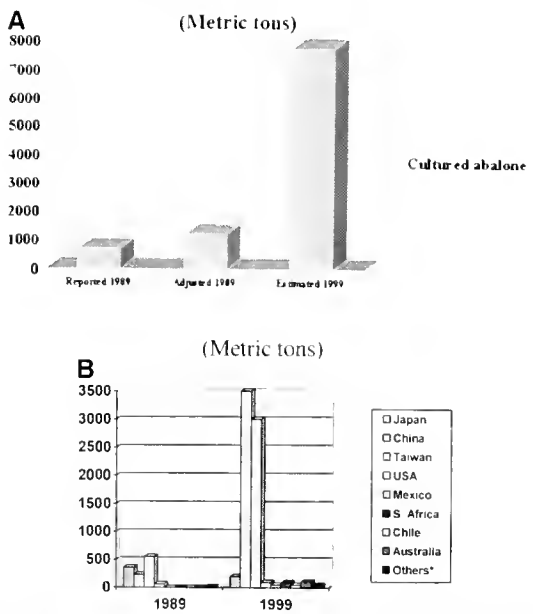

Figure 2. (a) Worldwide production of cultured abalone: ten-year comparison; (b) Cultured abalone production country by country: ten-year comparison.

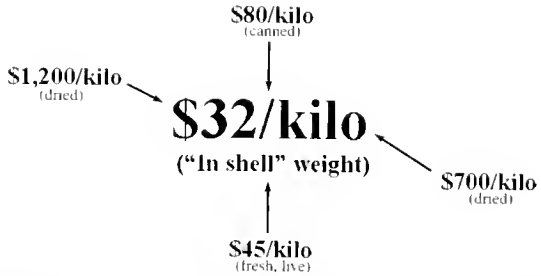

Figure 3. Prices for different market forms of abalone (for explanation see text).

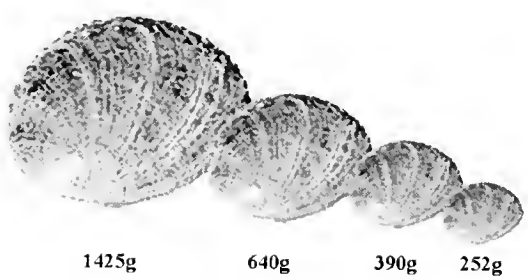
(auction) markets. There are fisheries pricing services that regularly publish an average of 10 major Japanese wholesale markets (Sunee 1999). For the sake of comparison, we will use a price of 4,700 yen/kilo. This equates to approximately US $45/kilo. Does that mean you might sell to these markets at a C&F level approaching these prices? Not by a long shot: there are auction commissions, wholesaler commissions, trading company commissions, local transportation, customs and duty—all to be deducted from your selling price along with possible mortality deductions. In effect, $45/kilo equates closer to $32/kilo.

Example three: weight losses during canning (illustrated in Figure 4). If the "in shell" weight is 1425 g (*H. rufescens*, 8 pcs, 100 mm "in shell", for example) shucking will yield about 640 g of meat which, after cleaning and trimming, will yield approximately 390 g. After cooking the meat, you will find only 252 grams. In effect, after shrinkage and canning cost, a $20 tin of 252 g meat equates to an "in shell" price of as low as only $12/kilo. Without the continued development of premium product and brand name tins, canned abalone will remain as a commodity with relatively lower prices.

ALTERNATIVES TO WORLD COMMODITY PRICING

As illustrated in Figure 5, the world abalone market is dominated by Asian countries. Prices are currently driven by a handful of Asian nations, guided by their historical and changing customs, preparations, populations and economies. An important additional influence is that of Asian populations living elsewhere in the world. As displayed earlier, regardless of the form to market (live, fresh, frozen, boiled, canned, dried etc) the abalone price "in shell" tends to equate worldwide. Of course, there will be shorter-term price variations as the economies of that handful of Asian buyer countries weakens or strengthens. In recent years, we have seen a substantial weakening of the Japanese economy—now recovering. On an equivalent yen basis, adjusted to US$, $37/kilo for a given



$20/Tin of just 252g Abalone = only $12/kilo "in shell"

Figure 4. Weight loss during canning of abalone.

Figure 5. 1999 World abalone market.

size and quality in January 1998, this would equate to $41/kilo in January of 1999 and $45/kilo in January 2000. During this same period, PR China's economy has markedly strengthened. Just a few years ago, the majority of the abalone farming production in China was designed to export this premium product to Japan and elsewhere. Today, virtually all 3,000+ tons of China's abalone production is consumed internally.

To break away from world pricing, a company responsible for large quantities of abalone, whether fished or cultured, would have some important choices to consider. These could include:

- Continue the selling pattern
- Develop premium market for export or within the exporting country
- Brand name product
- Multi functional processing and packaging
- Sous Vide and "skin packed" fresh and frozen
- Direct approaches to DWE's (distributors, wholesalers, major end users)

Continue the Selling Pattern

A company could continue along the lines of the patterns mentioned earlier (prices likened to a commodity—driven by Asian Markets—varying by species and size) which tend to equate to a similar "in shell" price worldwide.

Alternatively, a company could begin to break away from the "price equation" through implementing any one, or several, of the following choices.

Develop a Premium Market for Export and Within Currently Exporting Countries

Exporting nations should not take for granted that premium prices will continue for ever. Considerable effort will be required. You may hear "we had a strong abalone market within our country in the late 60s early 70s, however, that was when prices were very low". If we re-examine that statement on an inflation-adjusted basis, a $30/kg price today would equate to a $6.79/kg price in 1970 (Antweiler 2000). That "expensive" restaurant abalone meal at $45 today equates to a $10 "expensive" abalone meal in 1970. The premium pricing in the "home market" of the currently exporting nation will not remain as a "given". Abalone will never become a low cost food, however, effort and promotion will be needed to maintain the highest market pricing levels.

Brand Name Product

Much of the fisheries and aquaculture world has worked with brand names for many years, but this is rare in the "abalone world". Premium (higher than the most common denominator) pricing is achievable through developing a high quality, branded product and then telling the world about it.

Sous Vide and "Skin Packed" Fresh and Frozen

We live in a "food service—ready to eat—fast food" industrialized world, yet abalone traditionally goes to market in the same basic forms (live, fresh meat, frozen, canned etc.) and is distributed to the same standard markets. Larger producers should consider developing "heat and serve" processed, prepared abalone dishes. This may sound like heresy to the abalone traditionalist, but it is a clear path toward maintaining premium prices in the home markets of abalone exporting nations. Some companies have been promoting vacuum pack/skin pack for many years with rewarding results, but they represent only a small fraction of the marketplace. Fast food need not be a low-priced food. A Hong Kong food chain is currently promoting an abalone fast-food concept, with a single outlet generating over US$2,000,000 annually.

Multi Functional Processing and Packaging

Industrialized nations need to develop low cost production possibilities with highly mechanized food service facilities. (This level of processing is quite expensive, but could be accomplished on a co-op basis.) Today, several industrialized nations have such plants operating for bivalves. A modern, low-cost process complex might encompass six multifunctional production areas including raw material supply, raw material pre-treatment, processing/transformation, preservation, packing, storage.

Direct Approaches to DWE's

(Distributor, Wholesaler, and major End Users). This methodology requires considerable effort, yet is rewarding. It should be your market study that selects the DWE, not the reverse.

WORLD SUPPLY/DEMAND RELATIONSHIPS: 1977–1999–2004

Figure 6 illustrates the relationship between world supply and demand in 1975, 1999 and 2004 (predicted). In 1975 the supply was about 20,000 mt (on an adjusted basis, that might have been 24,000 mt or more). There was no major shortage of product, and this resulted in a demand/supply balance. The 1999 supply was 18,000 mt (or 13,000 mt after deducting "new market" *H. supertexta* which was not a factor in the 1975 demand) whilst the demand remained at over 20,000 mt, leaving a potential shortfall of about 7,000 mt. It is estimated that by 2004 the supply will be about 15,000 mt (after deducting "new market" *H. supertexta*) but

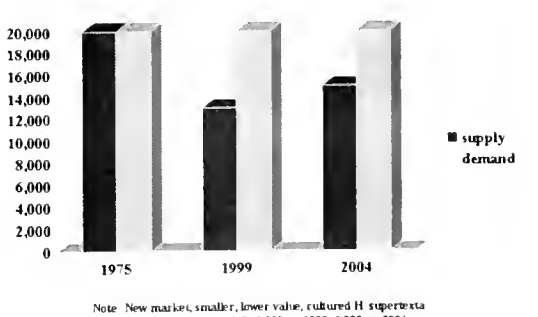


Figure 6. Abalone supply and demand in 1975, 1999 and 2004.

the potential demand is likely to remain over 20,000 mt. This will leave a potential shortfall of at least 5,000 mt.

CONCLUSIONS

World Abalone Supply

Over the past 10 years, the abalone fisheries of the world have declined by about 30% while the world's cultured abalone production has increased over 600%. The trend toward larger, cultured, premium species will continue. Ten years ago a 70 mm animal was considered "market size" whereas today market size is closer to 90 mm. Some production at 120 mm or larger will be required in the future.

Looking ahead to the year 2004, we anticipate the abalone fisheries to remain fairly flat at the 10,000 to 11,000 mt levels, while cultured abalone farms are anticipating very substantial increases. Political, environmental and pathological events will, of course, have some unknown impact on world abalone supply.

World Abalone Demand

We have been discussing a strong world demand and potential "shortfalls" but this does not necessarily imply an automatic demand at a premium price. Outside of the Asian world, the desire for this "caviar in a shell" priced animal will be directly related to the ability of the abalone industry to compete successfully in the marketplace. Among other things, this should include *Sous Vide* preparations, brand identification, sophisticated processing facilities and unique DWE programs.

For the sake of our own and future generations, we must do a better job of protecting the world's abalone fisheries, however, it is the cultured abalone industry that must not only expand production but must also increase efforts to assure a continual world premium market.

A REVIEW OF SETTLEMENT CUES FOR LARVAL ABALONE (*HALIOTIS* SPP.)

RODNEY ROBERTS*
Cawthron Institute, Private Bag 2, Nelson, New Zealand

ABSTRACT Settlement of abalone larvae involves larval attachment (a reversible behavior) followed by metamorphosis (which involves irreversible physical changes). Coralline algae induce attachment and metamorphosis in all abalone species tested, and there is some evidence of settlement preferences for certain coralline species. The settlement-inducing chemicals from corallines have not been identified. In one case (*Haliotis rufescens*) a small peptide is implicated, while in another (*Haliotis discus hannai*) halomethanes are thought to be critical. Corallines are generally regarded as unsuitable for use in hatcheries, but their potential use has not been fully evaluated. Many abalone hatcheries rely on biofilms to induce larval settlement. The activity of biofilms increases with their age. Ungrazed films are generally dominated by fast-growing benthic diatoms, and settlement on these films is variable and often low. Few diatom strains are consistently good for settlement, and strains that are excessively mobile, or form 3-dimensional colonies, can prevent successful settlement. The chemistry of settlement induction by biofilms, and the role that bacteria play, are poorly understood. Bacteria can induce settlement, but metamorphosis occurs gradually over several days, if at all. Pregrazing by conspecific abalone improves the settlement-inducing activity of a biofilm. The mucus from the foot of grazers probably contains chemicals (not identified) that trigger attachment or metamorphosis, particularly when combined with another cue (such as dibromomethane or a biofilm). Various pure chemicals induce attachment and/or metamorphosis of abalone larvae. These may bind to larval receptors (e.g., γ-aminobutyric acid = GABA) or act "downstream" of, or "parallel to", the receptors (e.g., compounds that depolarize membranes or alter levels of cyclic AMP or calcium). None of these chemicals is considered to be a natural settlement cue, and only GABA has been used in abalone hatcheries. The timing and end point of the abalone settlement response vary among cues, and among abalone species. Cues can combine synergistically to enhance settlement (e.g., GABA with lysine, biofilm or coralline extract, dibromomethane with mucus). Signal reception pathways are known only for the case of *Haliotis rufescens* and GABA-mimetic inducers. The response is controlled through a "morphogenetic pathway", which is subject to up- and down-regulation by molecules acting on a separate "regulatory pathway". Larval attachment and metamorphosis are often uncoupled in abalone. Cues for attachment are much more widespread than cues for metamorphosis.

KEY WORDS: abalone, attachment, metamorphosis, diatoms, biofilms, coralline algae, settlement cues

INTRODUCTION

Abalone larvae swim for several days before becoming competent to undergo settlement, which transforms them into a crawling, benthic snail. Settlement is triggered by external cues. Knowledge of these cues is critical in abalone culture where complete, rapid and predictable settlement is desired but seldom achieved (Searcy-Bernal et al. 1992a, Roberts et al. 1998). Settlement cues also play a role in determining where abalone recruit, and knowledge of cues may be useful in site choice for larval reseeding.

Several authors have previously reviewed aspects of abalone larval settlement. The extensive work by Daniel Morse and colleagues on metamorphosis induction in *Haliotis rufescens* has been reviewed in detail (A. Morse 1991, D. Morse 1992). McShane's (1992, 1995) reviews discuss settlement in natural habitats and attempt to draw links between laboratory and field data. Hahn (1989c) presented a detailed summary of the data on abalone settlement induction as of 1985. In the decade or so since these reviews there has been substantial research on abalone larval settlement. The new work has broadened the range of abalone species studied from its early focus on *Haliotis rufescens* and *Haliotis discus hannai*, and has also broadened the range of cues that have been addressed, and the depth of investigation for certain key inducers. The body of data now available is adequate to justify a comprehensive review. This study concentrates on abalone larval settlement cues, whether natural or otherwise. Ecological relevance is discussed only briefly. This review attempts to emphasize the distinction between the components of the settlement response, which has received little critical attention in previous reviews. It also attempts to highlight similarities and differences among abalone species. Both of these tasks were made difficult by varying methodology and terminology, which are discussed in detail at the outset in the hope that greater standardization will result. The review concludes by summarizing some major points arising from the review, making some comments on settlement cues for hatcheries, and providing some suggestions about priorities for future research in this field.

SETTLEMENT TERMINOLOGY AND METHODOLOGY

Terms Used to Describe Settlement Stages

Various terms have been used interchangeably in publications dealing with abalone larval settlement (Table 1) so clarification is required. In this review, the transition from a swimming larva to a crawling, feeding post-larva is divided into three stages. The first is larval "attachment"—the larvae stop swimming, sink to the bottom, and attach to the substratum by their foot. Larvae retain their velum during attachment and some larvae choose to resume swimming—attachment is a reversible behavior. The next stage marks the initiation of metamorphosis and is conveniently indicated by the shedding of the larval velum, committing the abalone to benthic life. This stage is here termed "metamorphosis", and involves an array of irreversible physical changes. If the post-larva continues to develop normally for a day or two after initiation of metamorphosis, then the mouth will open, feeding will begin, and flared peristomal shell will begin to grow. This further metamorphic development is sometimes separated from the earlier shedding of the velum, and is referred to here as "shell growth". The term settlement is used as a general term for the transition from a larva to a post-larva. Data that do not distinguish between attachment and metamorphosis are reported here as "settlement" (in quotation marks).

*E-mail: rodney@cawthron.org.nz

TABLE 1.

Examples of terms used in published abalone settlement studies and the corresponding term used in this review.

Term Used in Original Paper	Equivalent Term in this Review	Notes	Reference
Settlement	Attachment + metamorphosis	Settlement defined as being animals that had shed the velum. Attachment without metamorphosis was not quantified.	Daume et al. (1999a, 1999b, 2000)
Settlement	Attachment	Attachment scored separately from metamorphosis.	Morse et al. (1979b) Kawamura & Kikuchi (1992) Searcy-Bernal et al. (1992) Slattery (1992), Seki (1997)
Inferred settlement	Unknown	Calculated from number of larvae still swimming. "Settled" larvae would include those attached or metamorphosed plus any stuck to surfaces.	Moss (1999)
"Settlement"	Unknown	Paper does not define settlement.	Genade et al. (1988)
Behavioural metamorphosis	Attachment		Morse et al. (1980a)

Settling abalone larvae often do not progress rapidly through attachment, metamorphosis and shell growth. Larval attachment is not a useful end point for an abalone larva, or an abalone farmer, so the distinction between the stages of settlement is critical in interpreting data. It is difficult to make these distinctions in the hatchery, and even more so in the sea, so laboratory experiments have proven very useful in the study of abalone settlement cues.

Abalone Settlement Assay Methods

In static settlement bioassays the use of antibiotics to suppress bacterial growth is essential for some abalone species to ensure consistently high larval survival (Morse et al. 1979b). Different degrees of bacterial suppression led to conflicting results over the activity of γ-aminobutyric acid (GABA) (Morse 1992). Negative controls are crucial to ensure that settlement responses are not falsely attributed to particular cues. Several studies have reported high attachment or "settlement" in negative controls (Liu et al. 1986, Genade et al. 1988, Slattery 1992, Moss 1999) making it difficult to interpret settlement induction by other treatments. Some problems with antibiotic toxicity and interference have been reported. Streptomycin was toxic to *Haliotis diversicolor* at doses as low as 5 $\mu g\ ml^{-1}$ (Bryan & Qian 1998) and emetine toxicity caused abnormal loss of velum cells in *Haliotis rufescens* (Fenteany & Morse 1993). Anisomycin caused slight attachment induction in *Haliotis rufescens*, but also stimulation of swimming activity that partly antagonized the response to GABA (Fenteany & Morse 1993).

The methods used will depend on the objectives of an experiment. If the objective is to determine larval responses in hatchery conditions then full-scale hatchery systems should be used and antibiotics will be inappropriate. However, if the experiment is to determine the settlement response of larvae to particular cues then the assay system should be designed to eliminate all potentially confounding influences, including bacterial interference.

If larval mortality or morbidity in assays complicates interpretation then this needs to be discussed. For example, Moss (1999) recorded high "inferred settlement" by day five of an assay but then explained that mortalities were very high (88 to 97% by day seven) making interpretation of "settlement" data difficult. Larval and post-larval abalone have considerable ability to survive without particulate food (Searcy-Bernal 1999, Takami et al. 2000, Roberts & Lapworth 2001, Roberts et al. 2001). This suggests that high mortality within a few days of settlement induction (Daume et al. 1999b, Moss 1999) is likely to be caused by factors other than starvation. Dead or moribund larvae should be excluded from calculation of percentage settlement, but they still introduce uncertainty. Would those animals have settled if they were healthy? Is the larval settlement response influenced by the marginal conditions in the assay?

Similar attention needs to be paid to toxic responses that can cause velum loss and could be confused with the onset of metamorphosis. Typical symptoms of toxicity include partial loss of the velum, an increasing number of larvae found lying on their sides (rather than attached by the foot or swimming high in the water column) and lack of shell growth (Fenteany & Morse 1993).

Assay counts may need to include abalone on the walls of assay chambers (Genade et al. 1988) or on the surface film of the assay water (Roberts & Nicholson 1997). The difficulty of accurately counting swimming larvae has been circumvented by doing retrospective destructive counts (e.g. Roberts & Nicholson 1997) or removing the settlement substrate to aid counting (e.g., Moss 1999).

While larval attachment is generally rapid, many cues cause only a gradual rise in the percentage metamorphosis over a week or more (e.g. Kawamura & Kikuchi 1992, Roberts & Nicholson 1997). Thus, the period of observation influences the settlement observed, and this must be taken into account when comparing studies. The timing of observations should be tailored to the question being addressed, and multiple observations will be most informative.

Larval age can affect settlement responses. Abalone larvae have a pre-competent phase of several days during which they will not respond to settlement cues. Various morphological and behavioral features have been used to indicate competence to settle. These include the appearance of the fourth tubule on the cephalic tentacles (Seki & Kan-no 1977, Ebert & Houk 1984), exploratory

crawling (Seki & Kan-no 1977) and the presence of at least three rows of chitinized radula teeth (Moss & Tong 1992a). Morse et al. (1979b) used a 30–120 minute exposure to GABA to test larval competence to attach. An indirect method is to calculate larval stage based on larval age, rearing temperature and biological zero point (Seki & Kan-no 1977, Hahn 1989b). Larvae of many abalone species reach competence to settle after several days at 15 to 20° C (Hahn 1989b). The ability to attach arises earlier than the ability to metamorphose, and the speed of a settlement response can vary with larval age (e.g., Morse 1984a, Barlow 1990). *Haliotis diversicolor* larvae can begin attaching as early as 12 hours after fertilization (at 24 C) but may not metamorphose until several days later (Liu et al. 1986, Bryan & Qian 1998). Positive controls should be included in experiments to confirm larval competence. Data can even be normalized to a positive control to take account of inter-batch variability in larval responsiveness (Baloun & Morse 1984).

Other factors that may affect the outcome of abalone larval settlement assays include: (1) the use of vertical versus horizontal surfaces (Bryan & Qian 1998), (2) the size of the settlement substratum relative to the assay chamber (e.g., Daume et al. 1999a, Daume et al. 1999b versus Kawamura & Kikuchi 1992), (3) the increased sensitivity of older larvae to settlement cues (Barlow 1990, Moss & Tong 1992a, Yang & Wu 1995), (4) variability between batches of larvae (e.g., Baloun & Morse 1984, Trapido-Rosenthal & Morse 1986b, Roberts & Nicholson 1997), and (5) changes in light intensity causing attached larvae to resume swimming (Moss & Tong 1992a, Moss 1999).

CORALLINE ALGAE AS SETTLEMENT CUES

The Corallinaceae are divided into articulated (= geniculate) and non-articulated (= non-geniculate) forms (Johansen 1981). The non-articulated corallines are commonly referred to in the abalone literature as crustose corallines, so this review uses the terms crustose and articulated corallines. The crustose corallines occur in a wide range of growth forms (Woelkerling et al. 1993, Shepherd & Daume 1996).

In the wild, juvenile abalone are closely associated with crustose coralline algae (e.g., Morse et al. 1980c, Shepherd & Turner 1985, McShane & Smith 1988, Shepherd & Daume 1996, Day & Branch 2000). Laboratory experiments show that intact crustose coralline algae are among the best inducers of larval attachment and metamorphosis for all abalone species tested (Morse et al. 1980c, Morse & Morse 1984a, Moss & Tong 1992a, Roberts & Nicholson 1997, Takami et al. 1997, Daume et al. 1999a, Daume et al. 1999b, Moss 1999). Crustose coralline algae generally induce strong and rapid metamorphosis (>80% within two days) but *Haliotis rubra* and *Haliotis laevigata* sometimes show much weaker responses to three species of crustose corallines (Daume et al. 1999b, Daume et al. 2000).

Articulated corallines were much less effective (<10% attachment) than crustose corallines as settlement cues for *Haliotis rufescens* (Table 2, Morse et al. 1980c, Morse & Morse 1984a). The articulated *Corallina officinalis* showed moderate to strong activity with *Haliotis virginea* but was less effective than crustose corallines (Table 2). Settlement of *Haliotis cyclobates* on sea grasses may be triggered by the crustose corallines that cover 13–20% of the seagrass blades, or by other cues such as the sea grass or its surface biofilm (Stevenson & Melville 1999).

When given a choice of crustose coralline species larvae of *Haliotis laevigata* selected *Sporolithon durum* in preference to *Mesophyllum engelhartii* or *Hydrolithon rupestre* (Daume et al. 1999a). This is consistent with the disproportionately high number of *Haliotis laevigata* recruits found on *Sporolithon durum* in the wild (Shepherd & Daume 1996).

OTHER MACRO-ALGAE AND BLUE-GREEN ALGAE

Crustose red algae are the only seaweeds known to strongly induce *Haliotis rufescens* settlement while intact. This observation is based on a relatively small sample of "other" seaweed species (Table 2). Larval attachment was ≤1% after 24 hours of exposure to intact foliose algae or blue-green algae (Morse et al. 1980c, Morse & Morse 1984a, Morse et al. 1984). *Haliotis discus hannai* seems to be less discriminatory—Seki (1997) found that 6 out of 12 foliose macro-algae induced metamorphosis of *Haliotis discus hannai* larvae. The active species included brown, red and green algae (Table 2).

Ulvella lens is a small, crustose green alga that grows as prostrate rosettes on hard surfaces. It is common on heavily grazed surfaces such as abalone tanks, and has been used in commercial abalone hatcheries as a settlement cue. Pregrazed films of *Ulvella* produced >90% attachment (Takahashi & Koganezawa 1988, Seki 1997) and metamorphosis (Takahashi & Koganezawa 1988) of *Haliotis discus hannai* larvae while ungrazed *Ulvella* films induced 60–70% attachment and metamorphosis (Takahashi & Koganezawa 1988). Germlings of *Ulvella lens* induced 10–50% of *Haliotis rubra* larvae to metamorphose within one to three days (Daume et al. 2000). This was higher than the metamorphosis recorded on films of several benthic diatom species in that study.

Prostrate brown algae of the genus *Myrionema* are often abundant (along with *Cocconeis* spp. and *Ulvella lens*) on the pregrazed plates used successfully to settle abalone (Seki 1980, Suzuki et al. 1987). The author is not aware of any data on the settlement-inducing activity of *Myrionema* spp.

CHEMICALS EXTRACTED FROM ALGAE AND BLUE-GREEN ALGAE

Attempts to purify the chemicals that trigger abalone settlement have focused on crustose coralline algae because of the corallines' consistently strong activity and their role in abalone ecology. The extensive work on purifying chemical inducers of *Haliotis rufescens* settlement has been reviewed previously (A. Morse 1991, D. Morse 1985, D. Morse 1990, D. Morse 1992), so only a brief account is given here. When intact seaweed specimens were tested, only crustose red algae induced high levels of larval attachment and metamorphosis of *Haliotis rufescens* larvae (Table 2). However, testing of crude extracts revealed that blue-green algae and foliose red algae also contained inducers intracellularly, while two brown algae, a green alga and a bacterium did not (Table 2, Morse & Morse 1984a, Morse et al. 1984). Red and blue-green algae contain phycobiliproteins, which the other algae lack (Morse 1985). The activity from coralline *Lithothamnium californicum*, the foliose red alga *Porphyra* sp., and the blue-green alga *Spirulina platensis* was initially protein-associated, but could be chromatographically separated from proteins into a low molecular weight (~650–1250 *Mr*) form (Morse & Morse 1984a, b, Morse et al. 1984, Morse 1992). The activity of the protein-associated form was enhanced by boiling, proteolytic digestion, and acid hydrolysis, suggesting that the active product may have been an amino acid or small peptide (Morse et al. 1979a). The peptide-associated

TABLE 2.

[a] To prepare crude extracts, 4 g of fresh alga (or 1.5 g dry *Spirulina*) was disrupted with a Bellentini bead shaker in ~25 ml 0.01 M Tris-HCl (pH 7.0) then centrifuged at 24,000 × g for 10 min at 2°C. Protein content of the supernatant (= crude extract) was determined by the Lowry method and extracts were assayed as per Roberts and Nicholson (1997). Data presented are all for a dose of 20 μg protein ml^{-1} of assay medium. Greater doses generally gave higher attachment and metamorphosis, but often became mildly toxic to larvae within a few days.

Note: "Attach." = attachment. "Met." = metamorphosis. To read *Haliotis discus hannai* data: "+/– (3/2)" means induction by 3 species of foliose reds and lack of induction by 2.

inducer molecule is known to contain several unidentified unusual amino acids but its precise structure is still unknown (Morse 1992). The inducer purified from *Lithothamnium* mimics the activity of GABA.

The response of *Haliotis virginea* to algal extracts is complex. At a low dose, the activity of extracts from various algal groups (Table 2) appears similar to that reported for *Haliotis rufescens*, except that blue-green algae have low activity. At higher doses, the brown algae induced means of 72–76% larval attachment within two days but caused mild toxicity after five days (data not shown). While most extracts induced some degree of larval attachment quite rapidly, metamorphosis occurred only gradually (Table 2) and shell growth was almost completely inhibited. A similar response to coralline extracts (Fig. 1) has been reported previously for both *Haliotis virginea* and *Haliotis iris* (Roberts and Nicholson 1997). The lack of shell growth appears to result from toxicity of co-extracted compounds preventing normal post-larval development and activity subsequent to the shedding of the velum (Roberts and Nicholson 1997). Extracts from the coralline alga *Phymatolithon repandum* contained inducers in both low molecular weight (600–1100 *Mr*) and relatively high molecular weight (>10,000 *Mr*) fractions of polar extracts (Roberts et al. 1994), paralleling the situation with *Haliotis rufescens* and *Lithothamnium californicum* (Morse et al. 1984). The active chemicals have not been identified.

Attempts to purify chemical inducers of urchin metamorphosis from coralline algae (Taniguchi et al. 1994) led to the discovery that metamorphosis of *Haliotis discus hannai* larvae is induced by a combination of dibromomethane and mucus (Seki et al. 1997). Larval attachment and metamorphosis on corallines are hypothesized to be independently triggered by trail mucus and dibromomethane respectively (Seki et al. 1997). Dibromomethane is a volatile chemical naturally released from corallines and many other algae (Taniguchi et al. 1994).

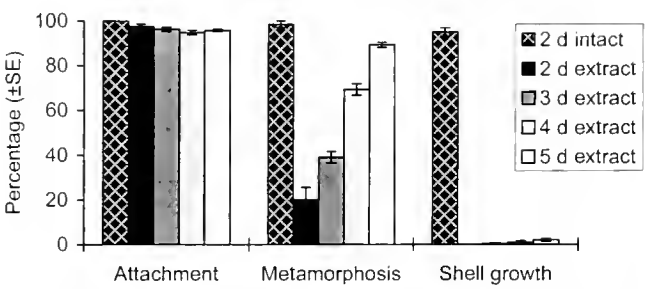

Figure 1. Comparison of the settlement response of larval *Haliotis iris* to intact plants and aqueous extract (440 μg dry extract ml^{-1}) of the coralline alga *Phymatolithon repandum*. Intact plants induced rapid attachment, metamorphosis and shell growth, whereas extracts induced rapid attachment, gradual metamorphosis and negligible shell growth. Data are from Roberts and Nicholson (1997).

BIOFILMS (INCLUDING BENTHIC DIATOMS)

Biofilm Composition

A biofilm is a layer of microorganisms and organic matter that develops on aquatic surfaces. Biofilms have long been used to induce larval settlement in abalone hatcheries around the world. Biofilms that develop in flowing seawater with light are often dominated by diatoms. The succession that occurs in the diatom community is important in abalone farming. The film is initially comprised largely of fast-growing, prostrate, benthic diatoms (Kawamura 1995). Over time, diatoms that grow as upright colonies (often referred to as 3-dimensional, overstorey or filamentous diatoms) grow above the prostrate forms (Kawamura 1995). Grazing by juvenile or adult gastropods removes the overstorey diatoms (Types C-H in Fig. 2), and loosely attached prostrate forms (Type A in Fig. 2), so only grazing-resistant, prostrate algae remain (Seki 1980, Suzuki et al. 1987, Kawamura 1995, Matthews and Cook 1995). The grazed (or secondary) film is often dominated by diatoms of the genus *Cocconeis* often along with small prostrate macroalgae such as *Ulvella lens* and *Myrionema* spp. (Suzuki et al. 1987, Seki 1980, 1997).

Use of Biofilms in Abalone Hatcheries

Some early abalone culture cued settlement with natural biofilms, without exerting any control over algal composition (Grant 1981, Chen 1989). The observation that filamentous diatoms were unsuitable for settlement (Seki 1980) led to the use of pre-grazing to select for tightly attached, prostrate diatoms (Type B in Fig. 2) and other algae (Seki 1980). Pregrazed films became the settlement method of choice in Japan.

Some other abalone hatcheries chose to select for small, prostrate diatoms by using filtered water to condition settlement surfaces, or by filtering diatom slurries prior to inoculation of tanks. An ungrazed film dominated by small, prostrate diatoms (Type A in Fig. 2) was the standard settlement preparation in many countries including Australia (Hone et al. 1997), Korea (Shallow Seafarming Research Institute 1990), New Zealand (Tong et al. 1992), and the USA (Ebert & Houk 1984).

Greater control of the diatom species in the film is introduced by isolating particular strains and growing them in monocultures (e.g., Hahn 1989a, Tong & Moss 1992, Kawamura & Kikuchi 1992). However, knowledge of the dominant diatom species still provides limited description of the characteristics of the biofilm. In addition to diatoms, a biofilm will contain many strains of bacteria, fungi and other microbes, as well as a variable amount of extracellular secretions, and a wide array of organic molecules. All of these components will change as the film develops. Given this complexity, it is perhaps not surprising that we still do not know which characteristics of a biofilm are responsible for settlement induction.

Settlement Versus Biofilm Age and Source-Habitat

Older biofilms appear to be better than younger ones for abalone larval settlement. The percentage of *Haliotis iris* larvae that settled on biofilms developed in flowing seawater increased with the age of the film (Moss & Tong 1992b). In this case maximum film age was nine days, and mean settlement was ~22% after six hours. A similar pattern was found with *Haliotis virginea* larvae—films grown for 36 days induced more attachment (77 ± 9%) and metamorphosis (25 ± 12%) within three days than films grown for 1, 4, or 12 days before assayed (Roberts et al. 1997b). This pattern with respect to biofilm age is reinforced by data from specific diatom strains reviewed below.

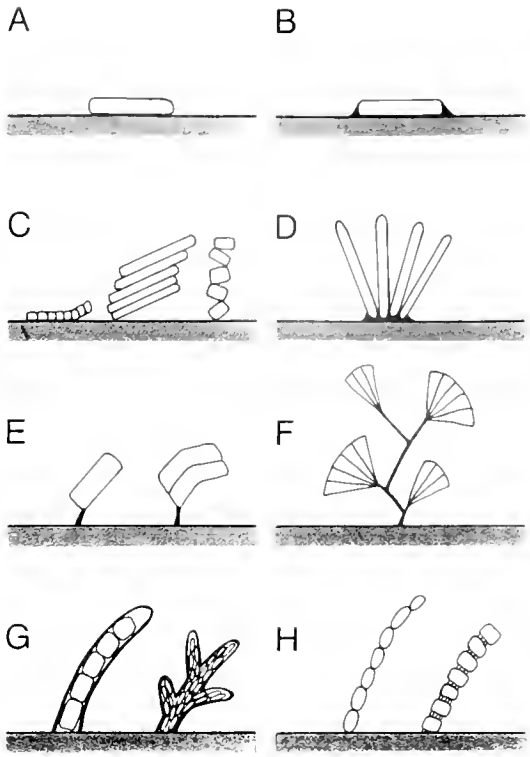

Figure 2. Schematic representation of eight growth forms of benthic diatom (Kawamura 1994). *Type A* (gliding prostrate type). Solitary cells with a prostrate form and swift gliding movements. Adhesive strength is very low. *Type B* (adhesive prostrate type). Solitary cells with a prostrate form, slow movement, and high adhesive strength. *Type C* (non-motile upright type). Non-motile solitary cells or simple, fan-shaped colonies standing upright with a relatively weak adhesion to the substratum. *Type D* (belt-shaped colonial type). Long, belt-shaped or zigzag colonies attached strongly to the substratum by a terminal cell of the colony. *Type E* (mucous thread solitary type). Solitary cells or short, belt shaped colonies attached strongly to the substratum with a mucous thread. *Type F* (mucous thread colonial type). Arborescent colonies connected with mucous threads and attached strongly to the substratum by a single mucous thread. *Type G* (tube-dwelling colonial type). Colony cells are enclosed in a filamentous or arborescent branched mucous tube. Cells can move within the tube, and the tube is tightly attached to the substratum. *Type H* (filamentous colonial type). Filamentous colonies attached only weakly to the substratum by a terminal cell of the colony.

The settlement inducing activity of biofilms is not limited to films from suitable abalone habitats. Biofilms grown in unsuitable habitats (rivers and estuaries) induced more attachment (site means ± s.e. of up to 83 ± 5 and 72 ± 5% respectively) than negative controls (6 ± 2%) after three to four days (Roberts et al. 1997b).

Diatoms

Diatom films have long been used to induce larval settlement in abalone hatcheries around the world. The species composition and other biofilm characteristics are often not controlled or recorded. Only a handful of studies have examined the settlement of abalone larvae in response to specific diatom strains. The picture they give

is one of variability and complexity that highlights the limited knowledge of settlement induction by diatoms. Some of the physical features of diatoms that affect their settlement-inducing activity are known (see later) but these explain relatively little of the variation seen among strains. It is likely that details of biofilm chemistry will explain settlement patterns, so detailed study of biofilm chemistry will be needed to significantly advance our understanding.

Features Making Diatom Films Favorable or Unfavorable for Settlement

Kawamura and Kikuchi (1992) quantified larval attachment, metamorphosis, shell growth and survival over two weeks of exposure to various densities of 22 diatom strains. Data representative of the major patterns of response are shown in Fig. 3. All strains induced over 70% attachment within two days of exposure, but few strains induced rapid and complete metamorphosis. Diatoms that induced relatively rapid metamorphosis were non-colonial, prostrate forms (Types A and B in Fig. 2), but many diatoms of this growth form did not give strong metamorphosis. At high densities, diatoms with three-dimensional growth forms entangled larvae and prevented them from metamorphosing. At low densities these diatoms induced gradual attachment and metamorphosis, as seen with many prostrate diatoms. An English summary of this study was presented in Kawamura (1996).

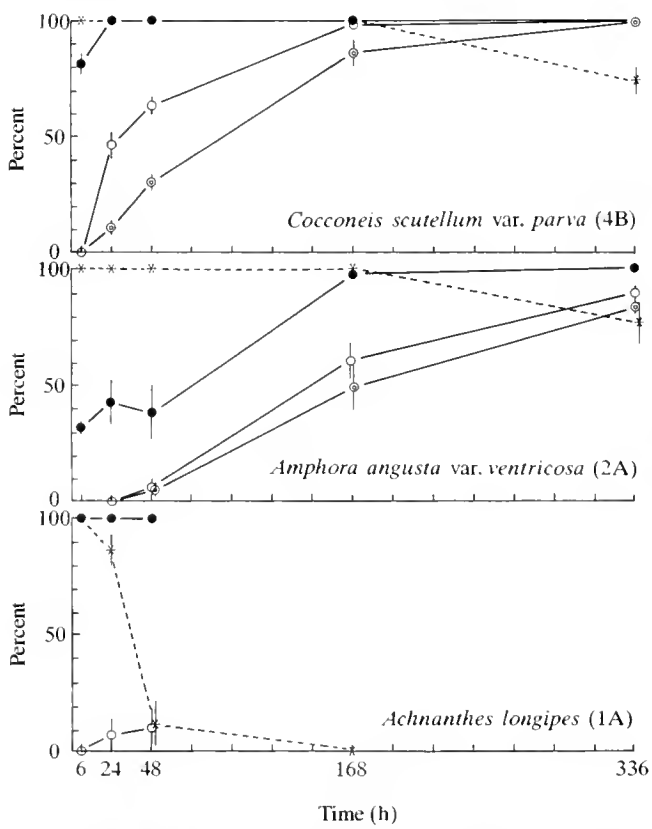

Figure 3. Examples of three patterns of response observed for *Haliotis discus hannai* larvae settling on benthic diatoms. Data (mean ± s.e.) show changes in attachment (— ● —), metamorphosis (— ○ —), shell growth (— ⊡ —) and survival (— * —) over 2 weeks of continuous exposure to three diatom treatments, 4B, 2A and 1A (Kawamura and Kikuchi 1992).

For prostrate diatoms, there is generally a positive relationship between diatom density and abalone larval settlement. This relationship is generally apparent for a given diatom strain within an experiment (Kawamura & Kikuchi 1992, Daume et al. 1999a) but does not necessarily apply across diatom species or across experiments. Larval attachment of *Haliotis discus hannai* within six hours was low when diatom density was less than 1×10^4 cells.cm^{-2}, and high mainly for diatom densities above 3×10^4 cells.cm^{-2} (Kawamura and Kikuchi 1992). Given that the size of diatom cells varies considerably, percent cover may be more useful than density as a measure of diatom abundance.

The abundance of a diatom film may be important in providing sufficient inducer to trigger larval attachment. As diatom films develop and age, they go through a series of growth phases (O'Meley & Daintith 1993) and many physical and chemical characteristics change along the way. It may be one or more of these factors that causes increased settlement rather than diatom abundance *per se*.

Diatom Species Favorable and Unfavorable for Settlement

It is not yet possible to list diatom strains that are consistently good or bad for abalone larval settlement. *Cocconeis* spp. have gained a reputation of being good for settlement because diatoms of this genus are often dominant on the pre-grazed plates that induce settlement in Japanese abalone hatcheries (Akashige et al. 1981, Suzuki et al. 1987, Seki 1997). Testing of pure strains reveals a more complex picture. *Cocconeis scutellum* is often effective as a metamorphosis inducer, although metamorphosis sometimes occurs gradually over several days (Kawamura & Kikuchi 1992, Roberts & Nicholson 1997). Daume et al. (1999b) reported only 10–30% metamorphosis of *Haliotis laevigata* larvae in response to *Cocconeis scutellum*. However, if Daume et al.'s much shorter observation period (24 hours) and lower diatom densities are taken into account, the results are comparable to those obtained with *Haliotis discus hannai* (Kawamura & Kikuchi 1992) and *Haliotis virginea* (Roberts & Nicholson 1997). Ohgai et al. (1991) found that settlement on *Cocconeis* sp. was 12 times higher than on *Nitzschia closterium* or a mixed biofilm of naturally seeded diatoms, but only 1.5 times higher than on *Navicula ramosissima*.

Cocconeis strains are not always good for abalone settlement induction. Induction of metamorphosis can be slow (see above) and some strains of *Cocconeis* have given poor settlement induction (Ishida et al. 1995). *Haliotis rubra* larvae did not respond within 24 hours to *Cocconeis scutellum* or any of the four other diatom strains tested (Daume et al. 2000). Mean metamorphosis within 24 hours was ≤6% in all cases. Similarly, less than 2% of *Haliotis rubra* larvae metamorphosed within three days on four diatom strains (6-day-old film, diatom densities not presented), while up to 25% of larvae settled on the coralline alga *Phymatolithon repandum* (Daume et al. 1999b). In equivalent bioassays, *Haliotis laevigata* larvae responded strongly to the same four diatom strains (Daume et al. 1999b) implying a major difference in the settlement requirements (or speed of response) between these two Australian abalone species.

Cylindrotheca closterium (and the physically similar *Nitzschia longissima*) are often poor inducers of attachment and metamorphosis, perhaps because of their high mobility and low attachment strength (Ohgai et al. 1991, Kawamura & Kikuchi 1992, Roberts et al. 1997a). However, *Cylindrotheca closterium* has on occasion strongly induced metamorphosis of *Haliotis discus hannai* larvae

(Kawamura & Takami 1995) and *Haliotis laevigata* (Daume et al. 1999b).

BACTERIA

Bacteria are ubiquitous in so-called "diatom" films, yet the role that they play in settlement induction is virtually unstudied. Roberts et al. (1997a) found that metamorphosis of *Haliotis iris* larvae was reduced by 60% if the inducing diatom (*Nitzschia ovalis*) was grown in the presence of antibiotics. The proportion of larvae that attached was similar between the treatments. No work has been done on settlement induction by axenic diatoms, so it is not certain that diatoms can induce abalone settlement without bacteria present. The fact that many diatom strains are active when assayed in the presence of antibiotics does not preclude (1) bacterial production of inducers prior to bioassay; or (2) activity resulting from bacteria unaffected by the antibiotic treatment. It is practical to obtain axenic diatom cultures, but keeping them axenic during a larval assay would be far more challenging. Detection of differences resulting from antibiotic treatments (e.g., Johnson & Sutton 1994) or near-axenic treatments would suggest a role for bacteria, but negative results would be equivocal.

The limited work done on abalone settlement induction by bacteria shows that bacteria can induce larval attachment and metamorphosis in some abalone species, but that settlement is slow. *Haliotis virginea* larvae incubated with a natural bacterial assemblage, took a week to reach 50% metamorphosis, and two weeks to reach 80% metamorphosis. Parallel assays with antibiotics retained low bacterial densities and had less than 2% metamorphosis over the same period (Roberts et al. 1997b). Similarly, gradual attachment and metamorphosis has been recorded with *Haliotis iris* exposed to bacteria in static assays without antibiotics (R. D. Roberts unpubl. data). Morse et al. (1979b) discussed gradual and inefficient attachment and metamorphosis of *Haliotis rufescens* larvae occurring in parallel with rising mortality and microbial growth. They suggested that such responses may reflect the production of GABA or the less active glutamate by bacterial metabolism. Bryan and Qian (1998) reported 20–50% attachment of *Haliotis diversicolor* within 24 hours on three bacterial strains isolated from a diatom film. Assays were conducted without antibiotics, and metamorphosis data were not reported. None of 33 strains of marine bacteria induced settlement in *Haliotis rufescens* (A. Morse's unpubl. data cited in Morse 1992, methods not presented).

PREGRAZED FILMS AND ABALONE MUCUS

Algal biofilms grazed by juvenile or adult abalone are widely effective as inducers of abalone larval attachment and metamorphosis (Takahashi & Koganezawa 1988, Ishida et al. 1995, Searcy-Bernal et al. 1992b, Slattery 1992, Conroy et al. 1996, Seki 1997, Bryan & Qian 1998, Daume et al. 2000). Where comparisons have been made between grazed and ungrazed films, the grazed films have performed better for both diatom films (Slattery 1992, Searcy-Bernal et al. 1992b, Seki 1997, Bryan & Qian 1998) and *Ulvella lens* (Takahashi & Koganezawa 1988, Daume et al. 2000).

There are varying reports on the activity of abalone trail mucus as a settlement inducer. Conspecific mucus alone was reported to induce only larval attachment in *Haliotis discus hannai* (Seki et al. 1997). In contrast, Yang and Wu (1995) found that mucus induced over 90% metamorphosis and shell growth of *Haliotis discus hannai* larvae within 48 hours. In Yang and Wu's study the mucus was laid down and assayed in the absence of antibiotics. In *Haliotis iris* mucus alone induced only a low percentage of attachment and metamorphosis when assayed in the presence of antibiotics (Fig. 4). For *Haliotis diversicolor* adult mucus alone induced moderate levels of larval attachment within six hours of exposure, but attachment subsequently fell as high mortality developed (Bryan & Qian 1998). Metamorphosis data were not presented. Morse et al. (1980c) recorded no settlement of *Haliotis rufescens* larvae in response to juvenile conspecifics (that would have produced trails of mucus).

The induction of *Haliotis discus hannai* larval attachment by trail mucus appears to be genus-specific. Larval attachment was induced by trail mucus from four Japanese abalone species but not by trail mucus from three other gastropods (Seki & Kan-no 1981b, see Seki & Taniguchi 1996 for a summary in English). The mucus left by abalone during grazing gave higher larval attachment than that left by crawling abalone, while mucus from abalone pressed or rubbed against settlement plates did not induce larval attachment (Seki & Kan-no 1981b, Seki & Taniguchi 1996). This pattern was hypothesized to result from differences in the physical or chemical properties of mucus produced during different activities (Seki & Kan-no 1981b). The presence of remnants of grazed biofilm in the grazing mucus treatment raises possible alternatives: (1) release of chemicals by grazing damage to biofilm organisms; (2) interaction between mucus and biofilm chemicals; (3) microbial proliferation on the trail mucus providing settlement cues.

The chemical basis of settlement induction by trail mucus or pre-grazed films has not been studied. Rodriguez et al. (1993) suggested that heparin-binding growth factors might be the substance responsible for settlement induction by abalone mucus, but there is no evidence to support this hypothesis.

PURE CHEMICALS

The Morphogenetic and Regulatory Signal Transduction Pathways

Before discussing pure substances that can trigger larval attachment and/or metamorphosis, it is necessary to briefly describe current understanding of the way in which inducer molecules bring about a response in larval abalone. This knowledge is based on

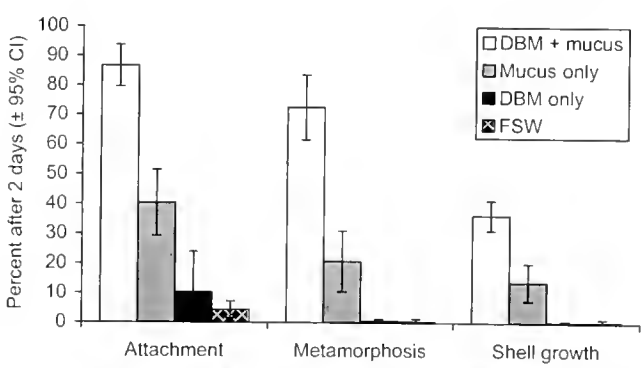

Figure 4. Synergy between dibromomethane (DBM) and mucus in settlement induction of *Haliotis iris* larvae. One juvenile *Haliotis iris* (~10 mm shell length) was held overnight in each well of a new multiwell plate (Falcon 3043), then removed before addition of 3 ml of 0.2 µm-filtered seawater, antibiotics (150 µg ml^{-1} penicillin + streptomycin sulfate), dibromomethane (175-700 µg ml^{-1}, no dose-response within this range) and 50-100 larvae. Counts were made after 48 hours of incubation (dark, 17±0.5 C). FSW = filtered seawater. R. D. Roberts (unpubl. data).

extensive research with *Haliotis rufescens* (previously reviewed by A. Morse 1991, D. Morse 1984b, 1985, 1990, 1992) and the degree to which it applies to other abalone is not known.

A simplified working model describes two interacting biochemical signal pathways—the morphogenetic and regulatory pathways. These pathways are well summarized and illustrated by Morse (1991). The morphogenetic pathway describes how an external chemical signal is translated into a nerve impulse. The model hypothesizes that binding of a GABA-mimetic molecule at stereochemically-specific receptors activates adenyl cyclase enzyme that catalyzes the synthesis of cyclic adenosine-monophosphate (AMP) as a secondary messenger. The cyclic AMP activates a protein kinase that phosphorylates an unknown protein. This protein somehow causes opening of an anion channel in the chemosensory cell membrane allowing efflux of anions and causing depolarization of the cell. This depolarization provides an electrochemical signal that can be transmitted by the larval nervous system (A. Morse 1991, D. Morse 1992). This nerve impulse can then trigger larval responses such as cessation of swimming, foot exploration behavior, and metamorphic changes in gene expression and morphology (Cariolou & Morse 1988, Barlow 1990, Groppe & Morse 1993, 1994, Degnan & Morse 1995, Degnan et al. 1995, 1997).

The larval response to GABA and GABA-like molecules (via the morphogenetic pathway) is subject to up- and down-regulation via a separate regulatory pathway (Trapido-Rosenthal & Morse 1985, Trapido-Rosenthal & Morse 1986a, Trapido-Rosenthal & Morse 1986b, Baxter & Morse 1987, Wodicka & Morse 1991). Larval sensitivity to GABA analogs can be enhanced by facilitating compounds (such as exogenous lysine or certain other diamino acids), or down-regulated by prolonged larval exposure to the inducer during the pre-competent phase. Facilitating compounds are not themselves acting as inducers (Baxter & Morse 1987).

Cues That Artificially Trigger the Morphogenetic Pathway

Larval attachment and metamorphosis can be induced by substances that bind to a specific larval receptor, or by treatments that artificially trigger the larval response at some other point in the morphogenetic pathway. The latter applies to several pure chemicals that are thought to bring about larval attachment or metamorphosis by affecting elements of the signal transduction pathway such as trans-membrane ion transport, or intracellular levels of Ca^{2+} and cyclic AMP (Morse et al. 1980a, Jensen et al. 1990, Morse 1992).

An interesting example of an "artificial" cue is the potassium ion (K^+). A concentration of K^+ ~10 mM above that found in seawater triggered up to 90% of *Haliotis rufescens* larvae to attach within 72 hours (Baloun & Morse 1984, Yool et al. 1986). Metamorphosis was also induced if exposure lasted at least 20 hours (Baloun & Morse 1984). *Haliotis discus hannai* also metamorphosed in response to excess K^+ but required a higher concentration (optimally 40 mM excess) (Yang & Wu 1995). Excess K^+ induces larval attachment, but not metamorphosis, in *Haliotis iris*, *Haliotis virginea*, (Roberts & Nicholson 1997) and *Haliotis diversicolor* (Bryan & Qian 1998). This difference does not appear to result from experimental methods. The latter three species were tested with natural seawater (in contrast to the artificial seawater used with *Haliotis rufescens*) but KCl addition to natural seawater was effective for *Haliotis discus hannai* (Yang & Wu 1995) and other marine invertebrates (Pearce & Scheibling 1994). Variation of larval age, assay container volume and shape, antibiotics used, and KCl concentrations all failed to produce significant metamorphosis in *Haliotis virginea* (Roberts & Nicholson 1997).

Excess K^+ induces metamorphosis in a wide range of marine invertebrates, including several gastropod species, and it is thought to act by depolarizing excitable membranes and thereby triggering the settlement response (Baloun & Morse 1984, Pearce & Scheibling 1994). The induction by K^+ of attachment without metamorphosis in some abalone species is interesting because it suggests that there could be separate cues for attachment and metamorphosis, and differences in the signal transduction pathways for these cues.

The inducing effect of K^+ is more specific than a simple excess of cations, *Haliotis rufescens* did not settle in response to excess Na^+, Ca^{2+} or Mg^{2+} (Baloun & Morse 1984). Low external K^+ or high external Ca^{2+} inhibit induction by GABA, apparently by hyperpolarizing the receptor cells so that the ion transport brought about by the inducer does not cause cell depolarization and a nerve impulse.

These artificial cues are useful in understanding the biochemical pathways of settlement induction, and can provide useful tools for industry or research, but compounds that bind to specific larval receptors are much more likely to be ecologically relevant. These are now discussed.

Cues that Bind to Specific Larval Receptors

The inducer molecules purified from *Lithothamnium californicum* (see above) mimicked the activity of GABA in binding to GABA receptors purified from mammals (Trapido-Rosenthal & Morse 1986a). Conversely, GABA mimicked the activity of the inducer from *Lithophyllum* by binding to abalone larval receptors and triggering larval attachment and metamorphosis (Morse et al. 1979a). Several lines of evidence suggest that GABA and GABA-mimetics bind to the same receptors, and that these receptors are involved in settlement induction (Trapido-Rosenthal & Morse 1986a). The location of the receptors is unknown, but they are probably external on the larval epithelium (Barlow 1990, Morse 1990). Label bound to receptors was shed at the time of metamorphosis (Trapido-Rosenthal & Morse 1986a) but the receptors are unlikely to be on the larval velum (Barlow 1990).

Published literature contains many contradictions regarding the efficacy and effective dose of GABA (Akashige et al. 1981, Morse 1992, Table 3). The susceptibility of GABA to degradation by marine microbes (Morse et al. 1979b; Kaspar et al. 1991, Kaspar & Mountfort 1995) probably explains much of the variation in results (Searcy-Bernal & Anguiano-Beltrán 1998, Morse 1992) yet no study has quantified the decline in GABA concentrations during settlement experiments. The use of antibiotics in settlement bioassays should reduce bacterial interference (Morse et al. 1979b) but assays using recognized antibiotic treatments can still produce quantitatively variable results for the same species (e.g., see results for *Haliotis gigantea* and *Haliotis virginea* in Table 3). Such variation may result from variations in the quantity or composition of the microbial flora (Searcy-Bernal et al. 1992b) and particularly the abundance of antibiotic-resistant microbes that degrade GABA. Variability between batches of larvae may also contribute (Baloun & Morse 1984, Trapido-Rosenthal & Morse 1986b).

Another possible source of variation in GABA experiments is the composition of assay water. The concentrations of GABA required to trigger settlement can be altered orders of magnitude

TABLE 3.

Settlement response of abalone larvae to various doses of GABA.

Abalone Species	Settlement Response After (× hours)	Percent of Larvae Responding to GABA Concentrations of: 10^{-3} M	10^{-4} M	10^{-5} M	10^{-6} M	Zero	Comments	Reference
Haliotis diversicolor supertexta	Attachment (24 h)	81	77	63	60	58	10^{-3} M & 10^{-4} M GABA lethal in 72 h. No errors. Control larvae attached. Used unspecified antibiotics	Liu et al. (1986)
	Attachment (48 h)	95	96	94	91	94		
H. diversicolor	Attachment (24 h)	**48 ± 12**	**45 ± 13**	**45 ± 14**	32 ± 10[a]	22 ± 9	No antibiotics used. [a] Was significantly higher than control at 18 and 72 h	Bryan and Qian (1998)
	Shell growth (96 h)	0 ± 0	0 ± 0	**14 ± 7**	0 ± 0	2 ± 2		
H. discus hannai	Shell growth (48 h)		Toxic	**58 ± 15**	35 ± 17	0 ± 0	24 hour exposure followed by 24 hours in seawater. No antibiotics	Yang and Wu (1995)
H. discus discus	Metamorphosis (96 h)				**59 ± 7**	5 ± 0	Used 150 μg/ml penicillin + streptomycin. Data from 2 experiments.	Fukazawa et al. (in press)
	Metamorphosis (96 h)				**83 ± 10**	21 ± 11		
H. gigantea	Metamorphosis (96 h)				**82 ± 3**	7 ± 3	Used 150 μg/ml penicillin + streptomycin. Data from 2 experiments	Fukazawa et al. (in press)
	Metamorphosis (96 h)				21 ± 7	2 ± 0		
H. midae	"Settlement" (18 h)	80	80	50	50	40	No errors. Used 33 ppm penicillin.	Genade et al. (1988)
H. iris	Attachment (48 h)				**98 ± 2**	9 ± 2	Mean ± 95% CI. Used 150 μg/ml penicillin + streptomycin	Roberts and Nicholson (1997)
	Metamorphosis (96 h)				**40 ± 10**	0 ± 0		
H. virginea	Attachment (48 h)				**75 ± 5**	9 ± 3	Mean ± SE of 7 experiments. Used 150 μg/ml penicillin + streptomycin	Roberts and Nicholson (1997)
	Metamorphosis (48 h)				3 ± 2	0 ± 0		
	Attachment (48 h)	**61 ± 5**	**87 ± 1**	**73 ± 1**	4 ± 0[b]	10 ± 3	Standard error, n = 3. [b] But 2.2×10^{-6} M GABA gave 55 ± 7% attachment. Methods as in Roberts and Nicholson (1997)	R. Roberts (unpubl. data)
	Metamorphosis (48 h)	1 ± 1	1 ± 1	1 ± 0	0 ± 0	0 ± 0		
H. australis	Inferred settlement (24 h)				**73 ± 3**	48 ± 2	High settlement in controls. Survival after 7 days was 3%. Flow through system without antibiotics.	Moss (1999)
	Inferred settlement (48 h)				**85 ± 2**	60 ± 3		
	Inferred settlement (96 h)				98 ± 0.5	96 ± 2		
H. corrugata	Metamorphosis (24 h)				100 ± 0		No antibiotics used. No biofilm present	Searcy-Bernal et al. (1992a)
H. rufescens	Attachment (24 h)	96		85	96	0	Convincing data but no errors/stats given. Probably used 150 μg/ml penicillin + streptomycin (Morse et al. 1979b).	Morse et al. (1980a)
	Metamorphosis (48 h)	0		40	92	0		
	Shell growth (48 h)	0		0	88	0		
H. rufescens	Metamorphosis (24 h)				**83**	12[c]	No difference between antibiotics (100–130 μg/ml penicillin + streptomycin) (86%) and no antibiotics = 83%. No biofilm present. [c] = diatom film without GABA	Searcy-Bernal et al. (1992a)
	Metamorphosis (24 h)				**86**	12[c]		
H. rufescens	Metamorphosis (24 h)				**75 ± 10**	8 ± 8[d]	Biofilm present and no antibiotics used. [d] = biofilm without GABA	Searcy-Bernal et al. (1992b)
	Metamorphosis (24 h)				**76 ± 4**	11 ± 5[d]		
H. rufescens	Attachment (18 h)						10^{-6} M GABA did not improve settlement. Biofilms present. No antibiotics used.	Slattery (1992)

Boldface type indicates settlement significantly greater than negative controls (zero GABA column). Controls lacked any deliberate cue, except where noted. [a–d] Superscript letters refer to explanatory comments.

by dissolved substances acting on the regulatory pathway (Trapido-Rosenthal & Morse 1986b). This suggests that the use of artificial seawater might reduce variability among experiments, but caution is required in the choice of seawater. Larvae of *Haliotis discus hannai* exposed to 1 μM GABA in "ASP-M" artificial seawater (McLachlan 1964) often initiate metamorphosis more slowly than sibling larvae in natural seawater, and always fail to develop a normal post-larval shell (T. Kawamura & H. Takami,

unpubl. data). Similar results have been obtained with *Haliotis iris* where metamorphosis induced by 2 μM GABA after 5 days was ~8-fold lower in ASP-M artificial seawater (11 ± 3%, mean ± 95% CI) than in natural seawater (86 ± 3%) (R. D. Roberts unpubl. data), while larval attachment was unaffected. Interestingly, *Haliotis rufescens* does initiate metamorphosis in two artificial seawater recipes (Baloun & Morse 1984, Barlow 1990). Effects of artificial seawater on the initiation of metamorphosis may be caused by complex interactions between the ionic composition of the water and membrane depolarization of chemosensory cells (Baloun & Morse 1984).

Data on abalone larval responses to GABA are summarized in Table 3 and Figure 5. Several additional abalone species are reported to settle in response to GABA, but data have not been presented. These include *Haliotis fulgens* (Salas-Garza et al. 1994, Castro-Galvez & Searcy-Bernal 1997), *Haliotis cracherodii*, *Haliotis kamtschatkana*, *Haliotis tuberculata*, *Haliotis midae*, and *Haliotis ruber* (Morse 1984a). Most abalone species will attach within 24 hours in response to concentrations between 10^{-6} M and 10^{-3} M, but doses of 10^{-4} M and 10^{-3} M GABA are toxic within a few days (Table 3). Most abalone species initiate metamorphosis at doses of between 10^{-6} M and 10^{-5} M GABA (Table 3, Fig. 5) but higher doses inhibit shell growth (10^{-5} M) or metamorphosis and shell growth (10^{-3} M) (e.g., Morse et al. 1980a, Searcy-Bernal & Anguiano-Beltrán 1998). While high concentrations of GABA are toxic within a few days, 10–30 minute exposures to 10^{-3} M or 10^{-4} M GABA have been successfully used to induce metamorphosis in *Haliotis rufescens* (Shilling et al. 1996, Buchal et al. 1998) and *Haliotis iris* (R. D. Roberts, unpubl. data).

Haliotis virginea and *Haliotis diversicolor* larvae attach in response to GABA, but few proceed to metamorphose within four days (Table 3, Fig. 5). For *Haliotis virginea*, fine scale dose-responses (Fig. 5) and several variations of assay methodology (Roberts & Nicholson 1997) have failed to produce significant metamorphosis.

Use of GABA as a settlement cue in commercial abalone hatcheries was initially discouraged by (1) poor results from GABA in the absence of antibiotics (Morse et al. 1979b, Slattery 1992, Searcy-Bernal 1994); (2) the toxicity associated with prolonged exposure to high concentrations of GABA (Morse et al. 1980a, Akashige et al. 1981, Liu et al. 1986); and (3) the fact that GABA causes larvae to settle on horizontal surfaces (Morse et al. 1980c, Leighton 1989) where conditions unsuitable for post-larval survival can develop (Leighton 1989). However, successful large-scale induction of metamorphosis by GABA without antibiotics and in the presence of biofilms has been demonstrated (Searcy-Bernal et al. 1992b, Searcy-Bernal 1994). To help counter occasional poor results with GABA, Searcy- Bernal and Anguiano-Beltrán (1998) showed that the GABA concentration can be doubled or tripled without compromising metamorphosis or post-larval survival and growth of *Haliotis rufescens*.

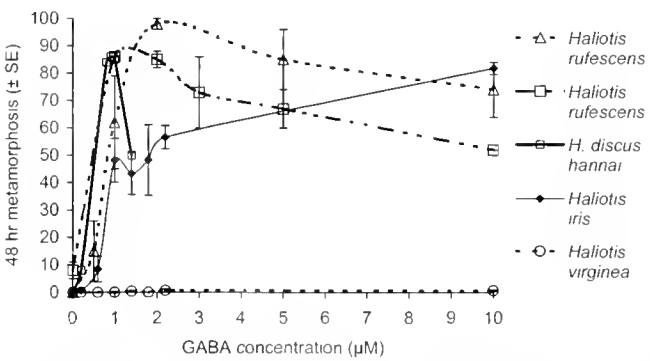

Figure 5. Metamorphosis of four abalone species in response to low doses of GABA. All assays used antibiotics and quantified metamorphosis after 48 hours of continuous exposure. The lines joining points are not fitted curves. All abalone species showed similar responses at the lowest doses with the exception of *Haliotis virginea*, which did not metamorphose at any concentration tested. Metamorphosis and shell growth of *Haliotis discus hannai* (Morse 1992, no errors presented) was lower at 1.3 μM than at 0.8 – 1.0 μM, but no other data suggest such a narrow dose response to GABA. Data for *Haliotis rufescens* (Searcy-Bernal and Anguiano-Beltrán 1998) are from two separate experiments. Methods for *Haliotis iris* and *Haliotis virginea* (R. D. Roberts unpubl. data) were as described in Roberts and Nicholson (1997).

GABA causes arrest of swimming cilia (Akashige et al. 1981, Hahn 1989c, Barlow 1990) so we expect indiscriminate settlement in the presence of GABA, but strong substrate selection in the absence of GABA (Morse et al. 1980c). In contrast, Yang and Wu (1995) found that *Haliotis discus hannai* larvae preferentially metamorphosed on certain substrates even in the presence of 1 μM GABA. These results may be explained by bacterial degradation of GABA in the absence of antibiotics.

A number of compounds that are structurally related to GABA also induced attachment of *Haliotis rufescens* larvae, presumably by binding to the larva's GABA-sensitive receptor (Morse et al. 1979a, 1980a, b). Investigation of stereochemical specificity revealed that attachment-inducing activity decreased as the carbon chain length was varied from that of GABA, and that the activity was dependent upon the presence of both the amino and carboxyl terminal groups (or on groups conferring similar functional activity) (Morse et al. 1980b). Most GABA analogs were tested only at 1 mM, while GABA was active at 1 μM (Morse et al. 1980b). Five common amino acids induced larval attachment only at concentrations three to four orders of magnitude higher than those required with GABA (Morse et al. 1980a). These studies quantified larval attachment, and did not say whether the active compounds also induced metamorphosis. *Haliotis virginea* larvae show little metamorphosis in response to GABA, yet its attachment response to several GABA-homologs (Berkett et al. 1994) mirrors that of *Haliotis rufescens* (Morse et al. 1980b), implying similar stereochemical requirements for attachment induction.

Other Chemicals whose Mode of Action is Unknown

GABA and other neurotransmitter-like molecules have been implicated in settlement induction of larval marine invertebrates other than abalone (Morse 1985). Various neurotransmitters have been tested as abalone settlement inducers but found to lack activity (Morse et al. 1980a, Akashige et al. 1981, Berkett et al. 1994, Fukazawa et al. in press). Epinephrine and serotonin stimulated the beating of the velar cilia in *Haliotis discus hannai* (Akashige et al. 1981).

Dibromomethane induces low levels of metamorphosis in *Haliotis discus hannai* (T. Seki, pers. comm.) but negligible attachment or metamorphosis in *Haliotis iris* within two days (Fig. 4). However, in both species the combination of dibromomethane and trail mucus gives rapid and complete settlement (Seki et al. 1997, Fig. 4). The biochemical basis of this synergy is not known. Mucus provides a substrate for microbial proliferation, and certain bacteria are capable of oxidizing dibromomethane (e.g., Goodwin et al.

1998). This oxidation would liberate bromide anions and (via methanol) carbon dioxide and water. *Haliotis rufescens* larvae were induced to attach by replacing 25–75% of the chloride in artificial seawater with various anions including bromide (Baloun & Morse 1984), but this represents a bromide concentration far in excess of the effective dibromomethane concentration (Fig. 4). Brominated compounds are involved in various chemical reception pathways (e.g., Wassermann et al. 1979, McKinney & Richelson 1986) but there is no evidence that such compounds are formed in the presence of dibromomethane, or are active in abalone. Organic solvents (e.g. ethanol at >0.75%) can induce abalone larval settlement (Fenteany & Morse 1993). However, the methanol generated by oxidation of dibromomethane would be short-lived, so would not reach concentrations expected to induce settlement in abalone larvae.

Thyroxine (T_4) at 33–132 μM induced 85% metamorphosis of *Haliotis rufescens* larvae in 44 hours (Carpizo-Ituarte & Rosa-Velez 1993). The thyroid hormones T_4, 3, 5, 3′-triiodothyronine (T_3), 3, 3′, 5′-triiodothyronine (rT_3) and tetraiodothyroacetic acid (tetrac) induced metamorphosis of *Haliotis discus discus*, *Haliotis gigantea* and *Haliotis iris* at concentrations as low as 0.1–1 μM, while 3, 5-diiodothyronine (3, 5-T2) and diiodotyrosine (DIT) were inactive (Fukazawa et al. in press, and unpubl. data). Thyroid hormones are involved in the metamorphosis, development or metabolism of vertebrates and some invertebrates (e.g., Galton 1992, Eales 1997, Johnson 1997). The abalone data support the case for an ancient evolution of the regulatory functions of thyroid hormones (Johnson 1997).

Algal extracts are often toxic to abalone larvae and can inhibit normal larval attachment, metamorphosis or shell growth (Morse & Morse 1984a, Roberts & Nicholson 1997). In the case of the brown alga *Dilophus okamurai* and *Haliotis discus hannai* the toxic compounds were found to be two spatane-type diterpene alcohols (Taniguchi et al. 1989, Shiraishi et al. 1990). Various environmental contaminants and temperature can also interfere with normal abalone larval settlement (Morse et al. 1979b, Steinbeck 1980, Conroy et al. 1996, Raimondi et al. 1997). Certain antibiotics have also caused positive or negative interference in abalone settlement assays (see above).

DISCUSSION

Do Attachment and Metamorphosis Occur Spontaneously?

The normal behavior of competent abalone larvae includes periods of crawling and substrate testing (Seki & Kan-no 1981a). Thus, it is not surprising that even clean, young negative controls with antibiotics often have a small proportion of larvae attached (e.g., Roberts & Nicholson 1997). This background level of attachment probably occurs in the absence of any cue but is quite distinct from spontaneous metamorphosis.

It is common to record a very low percentage of metamorphosis in negative controls, even in the presence of antibiotics (Table 3). Varying levels of apparently spontaneous metamorphosis do occur in aging abalone (Roberts & Lapworth 2001, Takami et al. unpubl. data, Searcy-Bernal pers. comm.). Given that microbes can induce metamorphosis, it is difficult to be confident that any metamorphosis occurred spontaneously unless the larval cultures are axenic.

Abalone larvae become increasingly sensitive to metamorphic cues during the week or so after first attaining competence (Morse 1984b, Barlow 1990, Moss & Tong 1992a) probably because of continued synthesis of chemical receptors by the aging larva (Degnan & Morse 1995). This will serve to heighten the larva's sensitivity to sub-optimal cues and may increase the chance of metamorphosis occurring without any obvious trigger. A more critical period for abalone comes later, when larvae are nearing the end of their life expectancy and are faced with the choice between spontaneous metamorphosis or death. There is no information on changes in settlement-related biochemical pathways in abalone larvae during this period. In some animals metamorphosis is regulated by internal inhibitory compounds as well as external cues (Youson 1997). If such a mechanism existed in abalone, the degradation of the inhibiting compound in aging larvae would offer a possible explanation for spontaneous metamorphosis.

Timing and Endpoint of the Settlement Response—Are There Multiple Cues?

The timing and end point of the abalone settlement response varies greatly among cues. Attachment can be uncoupled from metamorphosis in at least several abalone species (Leighton 1972, Kawamura & Kikuchi 1992, Roberts & Nicholson 1997, Bryan & Qian 1998, Moss 1999). A wide array of chemicals and organisms induce attachment of abalone larvae within a day, but few give rapid metamorphosis. It is possible that larval attachment and metamorphosis can be triggered by separate cues (Roberts & Nicholson 1997, Seki et al. 1997, Bryan & Qian 1998) acting via independent or interacting biochemical pathways.

The slow increase in percent metamorphosis commonly seen among larvae incubated with bacteria (Morse et al. 1979b) and many diatom strains (e.g., Kawamura & Kikuchi 1992) could be explained by infrequent encounters between larvae and sufficient quantities of inducers. The cues may be continually produced and degraded by microbes (Morse et al. 1979b, Kaspar et al. 1991, Searcy-Bernal et al. 1992b, Kaspar & Mountfort 1995) but not present in sufficient quantity to induce a synchronized settlement response.

An interesting aspect of induction by K^+ is that metamorphosis induction only occurred if the treatment was applied for at least 20 hours (Baloun & Morse 1984). In the case of coralline algae, or other fast-acting cues, metamorphosis begins within several hours (e.g., Barlow 1990, Seki 1997). Such differences (if not caused by confounding effects such as larval age) may provide clues about the biochemical pathways of settlement induction.

The GABA-mimetic receptor is strict in its stereochemical specificity (Morse et al. 1980b). Many of the molecules that induce abalone attachment or metamorphosis probably trigger the morphogenetic pathway downstream of the GABA-mimetic receptor (Morse 1992). The activity of other molecules, such as dibromomethane and thyroid hormones, cannot be readily explained by the existing model (A. Morse 1991, D. Morse 1992) and probably act at larval receptors not yet characterized. The diverse array of natural substances capable of inducing some degree of abalone larval attachment or metamorphosis suggests that either (1) there are multiple cues/receptors that can trigger settlement, or (2) the cues are widely available in marine biota.

Synergistic Effects Between Cues

The best described example of synergy between abalone larval settlement cues is the interaction between the regulatory and morphogenetic pathways proposed for *Haliotis rufescens* (Trapido-Rosenthal & Morse 1985, Trapido-Rosenthal & Morse 1986a, Trapido-Rosenthal & Morse 1986b, Morse 1991). Diamino acids

can amplify larval sensitivity to GABA-mimetic molecules by up to 100 fold. Other examples of synergy involve GABA plus coralline algal extract, GABA plus diatom film (Roberts & Nicholson 1997) and dibromomethane plus mucus (Seki et al. 1997, Fig. 4). The biochemical basis of these latter synergies is not known. Both cases involving GABA have a crude organic matrix (diatom film or crude extract) as the second cue. This matrix could yield diamino acids that act through the regulatory pathway. Alternatively, the synergy may involve inducers/receptors not yet characterized.

Settlement Cues for use in Hatcheries

Unpredictable settlement rates complicate post-larval culture by giving variable post-larval densities. Low or intermediate rates of settlement are very unpredictable, so hatcheries should aim for consistently high percentage metamorphosis. Ideally metamorphosis would also occur very rapidly so that full water flow and full aeration can be resumed as soon as possible, without risking loss of larvae. Very few settlement cues are able to deliver on these requirements.

Crustose coralline algae meet these settlement requirements but are generally regarded as unsuitable for use in hatcheries because they may harbor predators, are slow growing, must remain wet and lack established culture methods. Their potential use has not been fully evaluated, and selected species may prove valuable with further research. Very thin crusts grow relatively quickly (McShane 1996) and do not host the predatory worms that live within thicker crusts (Morse et al. 1979b, Naylor & McShane 1997). The food value of corallines for post-larval abalone is generally low (Leighton 1989, Kitting & Morse 1997), so they would need to be supplemented with diatom food. Some corallines will inhibit the growth of diatoms (A. Krsinich, pers. comm.) but corallines need only cover a small proportion of plates to trigger settlement. Controlled culture of certain corallines is feasible (S. Daume, pers. comm.) and growth rates are not critical if only a small proportion of the surface needs to be covered at settlement.

GABA is a very convenient and simple cue, and is used in some commercial hatcheries, particularly in Mexico and the USA (Morse 1992, Searcy-Bernal 1994, Searcy-Bernal & Anguiano-Beltrán 1998). Its performance appears to vary among abalone species, and between occasions (e.g., Table 3). GABA is susceptible to degradation by microbes but this can be counter-acted to some extent by doubling the GABA concentration (Searcy-Bernal & Anguiano-Beltrán 1998) or by settling larvae in clean tanks and adding diatom food a few days later (Searcy-Bernal et al. 1992a; Roberts et al. 2001). It may also become a non-issue if larval sensitivity could be affordably enhanced 10-fold by addition of diamino acids (Trapido-Rosenthal & Morse 1985), or if short exposures to high concentrations of GABA (e.g., Shilling et al. 1996, Buchal et al. 1998) prove practical in hatcheries. GABA causes arrest of swimming activity, so larvae attach and metamorphose largely on non-vertical surfaces. This is impractical in many systems (e.g., Leighton 1989), including those employing stacks of vertical plates (although see Salas-Garza et al. 1994). Angled plates may catch a large proportion of larvae, but a more elegant alternative would be to utilize a combination of diatoms and GABA. A diatom film is likely to induce attachment over filmed plates or tank surfaces within a day or so. Once attachment had occurred, addition of GABA would trigger metamorphosis of attached larvae, provided the GABA had time to act before it was degraded by microbes.

Ungrazed diatom films alone provide little certainty for larval settlement in hatcheries. Few strains induce consistently high metamorphosis, and the need for a dense film at settlement can rapidly lead to excessive biofilm and adverse conditions for post-larvae. By contrast, pre-grazed films generally induce high rates of attachment and metamorphosis, and the reduction of biomass by grazing will help avoid excessive biofilm. Films grazed for several weeks are expected to be more reliable because of the selection for certain algae that are favorable for settlement. However, even young films grazed for one to three days appear to be efficient settlement inducers. GABA could be used in conjunction with diatom films, as discussed above.

Differences and Similarities Among Abalone Species

Comparison between species is often complicated by differences in methodology (see above). A few studies have compared abalone species using equivalent assay methods, and provide compelling evidence of real differences in settlement responses between abalone species. Two examples (reviewed above) are the response of *Haliotis iris* and *Haliotis virginea* to GABA (Table 3, Fig. 5) and the response of *Haliotis rubra* and *Haliotis laevigata* to several diatom strains (Daume et al. 1999b). These examples warn of differences in chemical signaling that result in fundamentally different responses between abalone species. However, in many respects the larval settlement response appears to be conserved across abalone species. Examples reviewed above include the widely observed positive response to crustose coralline algae and pre-grazed diatom films.

Ecological Relevance of Chemical Inducers

Chemical extraction procedures liberate hundreds of compounds from the source material without preserving the spatial or stereochemical context of the intact surface. This creates the potential to identify inducers that are merely artifacts of the extraction and purification process (e.g., Morse 1990). It is accordingly difficult to prove that a compound isolated from a settlement substratum is ecologically relevant. The extensive work by Daniel Morse and colleagues, working with *Haliotis rufescens*, presents a compelling case for a GABA-mimetic peptide from *Lithothamnium californicum*. However, this molecule could be just one of many inducers available in the marine environment. Dibromomethane has also recently been suggested as an ecologically relevant settlement inducer for abalone (Seki et al. 1997), but further evidence is required to demonstrate this. Most other pure chemicals that induce abalone settlement are not proposed to be ecologically important.

Is Settlement Exclusive to Coralline Algae in the Wild?

This review has noted the close association between juvenile abalone and crustose coralline algae, and the consistently excellent inducing activity of corallines in laboratory settlement experiments. However, experiments show that abalone larvae can also settle in response to many substrata that are present in abalone habitat including other macroalgae, abalone trail mucus, and biofilms (reviewed above). These experiments are artificial in that they usually confine larvae with a substrate. In the wild, larvae may be more likely to settle on first contact if they land on coralline algae rather than some less effective cue. This contention is supported by the rapidity with which abalone metamorphose on coralline algae compared to many other cues in laboratory assays. Settlement choice experiments in laboratory conditions would be

instructive, and have already demonstrated that larvae exhibit preferences for certain coralline algal species (Daume et al. 1999a).

Artificial collectors conditioned with algal films or pre-grazed films then placed in abalone habitat do contain abalone post-larvae after 1–8 weeks in the sea (Keesing et al. 1995, Nash et al. 1995). These data suggest that abalone larvae do naturally settle on surfaces other than corallines, but it is possible that corallines had colonized the plates during conditioning or deployment and triggered larval settlement. Settlement deterrents from algae (e.g., Taniguchi et al. 1989) and sessile invertebrates may play a major role in discouraging settlement on many surfaces, although Morse and Morse (1984a) rejected the idea that abalone's preference for corallines was due to the toxicity of other algae tested.

The distribution of post-larvae or juveniles on natural surfaces can be influenced by post-settlement survival or migration, so it is not necessarily a reliable indicator of settlement sites. Corallines do not provide a perfect surface for abalone post-larvae. Corallines appear to give relatively slow growth rates of post-larval abalone when compared to benthic diatoms (Kitting & Morse 1997, Takami et al. 1997, Kawamura et al. 1998), they can harbor predators (Morse et al. 1979b, Shepherd & Daume 1996, Naylor & McShane 1997) and they generate moderately steep gradients in boundary layer water chemistry (Kaspar 1992). However, they may still represent a better option than other surfaces.

Research Needs

The ability of this review to generalize about the effectiveness of abalone settlement cues has been hampered by differences in methodology between experiments, and often by the lack of data on metamorphosis as distinct from larval attachment. It is hoped that this review will encourage the use of appropriate terminology and methodology. Most abalone larval settlement experiments will aim to either: (1) separate treatment effects from all possible alternatives in tightly controlled laboratory conditions; (2) determine the usefulness of selected treatments to commercial abalone farming; or (3) attempt to describe settlement patterns or processes in the sea. Small-scale experiments attempting to mimic hatchery or field conditions risk falling between two aims. Laboratory experiments will continue to be necessary and informative in research on abalone settlement cues, but there is currently a disproportionate amount of laboratory data and a corresponding need for laboratory results to be assessed in commercial abalone farming systems or natural habitats.

Despite many years of commercial abalone farming around the world there are very few published data describing settlement success in full-scale commercial conditions. The rigor of laboratory studies needs to be coupled with the reality of commercial scale hatchery conditions, and quantitative, microscopic observations made over time. This will create challenges in terms of controlling experimental conditions and obtaining adequate experimental designs and sub-samples, but when achieved will yield very valuable information. Further research on the hatchery application of coralline algae, trail mucus and commercially available chemicals such as GABA would be valuable. A chemical inducer that could be bound to plastic surfaces would be ideal for the many hatcheries that use vertical plates. Hatchery experiments should aim to assess cost-effectiveness as well as biological success. Issues such as practicality and predictability will influence the cost-benefit equation.

The chemistry of abalone settlement induction remains very poorly known, with the exception of the GABA-mimetic system studied in *Haliotis rufescens*. It would be interesting to screen for proposed "natural" cues (i.e., GABA-mimetics and dibromomethane) on various inductive substrates, to determine whether known cues explain the activity of diverse substrates, or whether there are multiple alternative pathways for settlement induction in abalone. The chemical basis of settlement induction by biofilms should be a priority, as biofilms induce settlement in a very wide range of invertebrates, and have economic importance in abalone farming and biofouling control. The mechanisms underlying the synergy between cues are academically interesting and have potential to aid abalone farming.

The role of bacteria in settlement induction by diatom films and trail mucus is unknown. Bacteria will certainly be degraders of organic inducer molecules, but may also play a critical role as producers or modifiers of inducers. Settlement assays conducted under axenic conditions would be useful in separating microbial effects from other cues, and in determining whether abalone can metamorphose spontaneously.

Field experiments offering a range of natural substrata should help clarify the apparent paradox between the wide range of potential inducers for abalone settlement and the tight association between juvenile abalone and crustose corallines in the wild (McShane 1995). The extent of settlement deterrence by algae and sessile invertebrates (McShane 1995), and further examination of preferences for certain coralline species (McShane 1996), could be incorporated in these studies. Observations from larval settlement through the post-larval period would provide direct evidence about the relative contribution of settlement and post-settlement processes in determining spatial variation in juvenile recruitment between microhabitats. These studies would be useful in site selection for larval reseeding programs.

ACKNOWLEDGMENTS

Special thanks to Hideki Takami and Tomohiko Kawamura for supplying literature and unpublished data, and for help with interpreting Japanese papers. Thanks to Henry Kaspar for many useful discussions, and comments on the manuscript. Thanks to Shirley Plant and two anonymous referees for critical review of the manuscript. Sabine Daume, Anton Krsinich, Daniel Jackson, Regina Counihan, Bernie Degnan, Ricardo Searcy-Bernal, Scoresby Shepherd, and Tetsuo Seki all contributed by supplying data. Thanks to Tomohiko Kawamura for supplying Figures 2 and 3. This review was supported by funding from contracts CAW 801 and CAW X0004 with the New Zealand Foundation for Research Science and Technology.

EFFECT OF BIOFILM DENSITY ON GRAZING AND GROWTH RATES OF *HALIOTIS FULGENS* POSTLARVAE

RICARDO SEARCY-BERNAL,* LUIS A. VÉLEZ-ESPINO, AND CASANDRA ANGUIANO-BELTRÁN

Instituto de Investigaciones Oceanológicas, Apartado Postal 453, Ensenada 22860, Baja California, México

ABSTRACT Grazing rates of *Haliotis fulgens* postlarvae of different ages (7, 15, 30, 45 and 60 days), feeding on the cultured diatom *Navicula incerta*, were estimated in 10 ml sterile plastic dishes previously inoculated with different densities of the diatom (100–4,000 cells/mm^2). Postlarvae (3–7 per dish) were allowed to graze for two to three hours and video recordings were taken to estimate postlarval size and grazing rates by digital image analysis. Seawater was changed every other day and postlarvae were measured again after six to eight days to estimate growth. Grazing and growth rates of postlarvae older than 15 days increased linearly with biofilm density. The highest grazing rates for seven and 60 day-old abalone were 79 and 10,999 cells/postlarva/hour, respectively. The most important increase in grazing activity occurred between ages 45 and 60 days when postlarvae reached 1.5–2.0 mm and started the formation of the first respiratory pore. Implications for the management of production systems are discussed.

KEY WORDS: abalone postlarvae, *Haliotis fulgens*, grazing rates, biofilms

INTRODUCTION

In culture systems, abalone (*Haliotis spp.*) postlarvae feed on biofilms dominated by benthic diatoms and bacteria (Hahn 1989, Kawamura 1996). A key problem in this production stage is how to keep an adequate balance between postlarval feeding and diatom supply. If grazing is excessive, starving conditions may severely impact postlarval survival and growth. In the opposite situation, overdeveloped biofilms may also create deleterious conditions leading to massive losses of postlarvae (Ebert & Houk 1984, Hahn 1989, Searcy-Bernal et al. 1992, Tong & Moss 1992, Searcy-Bernal 1996).

Most studies on abalone postlarval feeding, have focused on the effect of different diatoms on postlarval growth, on the factors affecting their food value (Kawamura et al. 1998a, Roberts et al. 1999), and on changes in diatom selectivity and digestion as postlarvae grow (Norman-Boudreau et al. 1986, Matthews & Cook 1995, Seki & Taniguchi 1996, Kawamura et al. 1998b, Takami et al. 1998, Roberts et al. 1999).

The quantitative assessment of postlarval grazing is crucial to understand these complex culture systems and to suggest better management options. However, despite its importance, this issue has received little attention. Martínez-Ponce and Searcy-Bernal (1998) provided the first estimates of abalone postlarval grazing, by measuring cleared areas by *H. rufescens* postlarvae fed known densities of the benthic diatom *Navicula incerta*, using the digital analysis of video-recorded images. Roberts et al. (1999) estimated consumption rates of *H. iris* postlarvae fed different diatom strains, by determining fecal production. Both studies concluded that grazing increases rapidly as postlarvae grow, after the first one to two weeks after settlement. Body size is one of the main factors determining grazing rates of juvenile abalone (Marsden & Williams 1996).

Preliminary data suggest that, besides postlarval size and diatom species, the density of biofilm may also affect postlarval grazing and growth rates. This article explores this relationship for *Haliotis fulgens* (Philippi 1854) fed the diatom *N. incerta*. According to general concepts on the response of consumers to food abundance (Valiela 1995), grazing rates were expected to increase with diatom density until saturation values were reached (type II functional response).

MATERIALS AND METHODS

Veliger larvae were produced at the hatchery of Cooperativa Emancipación, S.C.L. (Puerto Nuevo, B.C.S., México) and transported to the Instituto de Investigaciones Oceanológicas (I.I.O.) (Ensenada, B.C.), where they were reared in 1-μm filtered, UV treated seawater with chloramphenicol (10mg/l) added, changed every day. Competent larvae were induced to metamorphose in 20L plastic containers with 1.5 μM gamma-aminobutyric acid (Searcy-Bernal and Anguiano-Beltrán, 1998). The cultured diatom *Navicula incerta* (~200 cells/mm^2) was added at day 2 after settlement. This benthic diatom (~13 μm length) was isolated from local coastal waters and is currently used in research and commercial operations in México. Postlarvae were cultured in these containers with seawater (treated as described) changed every two days for the first two weeks, and with flowing 5-μm filtered seawater (~300 ml/min) thereafter. Constant fluorescent illumination (~50μE/m^2/s) and gentle aeration were provided. Temperature fluctuated between 17 and 19°C.

Postlarvae were collected from the culture system at days 7, 15, 30, 45 and 60 after settlement and introduced to containers (10-ml wells of sterile culture dishes, 3–7 postlarvae per well), previously inoculated with *N. incerta* at target densities of 100, 500, 750, 1000, 2000, and 4000 cells/mm^2 (with the exception of trials with seven-day-old postlarvae where the higher density was substituted by 1,500 cells/mm^2). Before the preparation of experimental densities, batch cultures of this diatom were immersed in an ultrasound bath for 3–5 min and filtered through a 20 μm sieve to disperse cells. A randomized block design with three replicates per diatom density was originally considered for each postlarval age (with the exception of age 45 days where only two replicates were used).

Two to three hours after the introduction of postlarvae to the experimental units, video-images were recorded (Sony SSC-C374 high resolution camera) on an inverted microscope (Meiji Techno) and digitally analyzed (NIH Image 1.59, PowerPC Macintosh computer) to measure postlarval shell length, and to determine

*Corresponding author. E-mail: rsearcy@faro.ens.uabc.mx.

cleared areas and actual diatom densities. Grazing rates (cells/postlarva/h) were estimated by multiplying cleared areas by diatom densities. Previous experience had shown that postlarvae start feeding activity almost immediately after their introduction in vessels (i.e. in less than 2 min) and that *N. incerta* growth and recolonization of cleared areas are negligible during this 2–3h period (Martínez-Ponce & Searcy-Bernal 1998).

Experimental containers were maintained for six days (19 ± 1°C, 4 μE/m^2/s) with seawater (treated as described) changed every 48 hours (with the exception of 7-day-old postlarvae). Postlarval shell length (SL) was measured at the end of this period to determine growth rates (μm/d).

Because of the high variability in diatom density among replicates (despite the efforts to minimize it), data (average growth and grazing rates) were analyzed considering wells individually. To estimate the maximum grazing and growth rates for each postlarval age, the three highest values were averaged.

RESULTS

Figure 1 shows the shell length of *H. fulgens* postlarvae collected from the culture system at the different ages tested. In the first 15 days growth was slower (14.9 μm/d) than in the period from days 15 to 60 (33.4 μm/d). Mortality of postlarvae of all ages in wells was negligible at all diatom densities during the experimental period (<5%).

Grazing rates of seven-day-old postlarvae averaged 54.5 cells/postlarva/h and were independent from diatom density ($r = 0.319$, $P > 0.05$) (Fig. 2). However, at age 15 days grazing rate increased dramatically, averaging 362 cells/pl/h and showing a positive and significant linear association with diatom density ($r = 0.773$, $P < 0.01$) (Fig. 3a) which was not significant for postlarval growth rates ($r = 0.345$, $P > 0.05$) (Fig. 3b).

At postlarval ages of 30, 45 and 60 days, the dependence of grazing and growth rates on diatom density was stronger (Figs. 4, 5, 6 respectively). Within the range of densities tested, most of these relationships were adequately described by linear regressions, although for 30-day-old postlarvae an asymptotic trend for grazing at higher diatom densities was observed (Fig. 4a). A logarithmic fit to these data resulted in an $r = 0.829$ which is higher than the value for the linear model ($r = 0.655$). In addition, at this age, linear correlation between growth rate and diatom density was not significant because of an outlier (slow growth at the highest density).

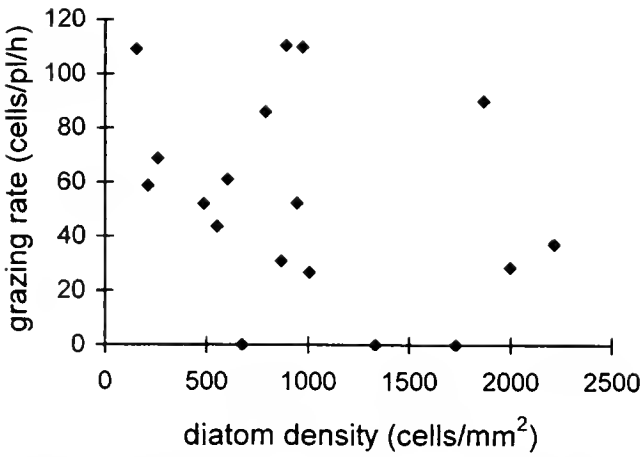

Figure 2. Grazing rates of seven-day-old postlarvae of *H. fulgens* at different densities of the diatom *Navicula incerta*. Data are means for 5–7 postlarvae in experimental units.

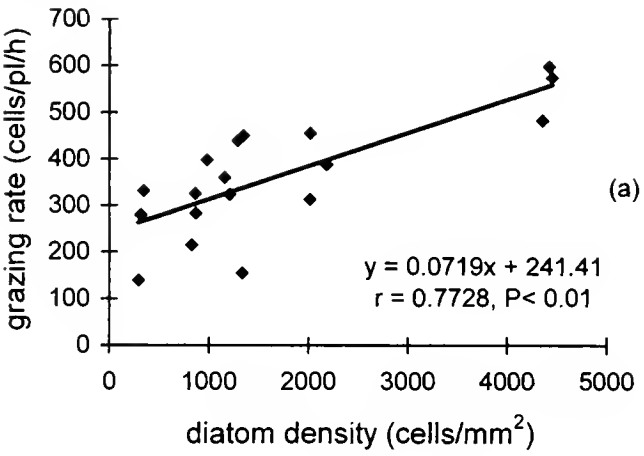

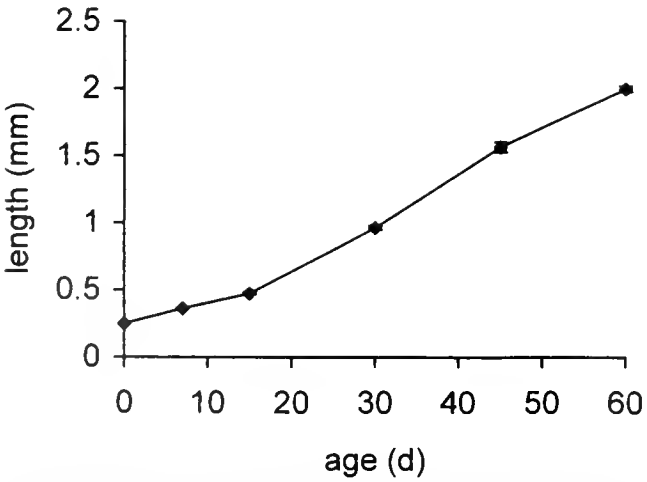

Figure 1. Shell length (mm) of *H fulgens postlarvae* collected from the culture system at different ages (days after settlement) Data are averages of 36–90 postlarvae.

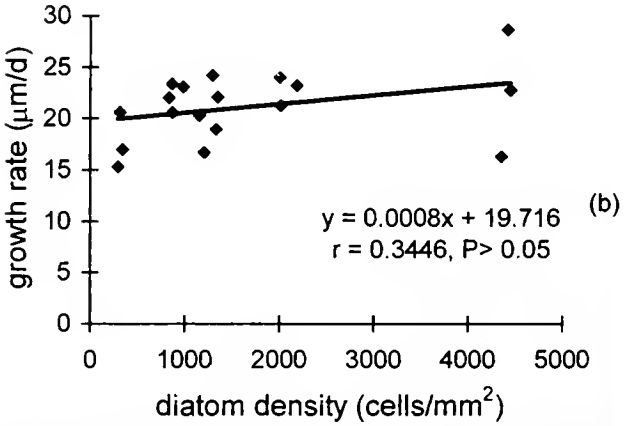

Figure 3. Grazing (a) and growth (b) rates of 15-day-old postlarvae of *H. fulgens* at different densities of the diatom *Navicula incerta*. Data are means for 5–7 postlarvae in experimental units.

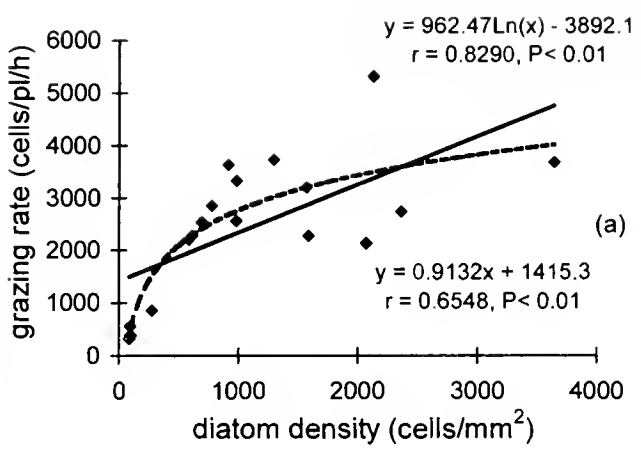

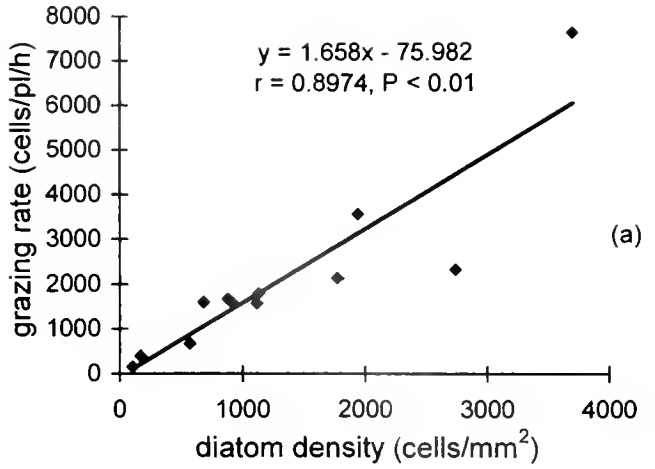

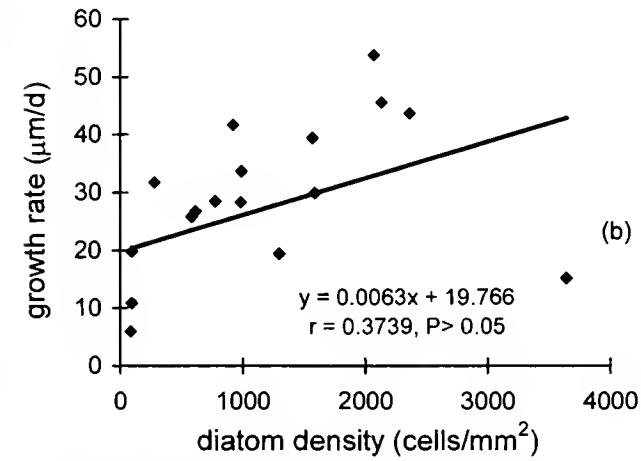

Figure 4. Grazing (a) and growth (b) rates of 30-day-old postlarvae of H. fulgens at different densities of the diatom *Navicula incerta*. Data are means of 3–5 postlarvae in experimental units.

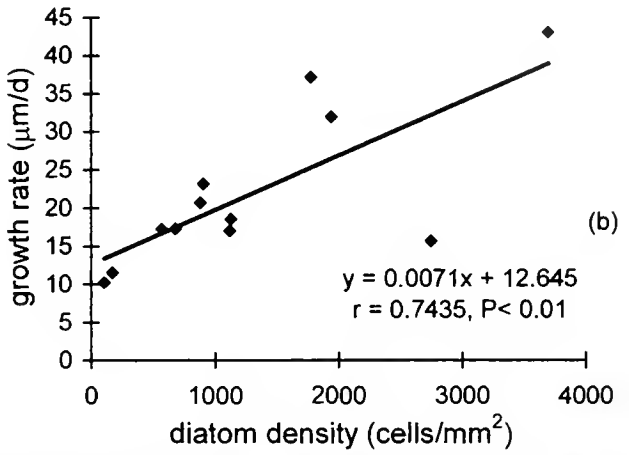

Figure 5. Grazing (a) and growth (b) rates of 45-day-old postlarvae of *H. fulgens* at different densities of the diatom *Navicula incerta*. Data are means of 3–5 postlarvae in experimental units.

The slopes of linear regressions of grazing rates on diatom density increased with postlarval age, but this trend was not observed for postlarval growth rates (Figs. 2–6).

Estimates of maximum grazing and growth rates are presented in Table 1. Maximum grazing rates ranged between 79 and 10,999 cells/pl/h for postlarval ages of seven days and 60 days, respectively, and increased non-linearly with postlarval shell length, following a trend consistent with a power function (Fig. 7). Maximum growth rates did not follow a similar pattern, reaching values of 25.6, 47.6, 37.4 and 39.6 µm/d for ages at 15, 30, 45 and 60 days, respectively.

DISCUSSION

Effects of Biofilm Density on Postlarval Grazing Rates

This study shows that grazing rates of *H. fulgens* postlarvae increase abruptly and become strongly dependent on diatom density the first one to two weeks after settlement. Grazing by earlier postlarvae (seven days) was minimal and independent of food abundance, in agreement with observations on postlarvae of this and other abalone species (Matthews & Cook 1995, Kitting & Morse 1997, Kawamura et al. 1998b, Martínez-Ponce & Searcy-Bernal 1998, Roberts et al. 1999).

Only for 30-day-old postlarvae, results are consistent with a type II functional response of grazing rates to diatom density (Fig. 4a). Grazing rates level off at about 3,500 cells/pl/h, corresponding to an approximate diatom density of 2,000 cells/mm^2. This type of functional response is common in marine consumers (Valiela 1995) and has been recently documented for juveniles (3–4 cm SL) of the abalone *H. asinina* feeding on macroalgae (Tahil & Juinio-Menez 1999) and for the periwinkle *Littorina littorea* feeding on biofilms (Sommer 1999).

In a previous study with one-month-old *H. rufescens* postlarvae an asymptotic trend in grazing rates was also detected, leveling off at around 1,000 cells/pl/h when *N. incerta* reached densities of ca. 1,000 cells/mm^2 (Searcy-Bernal & Cook, in prep.). Differences with *H. fulgens* might be explained by the smaller size of *H. rufescens* postlarvae (~750 µM SL), the lower temperature (~16°C) or might reflect actual inter-specific differences. In high diatom densities (~>2,000 cells/mm^2) many of the *H. rufescens* postlarvae crawled to the walls of wells almost immediately after their introduction into the bottom of containers. This behavior was never observed in *H. fulgens* regardless of the postlarval age or diatom density tested, which suggests that this species is able to cope with denser biofilms.

At the other ages tested—except at age seven days—grazing rates by *H. fulgens* postlarvae increased linearly with biofilm den-

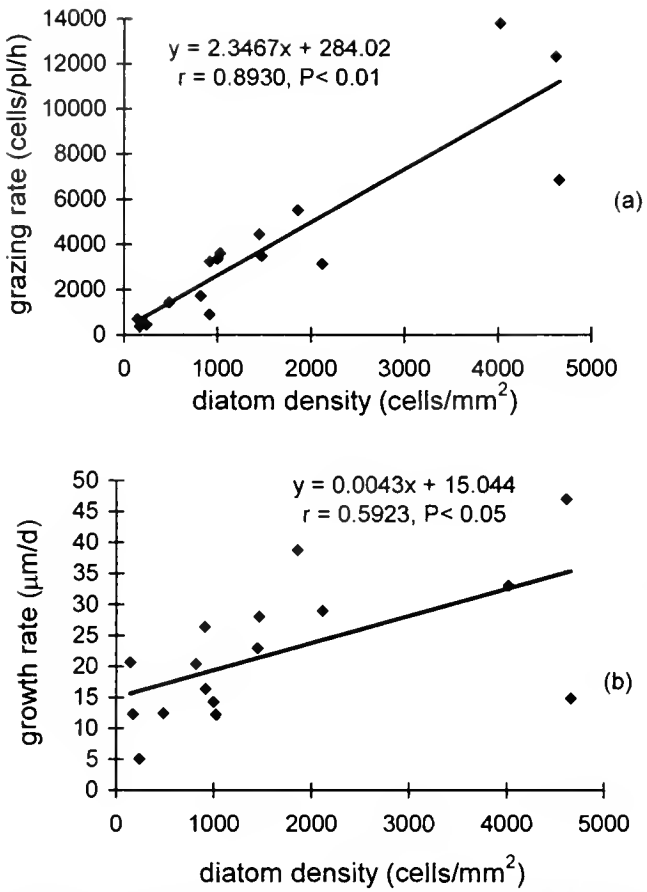

Figure 6. Grazing (a) and growth (b) rates of 60-day-old postlarvae of *H. fulgens* at different densities of the diatom *Navicula incerta*. Data are means for 3–5 postlarvae in experimental units.

sity and no evidence of leveling-off was observed. For older postlarvae (45- and 60-day-old), this pattern may indicate that densities tested were not high enough to produce an asymptotic trend in grazing activity. However, grazing rates of 15-day-old postlarvae would have been expected to level off at a diatom density lower than the correspondent for 30-day-old abalones. This result may be partially influenced by the low grazing activity by 15-day-old postlarvae, which increased dramatically (~10-fold) at age 30 days old (Fig. 3a and Fig. 4a).

TABLE 1.

Maximum grazing and growth rates of *H. fulgens* postlarvae of different ages. Data are means of the three highest values and standard errors are shown in parenthesis.

Age (d)	Length (µm)	Max. Grazing Rate (cells/pl/h)	Max. Growth Rate (µm/d)
7	363.4	78.9	—
	(2.1)	(15.4)	
15	473.5	553.5	25.6
	(8.0)	(35.6)	(1.5)
30	963.1	3,903.1	47.6
	(16.1)	(752.9)	(3.1)
45	1,563.7	4,984.5	37.4
	(37.6)	(2,646.7)	(3.9)
60	2,000.7	10,998.7	39.6
	(22.9)	(2,110.9)	(3.3)

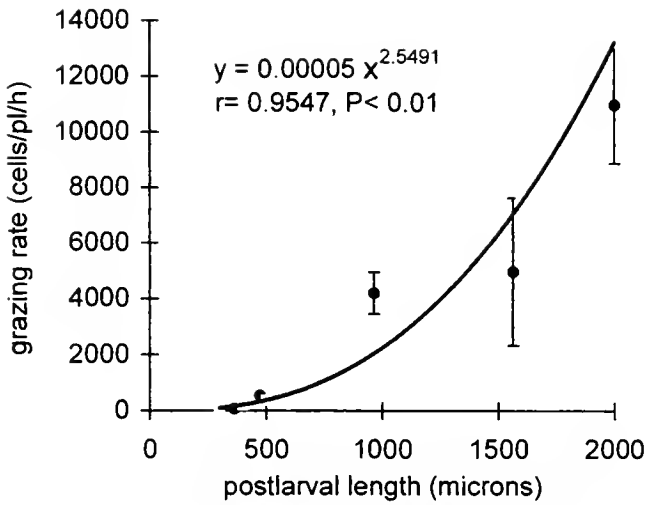

Figure 7. Relationship between maximum grazing rate and length in postlarvae of *H. fulgens*.

Effects of Biofilm Density on Postlarval Growth Rates

In general, postlarval growth rates also increased linearly with diatom density, following similar trends than grazing rates (Figs. 3–6). This may reflect the obvious relationship between food consumption and growth, despite the fact that grazing rates correspond to the first two to three hours of the experiment and growth rates to the total six-day period. Since diatom density at the end of that period was usually lower than the initial (although probably proportional), the quantitative relationships between growth and biofilm density can only be considered as a first approximation.

It should be noted, however, that moderate differences of diatom densities may produce dramatic differences in growth. In trials with 30, 45, and 60 days postlarvae, growth rates after 6 days at 2,000 cells/mm^2 were more than 50% higher than those at 1,000 cells/mm^2 (Figs. 4b–6b). This short-term effect, in conjunction with patchiness of postlarvae and biofilm densities (and composition) in culture systems, may create local areas of differential growth, influencing the size heterogeneity commonly observed since early culture stages (Hahn 1989). This initial size variability would be further maintained and even increased by intra-specific competition. Therefore, mechanisms underlying growth heterogeneity in abalone postlarvae, may not be only genetic or related to metamorphosis induction as commonly suggested (Hahn 1989, Morse 1992), but may also relate to early feeding history.

The effect of diatom density on abalone postlarval growth, should also be considered for research purposes. For instance, a study may conclude that postlarvae grow better in diatom A than in diatom B, only because diatom A was provided at a more adequate density.

Grazing and Growth Rates of Postlarvae as a Function of Shell Length (SL)

According to the power function fitted, (Fig. 7) maximum grazing rates were proportional to $SL^{2.55}$, which indicates a closer relationship to postlarval volume or biomass. Since, as discussed above, the maximum grazing rates calculated here probably underestimate asymptotic values for postlarval ages of 45 and 60

days the actual coefficient of that equation was probably higher. Roberts et al. (1999) found that fecal production (as an indicator of ingestion rate) of *H. iris* postlarvae was proportional to $SL^{2.73}$, which is consistent with our results.

Estimates of maximum growth rates were not proportional to postlarval age or length. The lowest value (25.6 μm/d), corresponded to 15-day postlarvae and the highest (47.6 μm/d) to 30-day postlarvae, reflecting an increased effect of diatom grazing. Again, potential growth rates for 45-day and 60-day postlarvae were probably underestimated as a consequence of the range of diatom densities tested. The low variability in growth rate of postlarvae during development, is consistent with the nearly linear increase in SL after the first one to two weeks of abalone postlarval culture, reported here (Fig. 1) and in other studies (Searcy-Bernal et al. 1988, Flores-Aguilar 1989, Kawamura et al. 1998b, Martínez-Ponce & Searcy-Bernal 1998).

ACKNOWLEDGMENTS

The authors are grateful to Cooperativa Emancipación S.C.L. (Puerto Nuevo, B.C.S., México) for the donation of *H. fulgens* larvae and to Enrique Valenzuela, head of the I.I.O. Microalgae Laboratory, for the supply of the diatom *Navicula incerta*. This study was partially funded by the Mexican government (CONACyT grants 4023P-B; SNI grant 5532) and the University of Baja California (grant 4040).

ABSTRACT Larval development of *Haliotis asinina* Linnaeus was observed under water temperatures of 25 C, 28 C, 31 C, and 34 C from fertilization to the formation of the fourth tubules on the cephalic tentacles. The larvae had 42 stages of development. The time-period of larval development depended on the water temperature: it was 65, 49, 41 and 41 h at water temperatures of 25 C, 28 C, 31 C, and 34 C, respectively. After settlement, the development of post-larvae through the formation of the first respiratory pore was observed under room temperatures (28°C–35°C). The velum was shed and the mantle began to secrete a new shell. Mouth, radula and digestive organs were developed by the third day of settlement. The heart was seen on the fourth day. The prominent structure on the roof of the mantle cavity was the etenidium. The second pair of epipodial tentacles began to form and the eyestalks were completely developed on the eighth day after settlement. From day 9 to day 24, the post-larvae increased in shell size and number of epipodia and tubules on the cephalic tentacles. The etenidium became more developed. The first respiratory pore began to form on day 24 to 30.

KEY WORDS: abalone, larval development, *Haliotis asinina*

INTRODUCTION

The life cycle of abalone is composed of larva, post-larva, juvenile and adult stages. The larval stage begins with fertilization and ends with the formation of the fourth tubule on the cephalic tentacles (Hahn 1989a). Then, the larvae begin to settle and undergo metamorphosis. The deposition of the peristomal shell marks the transition from the larval to the post-larval stage (Hahn 1989a). The post-larval period continues until the formation of the first respiratory pore (notch stage). From the notch stage until sexual maturity, the abalone is called a juvenile (Leighton 1974).

Larval development is a gradual process that does not occur in discrete stepwise stages. However, various stages can be recognized during larval and post-larval development (Hahn 1989a). In *Haliotis discus hannai* (Ino 1952), there are 41 distinct larval stages with recognizable external features, from fertilization until initiation of metamorphosis (Seki & Kan-no 1977). These morphological features and the order of their appearance in larval developmental stages provide guidelines for studies of larval development in other abalone species. After the larvae settle, 11 recognizable external features appear following the appearance of the cilia in the mantle cavity. These are confirmed to be the characteristics occurring before metamorphosis (Seki 1997).

The larval development rate is measured by the time required for larvae to exhibit features distinctive to each stage (Hahn 1989a). Water temperature is the major factor that affects the larval development rate (Leighton 1974, Ebert & Houk 1984, Owen et al. 1984, Hahn 1989c). Abalone seed production in Thailand has remained in a primitive and small-scale stage for a long period. This is partly because of the difficulty in planning spawning, and the high mortality in the early developmental stage (Seki 1997). Studies of developmental morphology, behavior and the biological requirements of abalone larvae during settlement and metamorphosis can be applied to improve the technology for the abalone seed production systems. An understanding and knowledge of larval development can thus lead to improved techniques and management in abalone hatchery systems. The objective of the present study was to study the larval development of *Haliotis asinina* Linnaeus.

MATERIALS AND METHODS

Conditioning of Broodstocks

The broodstocks of abalone *H. asinina* (81.4 cm in shell length, 132.6 g in weight) were naturally conditioned in 10 tons concrete race-way tanks at the Coastal Aquaculture Development Center, Prachuap Khiri Khan Province, Thailand. The water temperature was 30–33°C. A flow-through system with a flow rate of 2–3 l/min was employed. The broodstocks were fed macroalgae such as *Gracilaria fisheri*, *G. tenuistipitata* and *Acanthophora* spp. Every month, the abalone were examined for gonad maturation, which was determined by size and color according to Ebert and Houk (1984). When gonad maturation reached stage 2–3 (Ebert & Houk 1984), the abalone were transferred to the spawning room for induced spawning.

Induced Spawning

Spawning of *H. asinina* was induced during April to August, 1998, by using UV-filtered seawater. Males and females were separated in 500 L rectangular flow-through system tanks of filtered seawater with a flow rate of 2–2.5 L/min. The spawning tanks were illuminated by a 40-watt cool white fluorescent lamp (1000 lux). Each tank contained 50–60 abalone. The spawning room was set up with the following photoperiod: light (6:00 PM to 6:00 AM) and dark (6:00 AM to 6:00 PM). The abalone were reared under this reversed photoperiod for seven to ten days before spawning occurred. At 11.00 AM, the tanks were cleaned and the UV-filtered seawater was put in under a static condition. Released eggs and sperms were collected separately in a 5 L container. The fertilization period was 30 minutes after spawning. The water temperature during the fertilization period was 30–33°C.

Observation of Larval Developmental Stage

The observation of larval development of *H. asinina*, from fertilization to initiation of settlement, followed 41 stages of larval

*Corresponding author. E-mail: saowapa@bims.buu.ac.th

development described by Seki and Kan-no (1977) and Seki (1997). All experiments were performed with pooled larvae in 5-l containers until the larvae reached the last stage of larval development. Immediately after fertilization, the eggs were placed in the experimental container. Each container contained 5 eggs/ml. These were then placed under four temperature conditions: 25°C and 28° C (in controlled room temperature), 31°C and 34 C (in water baths) and at ambient temperatures of 28–35°C which served as controls. Each experiment was performed in triplicate.

The observation of larval development, carried out under a transmission compound microscope, started immediately after fertilization and was continued every five minutes until the embryos reached stage 10 or gastrula stage. After the gastrula stage, larval development was observed every 30 minutes until the embryos reached stage 41, which was the last stage of larval development. The observation of larval development continued once a day after settlement until the abalone produced the first respiratory pore. This was done in a 250 L settlement and hatchery tank containing diatom plates (*Nitzschia* sp.). The developmental stages after settlement through to the beginning of the juvenile stage followed those of Seki and Kan-no (1977) and Seki (1997).

Effects of Temperature on Larval Development

Biological Zero Point

The biological zero point is the critical water temperature at which the abalone larvae can develop completely until settlement. It was calculated from the development rate of some developmental stages (Seki & Kan-no 1977), such as hatch-out, formation of the larval retractor muscle, 90-degree torsion, formation of the epipodial tentacle and formation of the fourth tubule on the cephalic tentacles.

Effective Accumulative Temperature

The effective temperature is the difference between the water temperature and biological zero point and the quantity above the biological zero point that has an additive effect toward larval development. The summation of effective temperature value during larval development is called the effective accumulative temperature (EAT) which was calculated according to Seki and Kan-no (1977).

RESULTS

Spawning

According to the experiment, the reversal of photoperiod affected the spawning time of *H. asinina*. That is, they spawned during the day (12:00 AM–1:30 PM) instead of at night (12:00 PM–1:30 AM). The males spawned between 12:15 AM and 1:30 PM and the females spawned between 12:30 AM and 1:30 PM.

Larval Size

The eggs of *H. asinina* were dark green in color. The pigments were concentrated at the vegetal pole, while the animal pole was transparent yellowish. The average size of unfertilized eggs was 88.0 ± 8.0 μm in width, 102.4 ± 3.6 μm in length and the nuclear size of eggs was 70.4 ± 6.7 μm. After fertilization, the egg size increased; their width, length and nuclear size were 126.4 ± 17.1, 148.2 ± 10.4 and 99.5 ± 16.3 μm, respectively (Table 1). Egg size did not change until hatch-out stage. The width and length of *H. asinina* trochophore larvae were 105.3 ± 4.1 and 130.7 ± 4.8 μm, respectively (Table 1). After the larvae developed to completion of the larval shell, the size of the larval shell did not change until secretion of the juvenile shell. The first respiratory pore started building after they reached the size of 1142.4 ± 94.6 (width) × 1530.2 ± 140.7 μm (length) (Table 1).

TABLE 1.

The size of H. asinina larvae (μm), from fertilization to formation of the first respiratory pore.

Stage	Size (μm ± S.E.)	
	Width	Length
Unfertilized eggs	88.0 ± 8.	102.4 ± 3.6
Fertilized eggs to hatch out	126.4 ± 17.	148.2 ± 10.4
Trochophore larvae	105.3 ± 4.	130.7 ± 4.8
Completion of velum	108 ± 3.	135.3 ± 2.9
Larval retractor muscle	110.7 ± 4.	139.5 ± 4.2
Completion of larval shell	174.5 ± 6.	242.0 ± 6.4
Formation of operculum	175.5 ± 6.	239.8 ± 5.9
Fourth tubule on cephalic tentacle	178.3 ± 5.	245.7 ± 4.6
First day of settlement	178.8 ± 5.	247.7 ± 2.5
Beginning of first respiratory pore formation	1142.4 ± 94.	1530.2 ± 140.7

N = 30

Larval Development

The larvae of *H. asinina* had 42 stages of development (Table 2, Fig.1, Fig. 2). Shortly after fertilization (stage 1), the first polar body was discharged (stage 2) followed quickly by discharge of the second polar body (stage 3). Cleavage began after discharge of the polar bodies and development progressed to the gastrula (stages 4–11). Cilia grew along the top of the embryo forming the prototrochal girdle and apical tuft, and began beating (stage 12). The cilia caused the embryo to rotate intermittently inside the egg membrane. The stomodeum formed (stage 13) and cilia along the prototrochal girdle were completely formed (stage 14). At this stage, the embryo was classified as a trochophore larva. The larva began moving more frequently inside the egg membrane, the egg membrane became thinner, and finally burst (stage 15). The apical cilia aided the larva in bursting the egg membrane during hatch-out. The hatched larva immediately swam to the water surface.

Soon after hatch-out, the larval shell began to be secreted at the back of the larva (stage 16). The trochophore larva continued to develop until it became a veliger larva. The larva was classified as veliger when the apical region became flat and the velum was completely developed with long cilia present (stage 17).

The larval retractor muscle formed (stage 18), followed by formation of an integumental attachment to the larval shell (stage 19). The foot mass protruded from the top of the shell (stage 20) at completion of the larval shell (stage 21). During torsion, the cephalo-pedal mass rotated a 90-degree angle followed by the top of the mantle membrane tearing off from the top of the larval shell (stage 22). The velum and cephalo-pedal mass rotated relative to the region of the body covered by the larval shell. The region destined to become the mouth and the foot continued to rotate, until the cephalo-pedal mass was rotated at a 180-degree angle from its original position (stage 23).

TABLE 2.

The rate of larval development (hours) of *H. asinina* at water temperatures of 25, 28, 31, 34 C and room temperatures (28–35 C).

Sequence	Larval development stage	Time period of larval development (h)				
		25 C	28 C	31 C	34 C	28–35 C
1	Fertilization	0.00	0.00	0.00	0.00	0.00
2	First polar body	0.25	0.25	0.25	0.25	0.25–0.33

* the stages used for calculating the biological zero point.

There were three pairs of long spines at the posterior end of the metapodium after torsion (stage 24). The operculum formed (stage 25) and at this time, the cephalo-pedal mass could be retracted into the shell. In succession, fine cilia developed on the foot sole and began beating (stage 26), a vertical groove formed in the velum (stage 27), the eye spot appeared (stage 28), the propodium formed (stage 29), a cephalic tentacle formed on the velum (stage 30), and cilia began growing on the propodium (stage 31). Cilia formed in the mantle cavity up to the anterior edge of the velum and the cilia began beating (stage 32). The propodium twisted to the side and an apophysis appeared on the propodium (stage 33). A pair of epipodial tentacles formed on both sides of the foot under the operculum (stage 34) and crawling on a surface with its foot was now possible at this stage.

The otolith formed and was clearly visible (stage 35), short spines appeared on the cephalic tentacles (stage 36), production of the snout began from underneath the velum (stage 37), two tubules appeared on the cephalic tentacles (stage 38), a ciliary process formed on the roof of the mantle cavity (stage 39), and a third tubule formed on the cephalic tentacles (stage 40). The larval retractor muscle attached to the larval shell drew the enlarged mantle cavity toward the back of the shell (stage 41). Larval development was completed with the formation of the fourth tubule on the cephalic tentacles (stage 42).

The total time of larval development depended on the water temperature in the larval tank (Table 2). This was 65 h at 25 C, 49 h at 28°C, and 41 h at 31°C and 34 C. In the control group (28–35 C), the total time of development was 40–41 h.

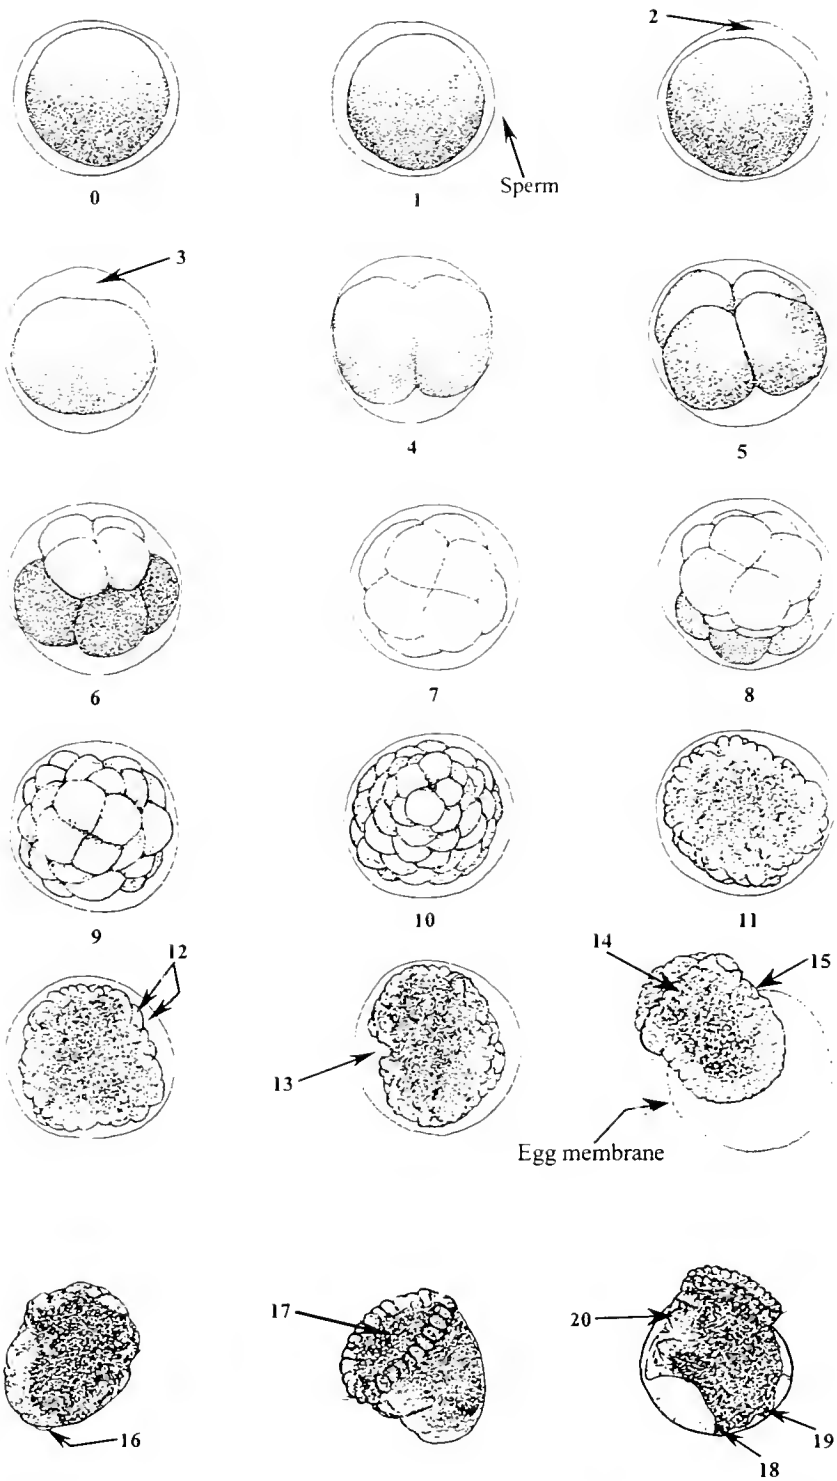

Figure 1. The development of *H. asinina* larvae from egg to the development of the foot mass. 0, unfertilized egg; 1, fertilized egg; 2, discharge of first polar body; 3, discharge of second polar body; 4, first cleavage (2 cells); 5, second cleavage (4 cells); 6, third cleavage (8 cells); 7, fourth cleavage (12 cells, top view); 8, fifth cleavage (16 cells); 9, morula; 10, blastula; 11, gastrula; 12, appearance of prototrochal girdle and cilia along the prototrochal girdle*; 13, appearance of stomodeum (rotation); 14, prototrochal girdle and cilia along the prototrochal girdle are completely formed.*; 15, hatch - out; 16, beginning of larval shell formation; 17, the apical region becomes flat and the velum is completely developed with long cilia present; 18, appearance of larval retractor muscle; 19, appearance of integumental attachment; 20, development of foot mass. * There are 24 cilia surrounding the velum along the prototrochal girdle.

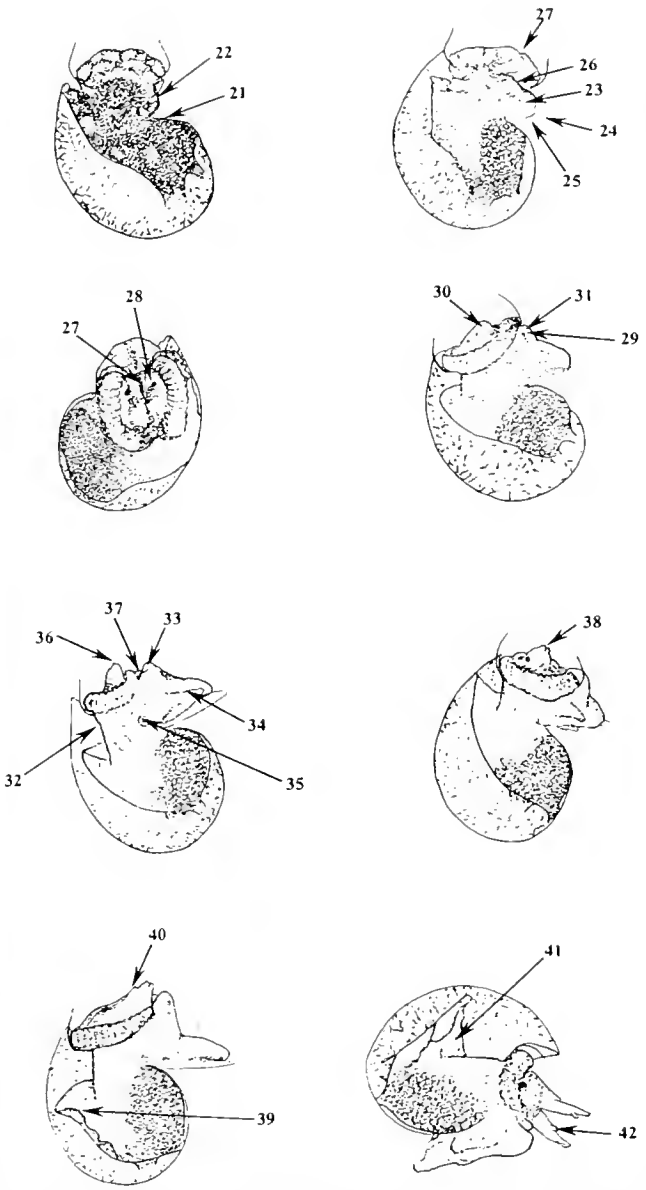

Figure 2. The development of *H. asinina* larvae from the completion of larval shell stage to the appearance of the fourth tubule on cephalic tentacles. 21, completion of larval shell; 22, cephalo-pedal mass 90 degree torsion; 23, foot muscle 180 degree torsion; 24, appearance of spine on end of metapodium; 25, operculum; 26, appearance of fine cilia on foot sole; 27, vertical groove formation in velum; 28, appearance of eye spot; 29, appearance of propodium; 30, appearance of cephalic tentacles; 31, appearance of cilia on the propodium; 32, appearance of cilia in mantle cavity up to the anterior edge of the velum; 33, formation of apophysis on propodium; 34, formation of first epipodial tentacle; 35, appearance of otolith; 36, appearance of spines on cephalic tentacles; 37, protrusion of snout underneath the velum; 38, appearance of two tubules on cephalic tentacle; 39, ciliary process forms on the roof of the mantle cavity; 40, third tubule appearance on cephalic tentacle; 41, the retractor muscle attached to the larval shell draws the enlarged mantle cavity toward the back of the shell; 42, fourth tubule appearance on cephalic tentacles.

After 44 hours, or when the larvae had already formed the fourth tubule on the cephalic tentacles, they were placed in the settlement tank. On the first day of settlement, they were still in the exploration and inspection stage. They were repeatedly swimming with the velum and temporarily crawling over the surface of the diatom plate. On the second day, most larvae were shedding the velum and the mantle membrane moved to the shell edge. Some larvae had already secreted the new shell. The settled larvae had already formed the fifth and sixth tubules on the cephalic tentacles and the ciliated process was already formed near the right cephalic tentacle. At this stage, all were crawling on the plate. In the mantle cavity, the cilia on the roof of the mantle were beating to circulate the water and functioned as a ctenidium. However, some larvae still had the velum and were still in the exploration and inspection stage. On the third day of settlement, the juvenile shell increased in length. The post-larvae began to feed on diatoms that were smaller than 10 μm. On the fourth day, the heart began to form and was beating. On the roof of the mantle was a prominent structure that developed into the ctenidium. The juvenile shell increased in length. On day eight, the second pair of epipodia began to form and the number of tubules on the cephalic tentacles increased. The eye stalks were completely developed. From day nine to day 24 of the post-larvae stage, the number of ctenidia and epipodia increased. The juvenile shell increased in size. The first respiratory pore began to form on day 24 to day 30.

Effects of Water Temperature on Larval Development

Biological Zero Point

The biological zero point was calculated from the developmental rates of hatch-out, formation of larval retractor muscle, 90 degree torsion, formation of epipodial tentacles and the fourth tubule on the cephalic tentacle stage of *H. asinina* at temperatures of 25°C, 28°C, 31°C, and 34°C. In this experiment, the biological zero point of the larval development rate at 34°C was not calculated because it was close to that of the development at 31°C. The average biological zero point of *H. asinina* was 15.0 ± 0.3°C (Table 3).

Effective Accumulative Temperature

The important stages of larvae in the aspect of abalone aquaculture management are hatch-out, completion of larval shell, formation of the first epipodial tentacle and the fourth tubule on the cephalic tentacles (Hahn 1989a). The effective accumulative temperatures at water temperatures of 25°C, 28°C, 31°C, and 34°C were 95, 98, 96 and 114°C-hour, respectively, in the hatch-out stage; 165, 176, 176 and 209°C-hours, respectively, in the comple-

TABLE 3.

Equation of relationship between water temperature and time inversion of beginning formation of the fifth larval developmental stage (1/time) and biological zero point of the important larval stages of H. asinina.

Larval developmental stage	Equation of relationship	Biological Zero Point
Hatch out	$1/t^a = 0.0102T^b - 0.1515$	14.9
Larval retractor muscle	$1/t = 0.0073T - 0.1091$	14.9
Torsion (90° twisting)	$1/t = 0.0052T - 0.0768$	14.8
First epipodial tentacle	$1/t = 0.0023T - 00356$	15.5
Fourth tubule on cephalic tentacle	$1/t = 0.0015T - 0.0220$	14.7
	Average	15.0 ± 0.3

[a] t = hours, [b] T = °C

tion of the larval shell stage; and 650, 637, 656 and 779.0°C-hours, respectively, in the formation of the fourth tubule on cephalic tentacle stage (Table 4). From observation, a high incidence of abnormal development and mortality was found in larvae reared in water higher than 31 C.

DISCUSSION

The pigments of abalone eggs were derived from maternal yolk and they were retained through the trochophore and veliger larvae. The color of abalone eggs and larvae varies among species. They were dark green in *H. asinina*, brown in *H. fulgens* Philippi, beige in *H. sorenseni* Bartsch, olive in *H. corrugata* Wood (Hahn 1989a), violet in *H. coccinea canarensis* Nordsieck (Harrison & Grant 1971) and green or blue-green in *H. cyclobates* Péron & Lesueur, *H. laevigata* Donovan, *H. scalaris* Leach and *H. roei* Gray (Shepherd & Laws 1974). In some abalone species, the color of the eggs varies in each stage of development, such as in *H. rubra* Leach (Shepherd & Laws 1974). The pigments in the eggs of *H. asinina* are concentrated at the vegetal pole, while the animal pole is transparent yellowish. This feature is in contrast with those of other abalone species, where pigmentation of the eggs is dark at the animal pole and light at the vegetal pole (Hahn 1989a). In *H. coccinea canariensis*, the animal pole is violet and the vegetal pole is slightly yellowish (Harrison & Grant 1971). The pigments in *H. asinina* also appear in the visceral mass, so that the visceral mass

TABLE 4.

The effective accumulative temperature (EAT) of larval development of *H. asinina* at water temperatures of 25, 28, 31, 34 C and room temperatures (28–35 C).

Sequence	Larval development stage	HEAT (°C – h)

of larvae is dark green, while the foot, velum and cephalic parts are transparent yellowish. *H. sorenseni* larvae are beige in color, while the velar margin is yellowish (Hahn 1989a). In some abalone species, the pigments seem to be concentrated at the velum: for example, *H. fulgens* larvae are generally brown with green velar margins, *H. corrugata* larvae are light yellow-green with a velar fringe of a darker shade of green (Leighton 1974), *H. coccinea canariensis* is orange in visceral mass and violet in foot, velum and cephalic mass (Harrison and Grant 1971).

The size of fertilized abalone eggs also varies from species to species. The diameter of the fertilized egg of *H. asinina* was 125.4 × 148.2 μm. It is 103 μm in *H. coccinea canariensis* (Pena 1986), 150–225 μm in *H. cyclobates* (Shepherd & Laws 1974), 200–250 μm in *H. laevigata* (Shepherd & Laws 1974), 200 μm in *H. sorenseni* (Leighton 1972) and *H. rubra* (Harrison & Grant 1971), 210 μm in *H. tuberculata* Linnaeus (Koike 1978), 230 μm in *H. discus* Reeve (Ino 1952) and *H. iris* Gmelin (Harrison & Grant 1971), 270 μm in *H. gigantea* Gmelin (Ino 1952) and 280 μm in *H. seiboldii* Reeve (Ino 1952) (Table 5). The size of the trochophore and veliger also varies depending on species (Table 5).

There are 41 stages of larval development in *H. discus hannai* (Seki & Kan-no 1977), *H. diversicolor supertexta* Lischke (Oba 1964), *H. sieboldii* (Ino 1952) and *H. discus* (Ino 1952). Only 32 stages were described in *H. rufescens* Swainson (Hahn 1989a). There are 42 stages of larval development in *H. asinina*. The previous studies on larval development of several species of abalone showed that there were no differences in the development from fertilization to trochophore larva in *H. discus hannai* (Seki & Kan-no 1977), *H. sieboldii* (Ino 1952), *H. discus* (Ino 1952) and *H. diversicolor supertexta* (Oba 1964). However, there are certain differences between larvae of these abalone species and that of *H. asinina*. In other abalone species, the fourth cleavage produced 16 cells, while 12 cells were observed in the fourth cleavage (stage 7) and 16 cells were observed in the fifth cleavage (stage 8) of *H. asinina*. *H. asinina* larvae had both long and short cilia on the prototrochal cell (stage 12), while larvae of other abalone species had only long cilia. In addition, *H. asinina* trochophores appeared to lack the apical tuft cilia that were reported in the trochophores of other abalone species.

The larval development of *H. asinina*, from trochophore stage to torsion, is similar to that of *H. discus hannai*, *H. sieboldii*, *H. discus* and *H. diversicolor supertexta*. The larval retractor muscle (stage 18) was formed prior to formation of the integumental attachment to the larval shell (stage 19). In addition, protrusion of the foot mass (stage 20) and development of the operculum (stage 24) occurred after these stages (Seki & Kan-no 1977, Ino 1952, Oba 1964). Similarly, *H. asinina*, *H. discus hannai*, *H. sieboldii*, *H. discus* and *H. diversicolor supertexta* formed cilia during early larval development and the cilia were retained (Seki & Kan-no 1977).

There are many differences in larval development from torsion to metamorphosis. As in *H. discus hannai*, the larval shell of *H. asinina* was completed (stage 21) before torsion (stage 22) occurred (Seki & Kan-no 1977). In *H. sieboldii*, Ino (1952) found that torsion occurred first and then the larval shell was completed about 13 hours later. In *H. asinina*, the spine at the end of propodium (stage 29) was very fine and very difficult to observe. It could be seen after the formation of the operculum. In *H. discus hannai*, the spine was found at the end of the propodium before the formation of the operculum. In addition, like *H. sieboldii*,, the spines on the metapodium (stage 25) of *H. asinina* were formed after the operculum (Ino 1952). In *H. discus hannai*, these spines were formed before the operculum (Seki & Kan-no 1977).

In *H. asinina*, the cilia in the mantle cavity (stage 33) up to the anterior edge of the velum were seen after the formation of the first epipodial tentacle (stage 32). In *H. discus hannai*, the formation of the first epipodial tentacle occurred before the appearance of apophysis and cilia in the mantle cavity. In addition, in *H. asinina*, the ciliary process on the roof of the mantle cavity (stage 40) was formed after the formation of the third tubule on the cephalic tentacles (stage 38). In *H. discus hannai*, the third tubule on the cephalic tentacles was seen before the formation of the ciliary process on the roof of the mantle cavity.

H. asinina and *H. discus hannai* developed all the larval stages from stage 34 to 42 (*H. asinina*), or stage 32 to 41 (*H. discus hannai*) before metamorphosis. As in *H. discus hannai*, the otolith (stage 35) was observed after the formation of the cephalic tentacle (Seki & Kan-no 1977).

The duration of the pelagic stage in gastropods is variable, and the larvae may spend from two to 14 days in the water column (Leighton 1974). Also the abalone larvae are pelagic and the duration of development varies from species to species. In general, tropical abalone species such as *H. asinina* and *H. diversicolor*

supertexta usually have a short larval development (Oba 1964). In *H. asinina*, the time durations for hatch-out, torsion and formation of the first epipodial tentacle were 6.0, 11.5 and 28.0 h, respectively (at 31°C) and 7.5, 14.0 and 36.0 h, respectively (at 28°C) (Table 6). These durations are quite similar to those in *H. diversicolor supertexta*, *i.e.*, 6.0, 13.0 and 38.0 h for hatch-out, torsion and formation of the first epipodial tentacle, respectively (at 26.2°C) (Owen et al. 1984) (Table 6). The first epipodial tentacle of *H. asinina* appeared before the formation of the apophysis on the propodium, and the larvae started to crawl on the bottom after the formation of the apophysis. In *H. discus hannai* larvae, the apophysis on the propodium was formed before the appearance of the first epipodial tentacle and the larvae started to crawl on the bottom when the first epipodial tentacle was formed (Seki & Kan-no 1977).

The induction of settlement could be done in *H. asinina* after the formation of the apophysis on the propodium. However, the larvae were not able to metamorphose at this stage until they reached the last stage of development. The abalone larvae are competent to metamorphose when they have four branches on the cephalic tentacles, the fully developed foot is able to pull the larvae upright and they can move by ciliary action (Seki & Kan-no 1977, Ebert & Houk 1984). The duration of complete larval development of *H. asinina* was 41.0 to 65.0 h or only 1.7 to 2.7 days (Table 6), while the duration of larval development of temperate abalone species was from 99.0 to 360.0 h or 4.1 to 15 days depending on the species and water temperature (Table 6). The duration of larval development in *H. asinina* at water temperatures of 31°C and 34°C was identical. However, from observation, water temperature at 34°C is rather high and may cause abnormal development and high mortality of larvae. The optimum water temperature of larval development in *H. asinina* was 28°C to 31°C.

Temperature is an important factor in many stages of development such as gonad maturation, spawning (Hahn 1989b, Hahn 1989c) and larval development (Seki & Kan-no 1977, Hahn 1989a). Normally, the animals grow faster in a higher temperature. Larval development in *Haliotis* spp. also occurs at a faster rate at higher water temperature (Hahn 1989a). The development of *H. asinina* larvae at water temperature of 31°C (41 h) was faster than that at 25°C (65 h). In *Haliotis rufescens* Swainson, the hatching time in water temperature of 17°C to 18°C was faster than that at 15°C (Table 6).

A successful culture and high yield are assured by changing the rearing conditions at three important stages during larval development: hatch-out, development of larval shell, and settlement (Hahn 1989a). So the information on the biological zero point and the effective accumulative temperature (EAT) is necessary for hatchery management. The biological zero point varies among abalone species, depending on water temperature in each location (Hahn 1989a). For example, the biological zero point of *H. rufescens* is 0.9°C which is below the ambient water temperature (Hahn 1989a). In *H. asinina*, the biological zero point (15.0°C) is also below the ambient water temperature (20°C).

Biological zero point is one of the values used to calculate EAT. The average EAT of larval development of *H. asinina* is lower than those of temperate abalone species such as *H. discus hannai* and *H. rufescens* (Table 7). The important EAT values in hatchery are during hatch-out, completion of larval shell formation and competency of settlement stage. After hatch-out, the healthy trochophore larvae will swim toward the surface immediately and can be collected near the water surface and transferred to the other tank (Shepherd 1975). The trochophore larvae of *H. asinina* should be decanted as soon as possible after they reach the EAT 101°C-hours, in order to reduce bacterial contamination from decomposition of egg membranes and unfertilized eggs. Moreover, the enzymes secreted by the larvae to facilitate hatching may contribute to the lowering of water quality (Hahn 1989a). From the trochophore stage to completion of the larval shell stage, the larvae

are very fragile, because they do not have a protective organ. The water in the tank should be changed after formation of the larval shell, or when the EAT of larval development reaches 181.4°C-hours. The EAT of settlement stage of *H. asinina* larvae was 680.5°C-hours when the larvae reached the formation of the third tubule on the cephalic tentacles. Settlement occurs rapidly on wavy-plate substrata if the larvae are healthy and competent to settle and metamorphose (Hahn 1989a).

ACKNOWLEDGMENT

This study received financial support from the Thailand Research Fund BRG/12/2542 and PG 21015/2539.

ABSTRACT We isolated seven strains of benthic diatoms from three abalone commercial fishery areas in the state of Baja California and in the proximity of several hatcheries and nursery. In all the cases, we isolated several strains of the genus *Nitzschia* and one strain of *Amphiprora paludosa var. hyalina*. Monospecific and non-axenic cultures of each strain were maintained on batch cultures under white and blue light at high (150 μE m^{-2} s^{-1}) photon fluence rates. For all the diatoms we observed that the growth rate (μ) in the second or third day of culture had high values of duplicated strains per day. We compared the growth rate of these strains with a control specie *Navicula incerta*, a strain used as food in several abalone farms in México, and found similar growth rates in some of the cases. For each strain, a covariance analysis was used to compare growth using white versus blue light wavelength. No significant differences in growth were observed between the two light conditions. We obtained high growth rate for *Amphiprora paludosa var. hyalina* with almost double values of those obtained with of the control species *N. incerta* and the others strains: *N. thermalis var. minor*, *N. fonticola var. pelagica* and *N. frustulum var. perminuta*. The sub-strains of *N. laevis* exhibit equal growth rate and nearly 50% less than that of *N. incerta*. Our results suggest that some strains of benthic diatoms offer a good potential for use in feeding abalone post-larvae, because they can be cultured under high light irradiance apparently without photoinhibition and may exhibit high growth rates and high cell concentrations.

KEY WORDS: benthic diatoms, growth rates, light quality, abalone, post-larvae.

INTRODUCTION

Benthic diatoms play an important role in abalone cultures, acting as inductors for settlement of the larvae and serving as the main source of nourishment during the early juvenile stage (Ebert & Houk 1984, Kawamura et al. 1995). To be used as nourishment in abalone cultures: the diatoms must be preferably of a size less than 10 μm, exhibit adequate nutritional level, and adhere strongly to the substrate so that they may be readily ingested by the abalone post-larvae and juveniles (Hahn 1989, Fleming et al. 1996, Kawamura et al. 1998).

Rearing of post-larva abalone under culture conditions relies on two different strategies to obtain the first microalgae food supply. The first method involves allowing the proliferation of natural populations of phytoplankton. This culture method has the disadvantage of being unpredictable, and results in uncontrolled species introduction and densities. The growth of the postlarvae may be insufficient or inadequate when natural populations of diatoms or other phytoplankton species are used, due to the seasonal variability that they present (Ebert & Houk 1984, Kawamura & Hirano 1992, Voltolina 1994). The second method uses controlled condition cultures of one or several benthic diatom species. This strategy has the advantage that the food densities can be controlled producing a more predictable growth rate, and a higher survival of abalone post-larvae. However, in some cases the species of benthic diatoms used in abalone culturing farms are non-endemic to the region, which may result in the introduction of species and the displacement or succession of local species. Therefore, it is important for farms to use benthic diatoms isolated from the area, to guarantee the quantity and quality of nourishment while avoiding the ecological unbalance of the organisms of the region.

Algae cultures may be influenced though the manipulation of environmental variables. Light is the driving force of photosynthesis. As such, its quantity and spectral composition and its fluctuation within the culture control biomass production rates (Dubinsky et al. 1995). The potential of this light-induced manipulation of the cultures has not been sufficiently explored in the context of aquaculture. Surprisingly, only few studies have used light manipulation to obtain different growth rates and nutritional values of plankton microalgae in culture (Flaak & Epifanio 1978, Correa-Reyes 1993, Sánchez-Saavedra & Voltolina 1994, Sánchez-Saavedra & Voltolina 1995).

The effect of light irradiance on the growth rate of benthic diatoms has been poorly studied (McBride 1990, Flores-Vergara 1998). It is generally considered that the light intensity and quality suitable for rapid growth, is related to the type of habitat utilized in the natural environmental. Usually for benthic diatoms culture for abalone post-larvae only a low light intensity is supplied, and in abalone farms, light is provided with fluorescent lamps at 80 μE m^{-2} s^{-1} on the water surface for less than a 12- hour period (Hahn, 1989). In several studies, the light regimen used for the culture of benthic diatoms was between 20 and 200 μE m^{-2} s^{-1} (Thompson et al. 1992, Cota-Sánchez 1998, Roberts et al. 2000).

In the natural environment, the spectral characteristics of light changes as function of depth, red light is the first wavelength that is absorbed in the water column. In the benthic environment, blue light is the light quality that is usually available and hence used by photosynthetic organisms. These are the conditions found in the habitat shared by benthic diatoms and abalone. Surprisingly, there is no previous work, relating the effect of light quality on growth of benthic diatoms; all studies have been conducted on planktonic diatoms (Gostan et al. 1986, Senger 1987).

The aim of this study was to compare the growth rate of several strains of benthic diatoms species isolated from different zones

close to abalone farms in México, and to culture these under two different light conditions: white and blue light.

MATERIALS AND METHODS

We collected biofilm samples of benthic diatoms from three different regions of fishery production and within the proximity of abalone farms: two in Baja California (Ejido Eréndira and Isla de Cedros) and one in Baja California Sur (Puerto Nuevo) in México (Fig. 1). The isolation techniques used to obtain the different species or strains of benthic diatoms, involved micropipetting and serial dilution as described by Hoshaw and Rosowski (1973) and by Voltolina (1994). The different benthic diatom strains were preselected based on morphology and attachment capacity. During the isolation process of the different stocks and with the purpose of eliminating bacteria and fungi, baths were applied with a mixture of 50 ppm penicillin and 100 ppm streptomycin during an eight-hour period.

For the taxonomic identification of the diatoms, we proceeded to eliminate the organic matter present in the cultures of each diatom strain. While preserving the ornamental structures by washing with concentrate H_2SO_4, K_2HPO_4 1M, 3% glutaraldehyde and different percentages of ethanol in a sequence of 10, 25, 50, 75, 90 and 100 (Nalewajko 1989). An aluminum film permanent slide was mounted for observation under scanning electron microscope (SEM) for each diatom strain. Phase contrast (100×) and planapochromatic (63×) microscopy was used in the taxonomic analysis. Taxonomic criteria were based on morphology of the frustule, using the classic literature and recent works (Navarro 1981a, Navarro 1981b, Navarro 1982, Navarro 1983, Round et al. 1990, Simonsen 1987, Siqueiros-Beltrones 1994, Siqueiros-Beltrones 1999, Siqueiros-Beltrones 2000, Siqueiros-Beltrones & Sánchez-Castrejón 1999, Siqueiros-Beltrones & Voltolina 2000). Curatorial records on cards for each taxon were made, including SEM photographs. The permanent slides were included in the "Diatom Collection of the Museo de Historia Natural" of the Universidad Autónoma de Baja California Sur, México.

We also used as control species a strain of *Navicula incerta* isolated from coastal waters of Bahía de Todos Santos, México by the Microalgae Laboratory staff of the "Instituto de Investigaciones Oceanológicas" Universidad Autónoma de Baja California, México. That strain was obtained from the abalone farm "Abulones Cultivados S. de R.L. de C.V." in Ejido Eréndira, Baja California, México.

Non-axenic monospecific batch cultures of each strain were placed in ten replicate 250-ml Erlenmeyer flasks with 150 ml of Guillard and Rhyther's (1962) "f" medium. The densities of the inoculum used to grow each strain varied as a result of differences in cell size (Table 1). However for comparison purposes, each one of the strains of diatom species on the experimental condition of light received the same quantity of inoculum. The culture conditions were salinity 34±1 ‰ and temperature 22 ± 1°C provided by air conditioning. These values are similar to those used in laboratory abalone production. The pH was not controlled and values ranged between 8.2 and 9.7.

Every other day we checked the cell concentrations. Ultrasound was applied to the culture flasks for fifteen to sixty seconds, depending on the age of culture, to dislodge the cells that were firmly attached to the walls (Voltolina 1985). Two flasks from each light condition and strain were used to determine cell concentrations; these were discarded to avoid the possible effect of the ultrasonic method on the growth of the diatoms. The evaluation of cell concentration was measured through direct counts using a haemacytometer. The growth rate and generation time was determined by

TABLE 1.

Benthic diatom strains isolated from three different zones close to abalone farms in Baja California (B.C.) and Baja California Sur (B.C.S.), México. Procedence, isolation techniques and average size in microns (length and width).

Strain	Procedence	Isolation Techniques	Size (microns)
Nitzschia thermalis var. minor (A)	Ejido Eréndira, B.C.	Micropipette	21.0 × 7.5
Nitzschia laevis (B)	Ejido Eréndira, B.C.	Micropipette	7.5 × 6.0
Nitzschia laevis (C)	Puerto Nuevo, B.C.S.	Serial dilution	8.0 × 5.5
Nitzschia laevis (D)	Puerto Nuevo, B.C.S.	Serial dilution	7.0 × 4.0
Navicula incerta (E)	Ejido Eréndira, B.C.	Serial dilution, Donated	14.5 × 5.5
Nitzschia cf. fonticola var. pelagica (F)	Isla de Cedros, B.C.	Serial dilution	16.4 × 4.3
Amphiprora paludosa var. hyalina (Donk.) Reimer *(G)*	Isla de Cedros, B.C.	Micropipette	13.2 × 4.6
Nitzschia frustulum var. perminuta (H)	Isla de Cedros, B.C.	Serial dilution	10.3 × 3.6

calculations the $\log_2$ cell concentration at different times for each strain as described by Sorokin (1973).

We exposed each strain to two continuous light conditions. The first one was obtained using normal laboratory Cool White 40 W fluorescent lamps (Sylvania F40CW) that provided a spectral emission with two main peaks of emission principally, one in the blue-green wavelengths (453–500 nm) and the other within the red (550–620 nm). In the second, ambient Blue Light was provided with 40 W General Electric F40B, and the peak of emission was primly within the blue-green light (430–470 nm). For the two light qualities, a photon fluence rate of 150 $\mu E\ m^{-2}\ s^{-1}$, because this irradiance is commonly used in several commercial abalone hatcheries in México. Photon fluence rates values were measured at the center of the culture surface with a QSL-100 (Biospherical Instruments) 4 π quanta meter. The spectral characteristics of the lighting sources were determined as described by Sánchez-Saavedra and Voltolina (1996a).

A covariance analysis and two ways ANOVA were used to compare cell concentration among treatments and culture days. A p-level of 0.05 was used to evaluate significance with the "Statistica 5.0 for Windows" program (StatSoft Inc., 1996).

RESULTS

As result of the sample collections, six stocks of benthic diatoms were isolated (Stocks: A through G, Fig. 2, Fig. 3, Fig. 4, Fig. 5), and one strain previously isolated was obtained by donation. In the majority of the localities, stocks belonging to the *Nitzschia* genus were isolated. The other one was identified as *Amphiprora paludosa var. hyalina*. Size ranged between 7 and 20 μ (Table 1).

In all cases, the mean cell concentration for a given strain grown under white or blue light conditions (Table 2), did not exhibit significant differences A: $p = 0.971$, $F = 0.001$; B: $p = 0.231$, $F = 1.534$; C: $p = 0.070$, $F = 3.695$; D: $p = 0.120$, $F = 2.644$; E: $p = 0.491$, $F = 0.494$; F: $p = 0.231$, $F = 1.534$; G: $p = 0.070$, $F = 3.695$). Due to differences in length and width of the cells, we obtained different cell concentrations between the eight strains. However the highest cell densities (for white and blue light respectively) were for *Amphiprora paludosa var. hyalina* and the size of this strain was one of the highest (48.4 and 44.58 10^5 cell ml^{-1}), two substocks of *Nitzschia laevis* (4.85 and 41.43 10^5 cell ml^{-1} and 37.98 and 53.94 10^5 cell ml^{-1}), and *Navicula incerta* (30.64 and 28.98 10^5 cell ml^{-1}). The lowest cell concentrations were found for *Nitzschia thermalis var. minor* (2.50 and 3.02 10^5 cell ml^{-1}) (Table 2), and the strain with the largest cell size (21.0 $\times$ 7.5 μ) (Table 1).

The mean cell concentration values for each of the eight benthic diatoms cultures under white or blue light for ten days, yielded significant differences in the covariance analysis (for white light $p = 0.000$; $F = 25.662$ and for blue light $p = 0.000$; $F = 25.075$). The growth rate for each strain was similar (Table 3) and with equal values under the two light treatments examined. The highest growth rates occurred during the first two days of culture. We obtained high growth rate values for *Amphiprora paludosa var. hyalina* (2.70 and 2.69), which was twice as high as that found for the control species *Navicula incerta* (1.62 and 1.58). Similar values were obtained for *N. thermalis var. minor*, *N. fonticola var. pelagica* and *N. frustulum var. perminuta* (1.18 to 1.62). For the sub-strains of *N. laevis*, we measured the same growth rate for each one; the values were nearly 50% less than that for *Navicula incerta*.

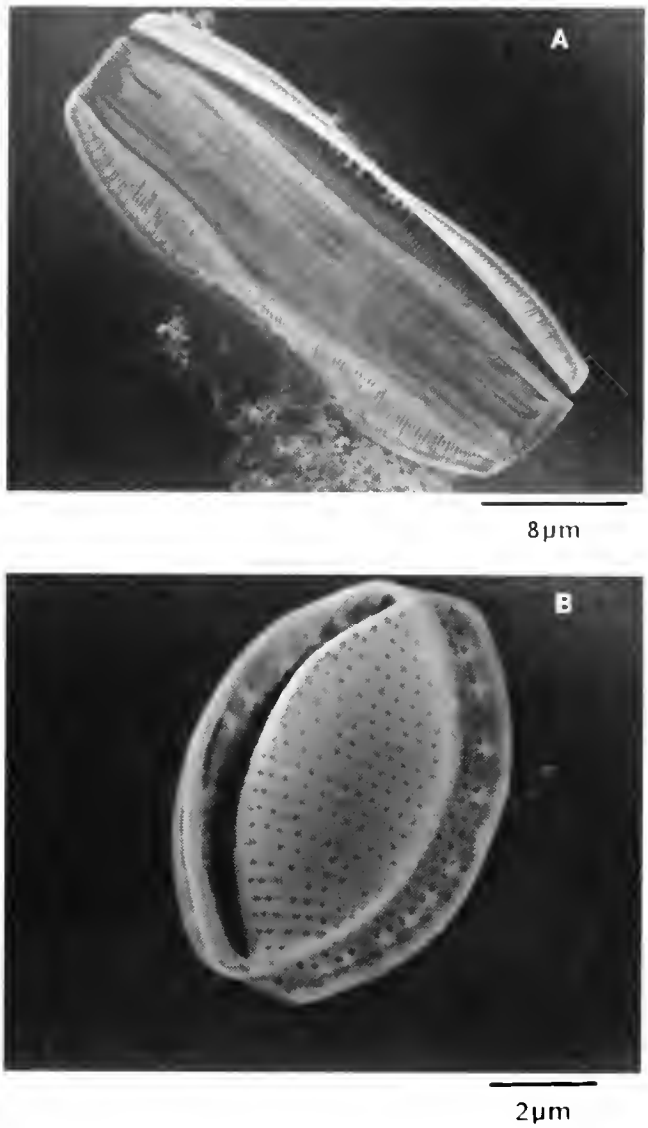

Figure 2. Images of *Nitzschia thermalis var. minor* (A) and *Nitzschia laevis* (B), isolated close to the post-larvae abalone farm Abulones Cultivados S. de R.L. de C.V. in Ejido Eréndira, Baja California, México.

Under the two light conditions, the generation time obtained for the eight strains as expected were lower than or close to one for the first two days and increased as corresponded to cell concentrations values. The lower value of generation time under white or blue light for the first days (0.37 for day two and 2.04 for day four), confirmed the higher cell concentration values for *Amphiprora paludosa var. hyalina* (Table 4). For days six to ten for both light conditions and for the eight strains, the inconsistency with the values of generation time, were due to minimum values of differences on cell concentrations on the last days of culture.

DISCUSSION

For the selection of benthic diatom species with a potential to be used in nutrition of abalone post-larvae, several suitable characteristics have to be considered. Among the suggested ones are: an adequate size, many authors recommend sizes around 10 μ, the degree of adhesion, the frustulum width or degree of silicification

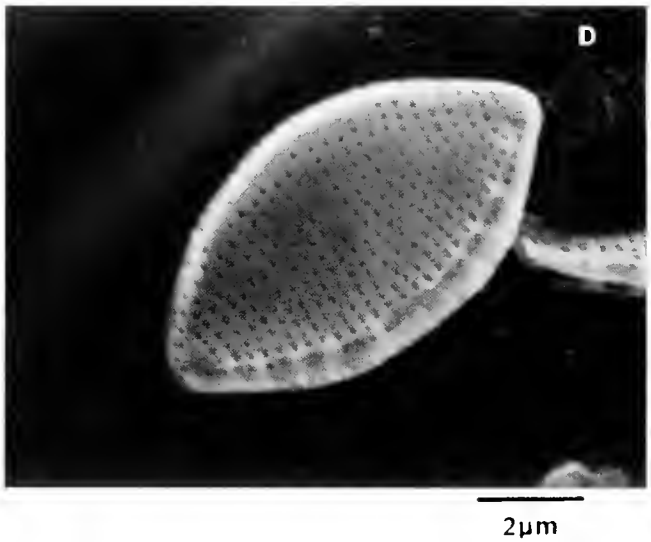

Figure 3. Images of *Nitzschia laevis* (C) and *Nitzschia laevis* (D), isolated close to the laboratory for abalone seed production SCPP Emancipación in Puerto Nuevo, Baja California Sur, México.

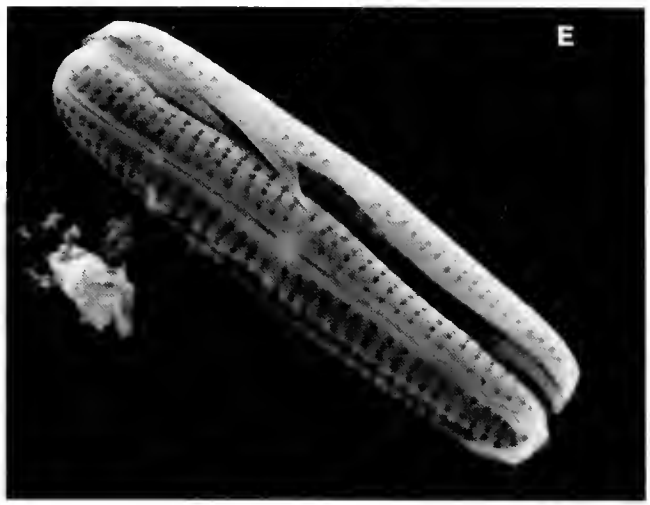

Figure 4. Images of *Navicula incerta* (E) isolated from coastal waters of Bahía de Todos Santos by the staff of microalgae laboratory of the Instituto de Investigaciones Oceanológicas of the Universidad Autónoma de Baja California, México. For this work this strain was obtained from the abalone farm Abulones Cultivados S. de R.L. de C.V. in Ejido Eréndira, Baja California, México.

and motility capacity (Kawamura et al. 1998). However for other cell sizes, apparently the abalone radula can cause the cell to become deformed and create physical rupture of the diatom cell, as described by Daume et al. (1997), who observed that abalone post-larvae settling over coralline algae were capable of breaking the theca of *Cocconeis* spp., and were capable of better assimilating the cellular content. This ability of the radula of abalone post-larvae is corroborated by the work of Roberts et al. (1999). In our results, the lowest values of cell concentrations corresponded to largest cell size, e.g. *Nitzchia thermalis var. minor*. Smaller cell sizes corresponded to medium cell concentrations, e.g. the three different strains of *Nitzschia laevis*. The highest cell concentrations and largest cell sizes corresponded to *Amphiprora paludosa var. hyalina* and *Nitzschia frustulum var. perminuta*.

We can isolated six strains of *Nitzchia* spp., because several *Nitzschia* species have fragile cellular walls and in some cases strong adhesion to substrates, making them susceptible to grazing by abalone post-larvae (Siqueiros-Beltrones, 1999). In addition Siqueiros-Beltrones, 1999 suggested that the diatoms may break when grazed, and lead to a better assimilation of the cellular material.

However, for the eight diatom strains isolated in this study there is no current information available regarding degree of silicification, adhesion and digestibility by abalone post-larvae. It has been proposed that the species of the *Nitzschia* genus may provide good nourishment for abalone post-larvae due to their high growth rates and dominance in successions in culturing systems (Siqueiros-Beltrones, 1999). In addition, the substratum from which benthic diatoms were isolated should be considered (Siqueiros-Beltrones 2000, Siqueiros-Beltrones & Voltolina 2000). The habitat were they are isolated determines the hardness of cellular walls. All the strains isolated for this study, were obtained of zones with lowest water movement or from tanks on abalone farms.

In this work, we observed high growth rates for all species during the first two days of culturing. Other studies (Cota-Sánchez 1998, Cuevas-Rocha 1998, Flores-Vergara 1998), recorded maximum growth rates between days four and five for benthic diatoms of the genera *Nitzschia*, *Amphora* and *Navicula*. However, for other benthic diatoms as such *Navicula cf. cincta* and *Nitzschia sp.* cultured individually or mixed with *Amphora cf. catenula*, the maximum growth rates were observed between days two and three. These studies proposed that the release of extracellular products could inhibit or promote growth (Cota-Sánchez 1998, Cuevas-Rócha 1998). Since these studies and ours used different species and culture conditions (light, nutrients, temperature, pH, salinity, and water movement), the growth rates obtained can be influenced directly. Thus, we propose that culture conditions are an important fact than must be considered, for explaining different growth rates and consequently differences on chemical composition and nutritional value.

Several abalone nurseries discarded the use of benthic diatoms when the mean generation time was higher than one day (Voltolina 1985, Voltolina 1994, Cuevas-Rócha 1998). All the diatom strains

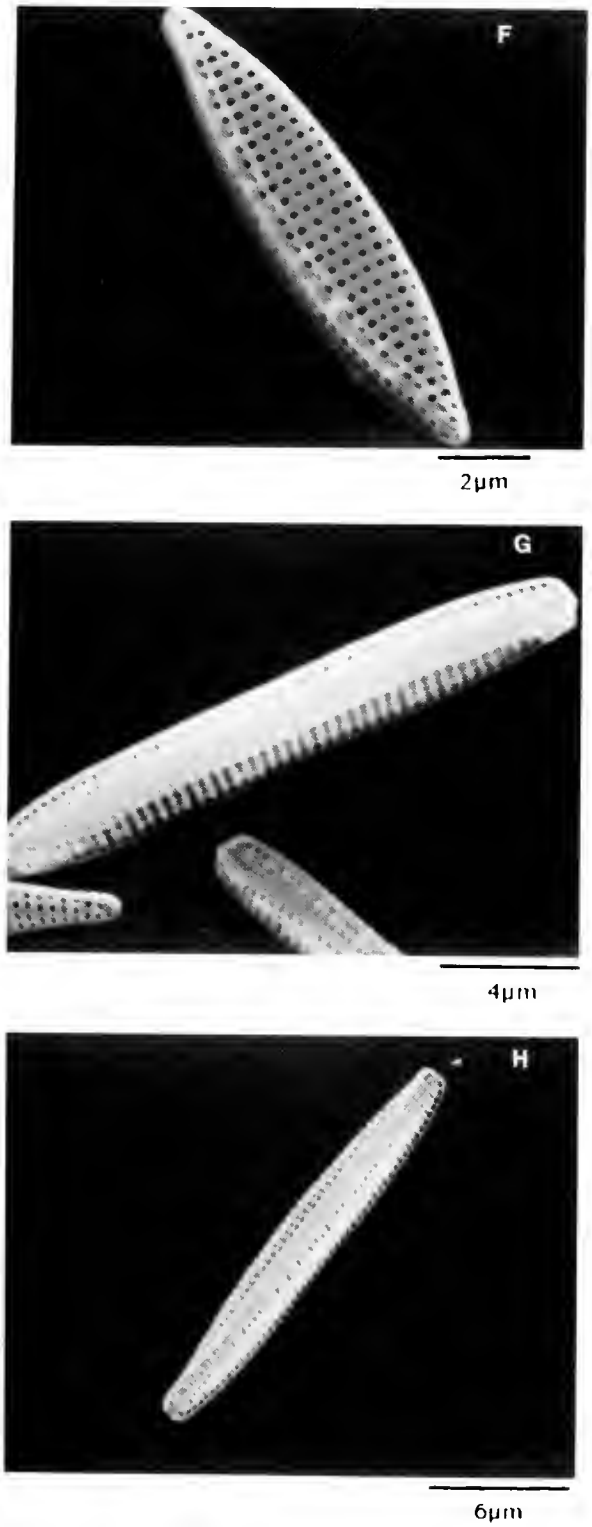

Figure 5. Images of *Nitzschia cf. fonticola var. pelagica* (F), *Amphiprora paludasa var. hyalina* (G) and *Nitzschia frustulum var. perminuta* (H), isolated near the laboratory for abalone seed production SCPP Pescadores Nacionales de Abulón in Isla de Cedros, Baja California, México.

used on this work had mean generation time closest to one, by this we can recommend using the eight isolated strains and experiment on this work for abalone postlarvae nutrition. High variations on generation time are due to the minimum difference obtained on cell concentration values. However, The sample strategy used may produce lower differences on cell concentration values due to minimum differences between Erlenmeyer flask culture replications.

Since light provides the energy that drives photosynthesis other parameters such as photoperiod, light energy or light intensity, and the light quality must be considered. Some algae adapt to very low light intensities and can live at depths as much as 200 m (Fallu 1991). No previous works about the effect of light quality on benthic diatoms or abalone ethology are available. However, it should be considered that research on this subject is needed to understand the ecology and physiological response of alga communities (macro and micro) and of abalone. Abalone have negative phototaxis and is usually found in refuges or cavities in their natural environment or in culture tanks (Hahn 1989).

Controlling the level of light available to the culture tanks has been the most important and most effective means of influencing the alga community on which abalone post-larvae feed. Commonly high light levels produce filamentous algae, this originates displacement of benthic diatom species and occasional loss of postlarva with the water circulation system exchange. Usually this practice is accomplished by utilizing greenhouse shading material, or black polyethylene plastic (McMullen & Thompson 1989). Depending on cell density, pigmentation and cell geometry, the optical density and the wavelength of light can be changed within the culture, depending on the light source of vessel configuration and pond depth (Dubinsky et al. 1995).

Benthic diatoms may be prolific at great depths <1% irradiance (Cahoon et al. 1993), where the main component of the light spectrum is blue wavelength. Abalone also dwells under low light conditions were benthic diatoms serve as their main food source *in situ*, especially for their postlarvae and juveniles.

However, other works reported good biomass production at high irradiance (around 300 $\mu E\ m^{-2}\ s^{-1}$) (Kromkamp et al. 1998). It was determined recently that they are in fact not reaching their optimal biomass production under low light conditions. The saturation light intensity may vary among diatom species. The results presented here suggest that light intensity was not limiting for growth, because we obtained good growth rates when compared to other reports for other benthic diatoms (McBride 1990, Simental-Trinidad 1999). With an adequate light quality we believe growth rate can be increased and metabolic changes induced by effect of deviation of carbon metabolism and cell number or biomass quantity increased as described for plankton diatoms (Flaak & Epifanio 1978, Sánchez-Saavedra & Voltolina 1996b). However, for the eight diatoms, strains cultured under blue light for this work, high growth rates or increase biomass production was not obtained compared with white light. These important differences in physiologic response could be related to the vertical natural distribution of benthic diatoms, and other factors may be the efficiency of light availability, that can be assumed different for each species according to its preference. The results obtained in this study differ from those reported by Sánchez-Saavedra and Voltolina (1994, 1996a, 1996b), who kept cultures of *Chaetoceros* sp. under blue and white light and observed significant differences in growth, finding greater cellular concentrations when cells were cultured under white light.

One other important consideration is, all the isolated strains are conditioned to local environmental fluctuations. Usually, many of the strains kept in laboratories are rarely suited to cooler environments and many of the algae are planktonic, therefore the disadvantage of poor culture conditions or lack on benthic habitat of abalone post-larvae. It is often considered desirable to have pure strains of microalgae. This may allow farmers complete control over what they feed their spat and controlled experimentation or commercial production. It is not generally desirable to feed a single species of microalgae, several pure strains can be mixed to improve the nutrition of abalone post-larvae (Fallu, 1991). Consideration of the chemical composition as protein, carbohydrates and lipid content of the strains, and abalone post-larvae requirements, could lead to the production of a more nutritional food value from diatoms promoting higher survival and growth rates of abalone.

The eight strains of diatoms used in this study offer a good alternative to be used in the nutrition of abalone post-larvae. These strains are acclimated to local environmental fluctuations (temperature and light principally). However, it is necessary to evaluate the nutritional value of these local diatom strains for abalone post-larvae, and relate their biochemical composition, adhesion to the substrate and digestibility with respect to the survival and growth of abalone post-larvae.

ACKNOWLEDGMENTS

We are grateful to Consejo Nacional de Ciencia y Tecnología (CONACYT) who granted a Ph.D. scholarship to the first author. We thank Israel Gradilla-Martínez and Nestor Vallez-Villareal for technical assistance on the preparation of the scan electron pictures. We also thank Juan Pablo Lazo-Corvera for manuscript review and two anonymous reviewers. BIOCHEMICAL COMPOSITION OF BENTHIC MARINE DIATOMS USING AS CULTURE MEDIUM A COMMON AGRICULTURAL FERTILIZER

J. A. SIMENTAL-TRINIDAD, M. P. SÁNCHEZ-SAAVEDRA, AND J. G. CORREA-REYES

Laboratorio de Biología y Cultivo de Microalgas del Departamento de Acuicultura. Centro de Investigación Científica y de Educación Superior de Ensenada. Apdo. Postal 2732, Ensenada, Baja California, México. C.P. 22800

ABSTRACT Three strains of benthic marine diatoms (*Nitzschia thermalis var. minor, Nitzschia laevis* and *Navicula incerta*) were grown individually in batch systems with 10 liters of non-conventional culture media formulated with three common agricultural fertilizers. The quantity and quality of the biomass produced using non-conventional culture media were compared to those obtained with a traditional culture media, "f/2". The objective of this study was to consider a low cost and alternative media to culture the benthic diatoms commonly used in commercial abalone hatcheries. No significant differences were found among the biomass produced with non-conventional or control media. The trend in chemical composition of each diatom culture had a significant difference during 10 days of experimentation for all species. For the cultures of diatoms *Nitzschia thermalis var. minor, Nitzschia laevis* and *Navicula incerta*, the chemical composition did not differ between media. Our results suggested non-conventional media did not affect biomass or biochemical composition and it cost eight times less than "f/2".

KEY WORDS: Benthic diatoms, agricultural fertilizer, chemical composition, mass culture

INTRODUCTION

When undertaking laboratory research on molluscs, and/or when commercially producing these, large quantities of microalgal biomass are needed as the main source of food required for their development and normal growth (Fabregas et al. 1987). Benthic diatoms play an important role in abalone culture, acting as inductors for larval settlement, and as food for the early juvenile stages before these can ingest macroalgae (Searcy-Bernal et al. 1992, Kawamura et al. 1995).

The biochemical composition of microalgae is dependent on numerous factors, including the nutrient concentration and composition of the growth medium (Fabrégas et al. 1986, Wilkfors 1986), temperature (Thompson et al. 1992), light intensity and wavelength (Figueroa et al. 1996, Sánchez-Saavedra & Voltolina 1996), photoperiod (Sicko-Goad & Andersen 1991) and growth stage at time of harvest (Dunstan et al. 1991). It can, therefore, be substantially altered by manipulating their culture conditions (Dubinsky et al. 1978, Ben-Amotz et al. 1987, Geldenhuys et al. 1988). Generally, where benthic diatoms are used in the production of abalone postlarvae, the nutrient enrichment of culture medium is not used to avoid increase of production costs (Ebert & Houk 1989). However, algal biomass production obtained is substantially less than that produced within an enriched medium. To obtain high quantities of diatom biomass of suitable nutritional quality, the development of microalgae cultures using alternate or non-conventional simplified and economical culture media becomes necessary. One possible source of economical nutrients for microalgae cultures is agricultural fertilizers. They have been used successfully to culture *Isochrysis aff. galbana* and *Chaetoceros mulleri* (Valenzuela-Espinoza et al. 1999).

One important consideration in the formulation of culture media is that they must have an adequate proportion of nutrients in relation to the nutritional requirements of the microalgae (Valenzuela-Espinoza 1997). It is also important that the production of benthic diatoms be of high density and of good nutritional quality for the abalone postlarvae. All this should be achieved at low cost (De la Cruz & Alfonso 1975, González-Rodríguez & Maestrini 1984). The culture media prepared with laboratory grade reagents are expensive (Simental-Trinidad 1999). It is also not practical to use these for aquacultural purposes since the conditions of commercial culture differ from laboratory conditions. One possible solution to this problem is to use the more economical agricultural fertilizers as culture media (González-Rodríguez & Maestrini 1984, Simental-Trinidad 1999).

Commercial production of mollusc larvae implies the production of massive cultures of high quality microalgae, since these are indispensable for the adequate nourishing of larvae, postlarvae or adults. This is where a "bottle neck" is found in commercial farms. Thus, several alternatives are being sought to decrease the production costs of culture media for microalgae. The aim of this work was to evaluate the chemical composition of three benthic diatoms *Nitzschia thermalis var. minor, Nitzschia laevis* and *Navicula incerta* cultured in an alternative media made with commercial agricultural fertilizer as a supplement of nitrogen, phosphate and silica compounds required to grow diatom cultures.

MATERIALS AND METHODS

For this work, we used the benthic diatoms *Nitzschia thermalis var. minor* (29.57 μ), *N. laevis* (7.56 μ) and *Navicula incerta* (12.82 μ) (Fig. 1). Both *Nitzschia* species are potentially useful in abalone aquaculture and were isolated from production farms in the locality of Ensenada, Baja California, México (Correa-Reyes et al. *in preparation* b). *Navicula incerta* (12.82 μ) was isolated in coastal waters off Bahía Todos Santos, México by the staff of the Microalgae Laboratory of the "Instituto de Investigaciones Oceanológicas, Universidad Autónoma de Baja California, México". The strain of *Navicula incerta* was obtained from the abalone farm "Abulones Cultivados", Ejido Eréndira, Baja California, México.

The commercial medium "f/2" (Guillard 1975) was used as the control culture medium in all the experiments. Nutrients available from non-conventional cultured medium lacked trace metals, and vitamins were added in an equal concentration to that indicated in the formulation of the control medium "f/2" (Table 1). We used liquid agricultural fertilizers for the preparation of the non-conventional medium. The fertilizers were obtained from "Insumos y Servicios Agrológicos S.A. de C.V.", Ejido Camalú, Baja California, México. Nitrogen density was 1.37 grl^{-1}, total nitrogen

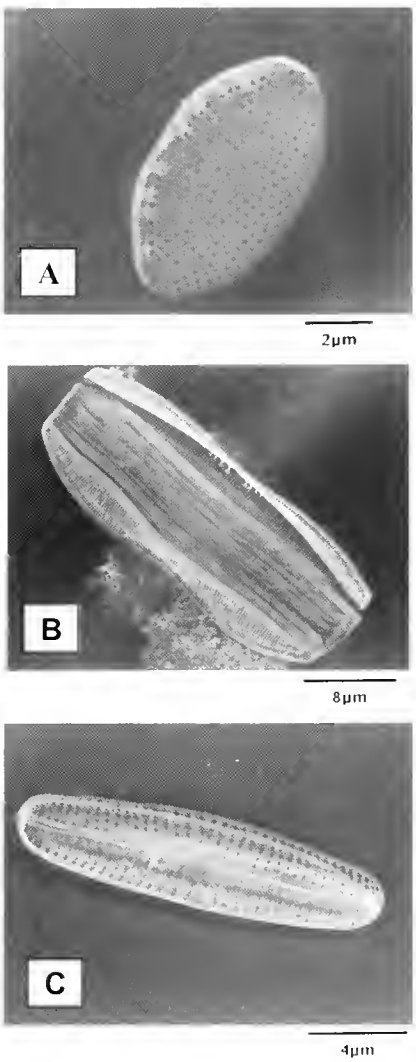

Figure 1. Benthic diatoms *Nitzschia laevis* (A), *Nitzschia thermalis var. minor* (B) and *Navicula incerta* (C).

was 32% and the cost US$0.39 l^{-1}. Phosphorous density was 1.69 grl^{-1}, total phosphorous was 72% of phosphoric acid and the cost US$0.78 l^{-1}. Silica was as sodium methasilicate with 0.107 moles l^{-1} and was obtained from a distributor "Química Internacional de Tecate S.A. de C.V.", México, at US$0.85 l^{-1}.

Cultures were prepared from the production of inoculum in progressive volumes of 10 ml, 250 ml and 900 ml. Each of the three species was acclimated to the cultured medium before experimentation. These cultures were maintained under controlled light conditions (150 μEm^{-2} s^{-1}), environmental temperature (21 ± 1 °C) and pH (between 8.7 and 9.0).

Batch cultures were kept in circular 18 l plastic containers of 38 cm by 30 cm. White plastic containers were used for the assay. The containers were provided with a lexon acrylic lid with two orifices, one for the incoming air and the other for the outcoming air. Air was not injected to the culture medium and it was only used on the surface to create a circulation cell to maintain a constant temperature. The seawater for the culture medium was disinfected chemically following the methodology described by Hemerick (1973).

A sampling strategy, without sampling replacement, was made for biomass quality and quantity, due to the benthic diatoms characteristics and the presence of a biofilm on the bottom of the container. Sampling for each species and culture medium consisted of taking two containers every 48 hours and harvesting the whole culture to determine the proximal composition and biomass in triplicate. To determine microalgal biomass, microalgae cells were counted in a 0.1-mm depth haematocytometer with the aid of a compound microscope.

For the proximal analyses, the microalgae were harvested from each container, concentrated and placed in ultrasound water to eliminate possible lumps. Subsamples were taken from the concentrate and were reconcentrated in Poretics GF-C glass fiber filters (2.5 cm diameter) previously rinsed with distilled water, and incinerated at 470 °C for four hours. After filtering, the samples were stored at −20 °C as recommended by Cordero-Esquivel et al. (1993). The analytical technique used for total and ash free dry weights was as those described by Sorokin (1973). Samples were dried at 60 °C to constant weight in a conventional oven, and ashed in a muffle furnace at 470 °C for eight hours.

Analysis of proteins were performed by varying the extraction time and NaOH concentrations for optimum extraction, as proposed by Correa-Reyes et al. (*in preparation* a). Protein determination was undertaken using the protocols proposed by Lowry et al. (1951). Carbohydrates were extracted following the Whyte method (1987) and their determination was made according to the methodology of Dubois et al. (1956). Lipids were extracted following the methodology of Bligh and Dyer (1959) and their quantification was estimated by the method of Pande et al. (1963). Calibrations curves were obtained for each one of the analyses following the indications described by the colorimetric techniques specified for each case, using a Shimadzu spectrophotometer model UV-1201. Bovine albumin (98%) was employed as a protein standard, glucose (99%) as a carbohydrate standard and tripalmitin (99%) as a lipid standard.

We used a covariance statistical analysis to determine differences between the productions obtained within different culture media and the three strains.

RESULTS

Nitzschia laevis

The percentage of protein content for *Nitzschia laevis* (Table 2) cultured in "f/2" medium, had a maximum (31.257) on the eighth day of culture, while that cultured in the experimental media showed the highest protein percentage (25.470) on the fourth day. There were significant differences in the protein percentage between both treatments ($F = 18.821$, $P = 0.000$). There were no significant differences in carbohydrate ($F = 2.726$, $P = 0.115$) and lipid percentage ($F = 0.878$, $P = 0.360$) for this strain cultured on the experimental medium.

Organic dry weight and ash content increased significantly with culture age and were similar to those obtained when the diatom were grown on the experimental medium (Table 2).

Nitzschia thermalis *var.* minor

Nitzschia thermalis var. minor (Table 3), showed a maximum protein percentage (33.505) on the fourth day of culture in the control medium. The microalgae cultured in the experimental medium reached the maximum protein percentage (35.579) on the second day of culture. There were no significant differences between both treatments ($F = 3.233$, $P = 0.084$).

TABLE 1.

Chemical composition and cost for 1000-l of prepared culture media used to grow benthic diatoms. Agricultural fertilizers were used as experimental media and "f/2" media as Guillard and Ryther (1975) for control medium.

Source	Agricultural Fertilizer Chemical form	Ionic form	Cost (US $)	"f/2" Medium Chemical form	Ionic form	Cost (US $)	(μmol)
	Nitrate	NO_3					
Nitrogen	Ammonium	NH_4	3.09×10^{-5}	Sodium nitrate	$NaNO_3$	1.01×10^{-2}	
	Urea	$CO(NH_4)_2$					882.0
Phosphorus	Phosphoric acid	H_3PO_4	2.26×10^{-6}	Sodium phosphate	$NaH_2PO_4 \cdot H_2O$	5.90×10^{-4}	36.3
Silica	Sodium methasilicate	$Na_2SiO_3 \cdot 9H_2O$	4.25×10^{-4}	Sodium methasilicate	$Na_2SiO_3 \cdot 9H_2O$	6.80×10^{-4}	107.0

Source	Common chemicals for the two media Chemical form	Ionic form	Cost (US $)	(μmol)
	Ferric chloride	FeEDTA	1.05×10^{-3}	23.3000
	Copper sulphate	$CuSO_4 \cdot 5H_2O$	1.10×10^{-6}	0.0395
Trace metals	Zinc sulphate	$ZnSO_4 \cdot 7H_2O$	2.30×10^{-6}	0.0765
	Cobaltous chloride	$CoCl_2 \cdot 6H_2O$	1.90×10^{-6}	0.0425
	Manganese chloride	$MnCl_2 \cdot 4H_2O$	2.14×10^{-5}	0.9000
	Sodium molibdate	$Na_2MoO_4 \cdot 2H_2O$	1.23×10^{-5}	0.0260
	Biotin	$C_{10}H_{16}N_2O_3S$	4.20×10^{-7}	1.336×10^{-6}
Vitamins	Cianocobalamin	$C_{63}H_{88}CoN_{14}P$	3.90×10^{-7}	0.393×10^{-6}
	Thiamin	$C_{12}H_{17}ClN_4OS$	4.90×10^{-9}	0.18726

The carbohydrate content in microalgae cultured in the control medium had a maximum percentage (23.923) on the second day of culture, while the experimental group did not show significant differences along the whole culture period. There were differences between both treatments only on the second day of culture in which the cultured microalgae in the control medium obtained the highest percentages (Table 3) ($F = 7.694$, $P = 0.012$).

The lipid percentage in the experimental culture showed the highest values (21.06) on the tenth day of culture, while the cultured microalgae in the experimental medium showed the highest values from the sixth (34.247) to the tenth day (44.549). There were significant differences between both treatments only on the tenth culturing day, on which the cultured microalgae in the control medium had a higher percentage ($F = 6.791$, $P = 0.015$).

The fraction of organic dry weight and ash content showed a similar trend to those of *Nitzschia laevis*. Their final concentrations were also similar to those obtained for that species (Table 3).

Navicula incerta

Navicula incerta showed a maximum protein percentage during days two (35.153) and four (35.405) when cultured in the control medium, whereas when cultured in the non-conventional medium, maximum percentage was obtained during the second day (33.530)

* Not measured

The standard deviation is included in parenthesis.

The different letters on the side of the quantities indicate significant differences (two-way Anova and Tuckey's *a posteriori* test, $\alpha = 0.05$): a < b < c < d.

(Table 4). There were no significant differences between both treatments ($F = 0.082$, $P = 0.777$).

The highest carbohydrate percentage was obtained on the last culturing day in the control medium, whereas in the experimental medium, the higher value appeared on the fourth culturing day (13.193). There were no statistical differences between both treatments (Table 4) ($F = 2.965$, $P = 0.097$).

The lipid percentage both in the control and experimental media showed the highest values on the eight culturing day (15.161 and 13.034 respectively). There were no significant differences in lipid percentage between both treatments ($F = 0.225$, $P = 0.639$).

The organic dry weight and ash content for *Navicula incerta* were similar to those of the other two species. However, for this diatom, protein, carbohydrate, and lipid concentrations were around two or three times higher than those of the other two species, especially at the end of the culture irrespective of treatments (Table 4).

DISCUSSION

Some of the most important factors that must be considered for the production of microalgae biomass are quality and availability of nutrients, quantity and quality of light, pH, and temperature. All these variables can modify or limit growth rate, biomass production and the chemical composition of the microalgae and, as a result, their nutritional value (Kawamura & Hirano 1992, Flores-Vergara 1998).

The results obtained in this study showed that the chemical composition of each benthic diatom species used was similar irrespective of whether it was cultured in the experimental or control "f/2" medium. However, from the three strains evaluated *Navicula incerta* showed the highest values on protein, organic dry weight and ash content, as well as some important differences in chemical constituent. The weights evaluated showed that this strain is heavier and bigger than the other two benthic diatoms used in this work; supporting López-Elias and Voltolina (1993) and Perera-Carbonell (1994) who worked on planktonic microalgae. These authors did not find differences in the growth rate and chemical composition of microalgae reared in a traditional culture medium or one with agricultural-type fertilizers. Gracida-Valdepeña (1999) found some differences in the microalgae quality, but not in their quantity when cultured with agricultural fertilizers rather than in the "f/2" medium.

The chemical composition of our three diatoms strains was similar to those of other benthic diatoms (e.g. *Amphora catenula, Navicula cincta, Nitzschia closterium* and three other strains of *Nitzschia* sp.) cultured in medium "f" described by Guillard and Ryther (1962). However, these cultures were maintained under different light intensity (80 and 160 $\mu Em^{-2}\ s^{-1}$) and temperatures (15, 20 and 25 °C). Flores-Vergara (1998) reports values of proteins from 20 to 40%, carbohydrates from 4 to 25% and lipids between 5 and 45%.

The high ash content resulting in the benthic diatoms cultured could have originated from satisfied requirements for silica for frustule formation, as this trend was similar in both culture media. Several diatoms may be capable of continuous uptake and storage of silicon in their vacuoles (Werner 1977). Studies on planktonic diatoms *Thalassiosira pseudonana* and *Chaetoceros calcitrans* indicated that ash content can vary between 27 and 35%, and that low ash percentage in phytoplankton implied low levels of intracellular potassium and sodium (Whyte 1987).

The structural strength of diatom cells may depend on factors such as culture conditions and diatom growth phase (Kawamura & Hirano 1992). This strength could affect the ability of the abalone postlarvae to digest these diatoms (Roberts et al. 1999), as when the diatom cells are weakly silicified, the abalone radula appears to deform the cell easily. Since physical rupturing of diatom cells probably relies solely on the radula or other bucal apparatus (Roberts et al. 1999), if the postlarvae cannot break the cells of the diatom strain, it cannot absorb the diatom's cell contents (Kawamura 1996).

No previous work has considered the use of agricultural fertilizer to grow benthic diatoms, although they are often used as sources of nitrogen and phosphorous on several Mexican abalone farms. However, no previous evaluation of quantity or quality of microalgal biomass production using this method has been made. The use of fertilizers on Mexican farms reduces production costs. There, commercial "f/2" medium is used exclusively for inoculum, while culture medium, prepared with fertilizers, is used frequently in the massive production.

In this work, the experimental culture medium contained three nitrogen forms: ammonia, nitrate and urea. Physiological studies on phytoplankton cultures showed that assimilation of the reduced form, ammonium, is preferred and inhibits the nitrate reductase production in the microalgal cell and provides lower energetic cost (Wheeler 1983). Usually higher concentrations from 0.5 to 0.1 $\mu mol\ l^{-1}$ inhibits the nitrate uptake (Syrett 1981). These reasons could explain the good chemical composition of our three benthic diatoms strains cultured on the experimental medium. However, no previous studies have been found concerning the production of benthic diatoms using fertilizers as a culture medium, although this is very common in planktonic algae (e.g. *Thalassiosira pseudonana*) (Dortch et al. 1991).

The lower production costs achieved when using the alternative medium, compared to when using the control culture medium, is a great advantage. We found that it was eight times lower than when the control culture was used (Table 1). Many researchers have emphasized this fact. For example, McAnally-Salas et al. (1992) established a 98% saving by formulating a cultured medium from agricultural fertilizers, compared to the cost of the "f/2" culture medium. Valenzuela-Espinoza (1997) reports that the agricultural fertilizer medium is up to eight times less expensive than the "f/2" culture medium. This alternative medium could be successfully used in abalone farms, where large quantities of microalgal biomass with adequate chemical composition is required at a low cost. Liquid fertilizers appear potentially useful for preparation of culture media. The advantage of these fertilizers is their high solubility compared with those of solid fertilizers (González-Rodríguez & Maestrini 1984, Simental-Trinidad 1999). Finally, we recommend the utilization of the studied agricultural fertilizers for the culture of benthic diatoms, since the biochemical composition of the cells was similar to those obtained with the culture medium "f/2".

CONCLUSIONS

The utilization of agricultural fertilizers in mass culture of benthic microalgae is possible because they have a biochemical composition and growth rate similar to those obtained with the control culture medium "f/2" and production costs are substantially reduced.

ACKNOWLEDGMENTS

We thank Consejo Nacional de Ciencia y Tecnologiá (CONACyT) for the granted master of science scholarship. Thanks to Israel Gradilla-Martínez and Nestor Vallez-Villareal for technical assistance in the preparation of the scanning electron microscopy pictures. Carmen Paniagua-Chávez reviewed the manuscript. This project was supported by funding from Centro de Investigación Cientifica y de Educación Superior de Ensenada (CICESE) project 623101.

ECOLOGY AND POST-SETTLEMENT SURVIVAL OF THE EZO ABALONE, *HALIOTIS DISCUS HANNAI*, ON MIYAGI COASTS, JAPAN

RYO SASAKI[1]* AND SCORESBY A. SHEPHERD[2]

[1]*Miyagi Prefectural Sea Farming Center, Yagawa Beach, Oshika Town, Miyagi Prefecture, 986-2402 Japan;* [2]*South Australian Research and Development Institute, PO Box 120, Henley Beach, South Australia 5022*

ABSTRACT Settlement and survival of the ezo abalone, *Haliotis discus hannai* were examined in near-shore habitats at exposed to sheltered sites on Miyagi coasts, Japan from 1996–1999. Larvae settled mainly in the boundary zone at 2–7 m depth according to site between shallower *Eisenia* forests and deeper crustose coralline flats at densities of ~200–800/m^2. Growth rates were 30–40 μm/day. Instantaneous natural mortality rates, M, in the first 55 days after settlement were 3.7–5.5/month. Sampling of the habitat during the week after settlement showed a 29–37% incidence of atrophied post-larvae of ~500 μm shell length indicative of starvation. Laboratory experiments suggested that post-larvae exhaust the natural food supply on crustose coralline algae in the first week after settlement and begin to starve at a size of ~450–500 μm in the absence of a suitable diatom diet. One-year-old juveniles were mainly found in the boundary zone but with increasing age juveniles moved into the shallower *Eisenia* forest where food algae is abundant.

KEY WORDS: settlement, recruitment, survival, density-dependent mortality, crustose coralline algae, isoyake, *Haliotis discus hannai*

INTRODUCTION

An understanding of the ecology and dynamics of recruitment in abalone populations is crucial to management of their fisheries (McShane 1992, McShane 1996), especially when those fisheries are in decline through overfishing. Numerous studies have shown the importance of crustose coralline algae (CCA) as a preferred substratum for larval settlement of abalone (Saito 1981, Shepherd & Turner 1985) but few studies have examined the survival of settlers (Shepherd & Daume 1996) or the causes of mortality.

Two hypotheses, predation and food availability, have been proposed to explain the early high mortality (M) of post-larval abalone. Morse et al. (1979) and Naylor and McShane (1997) suggested that infaunal polychaete predators controlled the abundance of abalone post-larvae and McShane (1991) thought that bulldozing by urchins may also inflict high M. A corollary of this hypothesis is that the characteristics of the CCA substratum may be critical, either by providing a protective micro-habitat, e.g. in the lumpy growth-form of certain CCA (Shepherd & Daume 1996), or conversely by favoring loss from wave-shear on smooth forms of CCA (McShane 1996).

Alternatively, food availability has been considered to play a key role in the growth and survival of post-larvae (Kawamura et al. 1998). While growth and survival on a CCA substratum is superior to those on any other substratum in the first few days to a week after settlement (Morse 1984, Hooker & Morse 1985, Daume et al. 1999a), thereafter the quality, type and abundance of diatoms become critical for growth and survival. Both factors, predation and food availability, together were considered by Shepherd et al. (2000) to be the main determinants of the carrying capacity of the CCA habitat.

Our earlier study on the spawning, larval dispersal and settlement of *Haliotis discus hannai* Ino on Miyagi coasts (Sasaki & Shepherd 1995) showed that spawning was epidemic and induced by typhoons. This enabled the prediction of spawning events from the occurrence of typhoons and the estimation of the time of larval settlement. We monitored larval settlement of *H. d. hannai* following annual typhoons from 1995 to 1999 in Samenoura Bay. Specifically we asked what the characteristics were of the habitat in which larvae of this abalone settled, in what density did they settle and were post-settlement processes limiting recruitment to wild populations. In this article we describe the preferred zone of settlement within the near-shore rocky reef ecosystem, post-larval survival and subsequent movement and habitat of juveniles to age five years. We also carried out ancillary experiments to elucidate the cause of post-settlement mortality.

MATERIALS AND METHODS

Description of Study Sites

The coast of Samenoura Bay in northeast Honshu Island where the study was done (Fig. 1) ranges from sheltered to exposed. Following the description of Taniguchi (1991) we recognize three distinct sublittoral zones according to algal dominants, named A–C in this article, on rocky bottom.

Zone A is an *Eisenia bicyclis* forest going from low water to a depth of 2–4 m. The zone is shallowest in sheltered conditions and its depth increases with increasing exposure to wave action. *Sargassum yezoense* is a sub-dominant at the shallowest depths.

Zone B is a boundary transition zone between the *Eisenia* forest and the deeper CCA zone C, and is characterized by *Acrosorium polyneurum*, and, to a less extent, by *Chondrus ocellatus* and *Dilophus okamurai*.

Zone C, called the CCA flats (in Japanese isoyake), comprises boulders with high CCA cover but bare of erect algae and grazed intensively by the sea-urchin *Strongylocentrotus nudus*. We have no data on the species of CCA present, but in southern Hokkaido the main species are (with mean percentage cover in brackets): *Lithophyllum yessoense* (69%), *L. okamurai* (5%), *Lithothamnium japonicum* (8%) and *Neogoniolithon* sp. (6%) (Noro et al. 1983).

The distribution of common algal dominants (Taniguchi 1991) in the three zones is shown in Figure 2 and illustrated in Figure 3.

Post-Larval Sampling

We chose three sampling sites, numbered 1–3, to provide a range of exposures to wave action (Fig. 1). The three zones and the same algal flora were present at each site, but the zones differed in

*Corresponding author.

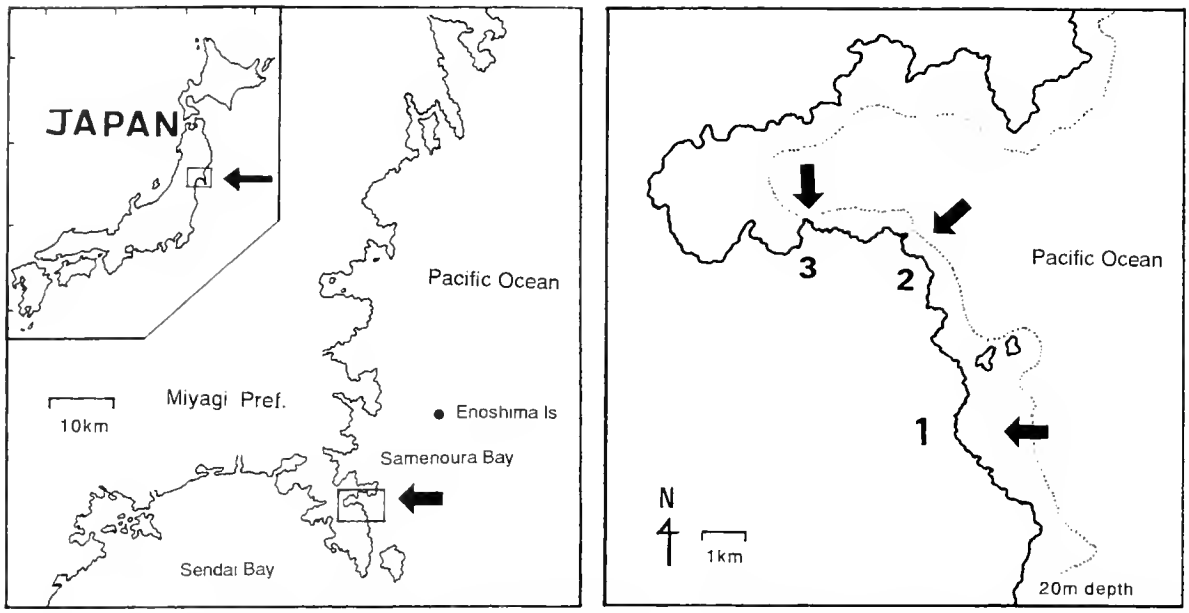

Figure 1. The coast of Miyagi Prefecture (left) and the study sites in Samenoura Bay (right) in northeast Honshu island, Japan (inset).

horizontal extent. Site 1 is the most exposed, facing the Pacific Ocean, with a gentle slope of 4/100, Site 2 at the entrance of Samenoura Bay is moderately exposed with a bottom slope of 6/100 and Site 3 within the Bay has a slope of 6/100 (see Figs. 3, 4, 5 for the horizontal extent of the respective zones).

At each site we estimated the abundance of newly settled abalone spat by taking, with the aid of SCUBA, 4–6 boulders, each 20–30 cm diameter, per sample at regular sampling intervals along a transect normal to the coast and intersecting each of the three zones. The boulders were taken to the laboratory and immersed in 0.4% formaldehyde solution; then the spat was washed off the substratum with a water jet, examined under a binocular microscope, and individual shell lengths measured. We also recorded those spat showing atrophy (i.e. shrinkage) of the soft tissue within the shell. The length, width and depth of each boulder were measured and the total area of the sides and top of a rectangular box of those dimensions was taken as an estimate of the area of the boulders. Densities were converted to numbers/m^2.

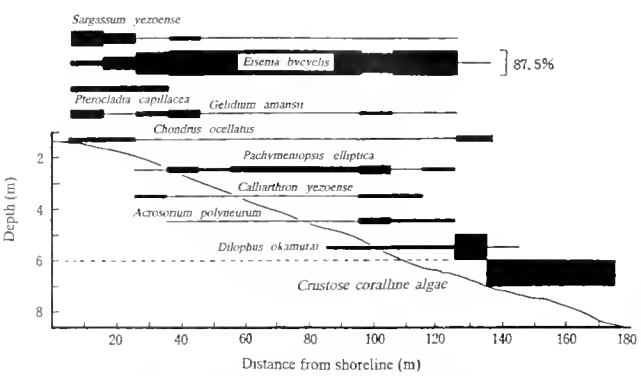

Figure 2. Schematic horizontal distribution with depth of major benthic algae at Site 1 (after Taniguchi 1991). The sloping line represents rocky bottom, the thickness of the distribution lines indicates % cover and the dashed line at 6 m depth is the boundary between Zones B and C.

Sampling of boulders for newly settled spat was done annually for 2 y at Site 1, for 3 y at Site 2, and for 2 y at Site 3. In 1997, boulder sampling at Site 1was repeated four times over 55 days and the natural mortality rate of spat estimated by regressing the natural logarithm of density versus time.

At Site 1 we also deployed strings of 80 scallop shells anchored just above the bottom as artificial collectors at regularly spaced intervals to independently monitor spat settlement. The surface area of the shells was estimated and the results presented as numbers/m^2.

Post-Larval Survival Experiments

Two experiments, one using dried boulders in the field, and the other with cobbles covered with living CCA in aquaria, were carried out to measure post-larval survival in different conditions. In the former experiment we placed sun-dried boulders in Zone B at Site 1 and compared the number and size of post-larvae on dead substrata and nearby natural control substrata. We placed the boulders in the field on 22 September 1997 on the same day that settlement began, and retrieved them four days later.

In the second experiment (called the aquarium experiment) 2,500 *H. d. hannai* larvae were released into each of five 10-L aquaria with living CCA cobbles of ~10 cm diameter set on the bottom and their survival monitored over 14 days. The cobbles had been previously brushed and washed in filtered sea-water to remove predators and microalgae including diatoms. The aquarium water temperature was 18–20°C. The contents of the aquaria were preserved in formalin successively at two- to three-day intervals and the empty shells and those living to that time measured and counted. The aquarium experiment was repeated twice with the same protocols.

Juvenile Sampling

The abundance of juvenile (one to five y) abalone was estimated at each site in January 1998 by searching within each zone within a 5 × 5 m quadrat with three replicates. All such surveys were done by one of us (RS) to standardize searching

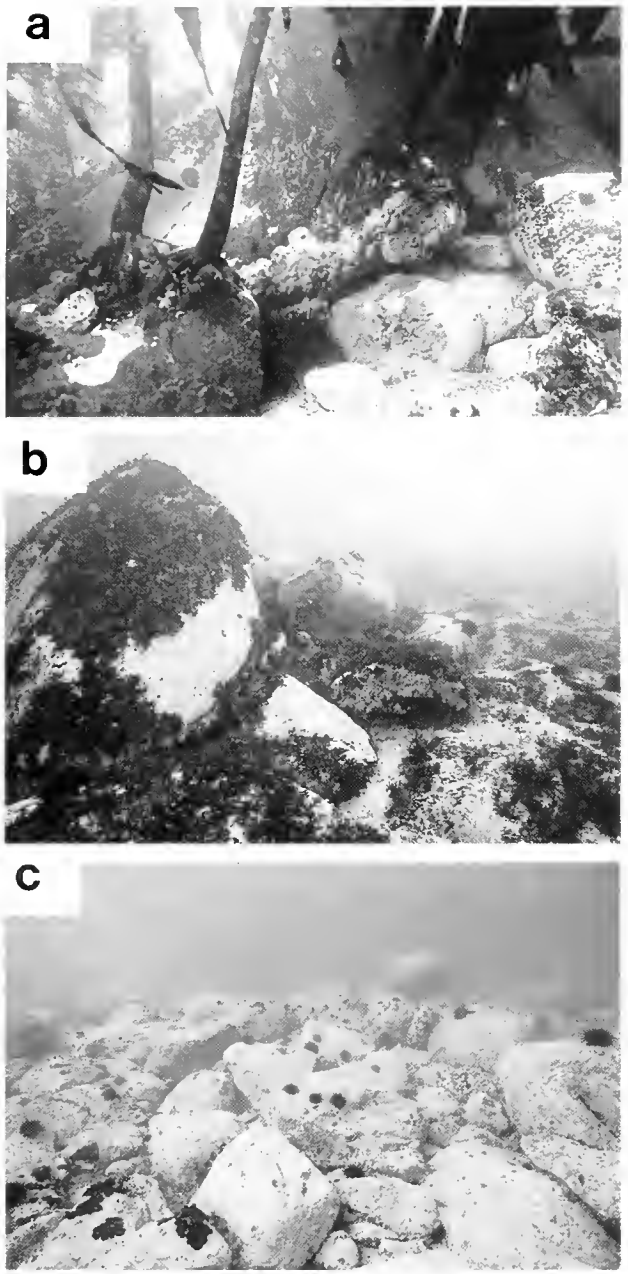

Figure 3. Photographs of the bottom at Site 1 at the entrance to Samenoura Bay. a: Zone A showing canopy of *Eisenia bicyclis*; b: boundary Zone B showing low cover of the macroalgae, *Acrosorium polyneurum* and *Dilophus okamurai*, and c: Zone C showing sea-urchin *Strongyloceutrotus nudus* in isoyake area.

efficiency. Small abalone were aged by the annual growth check which is conspicuous in this species (Sakai 1960).

RESULTS

Distribution and Density of Post-Larvae

The distribution of density of post-larvae along transect lines in relation to depth and habitat is shown in Figures 4–6.

At Site 1 (Fig. 4) settlement was monitored on scallop-shell collectors and showed a maximum density at a distance of 160 m from shore at 5 m depth in the boundary zone (B). Mean post-larval shell length was 415 μm (SE 60 μm) five days after settlement. In 1996 post-larval density ranged from 0–30/m^2 in Zone A to 220/m^2 in Zone B with intermediate values in Zone C. Mean shell length was 425 μm (SE 75 μm). In 1997 with increased sampling intensity at 15 m intervals there is a clear modal density of 340 spat/m^2 at a distance of 180 m from shore at the outer edge of Zone B. Mean shell length was 510 μm (SE 40 μm).

At Site 2 (Fig. 5) there was a peak in spat density in Zone B in 1997 (mean shell length 340 μm, SE 20 μm), nearly uniform spat density in 1998 in all zones to a depth of 6 m (mean shell length 910 μm, SE 830 μm), and in 1999 a modal density at 80 m from shore in Zone C (shell length 380 μm, SE 45 μm).

At Site 3 (Fig. 6) there was a weak settlement in 1998 with a peak density in Zone C (mean shell length 695 μm, SE 575 μm), and a stronger settlement in 1999 with a peak density at the inner edge of Zone C (mean shell length 370 μm, SE 50 μm).

In summary the results show trends of declining spat density with increasing shelter and peak densities at the boundary between Zones B and C with lower densities further in- and off-shore at each site.

Post-Larval Growth and Mortality

Length-frequency data at Site 1 after the 1997 settlement (Fig. 7), shows modes at 390 μm and 410 μm on 25 September increasing to 490 μm and 560 μm respectively 6 days later, and finally a single apparent mode at 1–2 mm 13 days after that. In contrast, the "dead" boulders showed a single peak at 290 μm early after settlement. The length-frequency distribution of spat on "dead" boulders differed significantly from that on natural boulders obtained in the same period ($\chi^2 = 42.2$; $P < 0.001$), but the mean size of spat did not differ significantly between the two sets of boulders ($t = 1.6$; $P = 0.1$) although mean size was 10 μm smaller on the dead boulders.

The density of post-larvae at Site 1 sampled up to day 55 after putative settlement declined exponentially (Fig. 8). The estimated instantaneous monthly mortality rate, M, for the first 27 days was 5.3 (SE 0.7) and for the whole 55 days was 3.7 (SE 0.6). Length-frequencies of post-larval samples obtained at Site 1 after the 1996 and 1997 settlements (Fig. 9) showed that the mean length of spat with atrophied foot was 504 μm (SE 78 μm) and that of normal spat was 387 μm (SE 56 μm) in 1996, and 508 μm (SE 44 μm) and 512 μm (SE 41 μm) respectively in 1997. The spat with atrophied foot comprised 37% of the 1996 sample (N = 92) and 29% of the 1997 sample (N = 304).

In the first aquarium experiment 98% of the released larvae settled on the cobbles and survived to day 5, but declined sharply and more or less linearly after day 7 to 53% on day 14 (Fig. 10). Mean shell length increased at a daily growth rate of ~40 μm to a mean length of 478 μm (SE 13 μm) and then practically ceased, reaching a mean length of 499 μm (SE 22 μm) at day 14 when the experiment ended.

The mean shell length of spat that died was 435 μm at five days and increased only slightly after that; the mean shell length of "dead" shells was 468 μm (SE 19 μm) for the whole 14 days. In the second experiment, survival was 85% after 14 days and in the third experiment 27% after 16 days; in both the last two experiments survival was 99% for the first week and declined steeply after that.

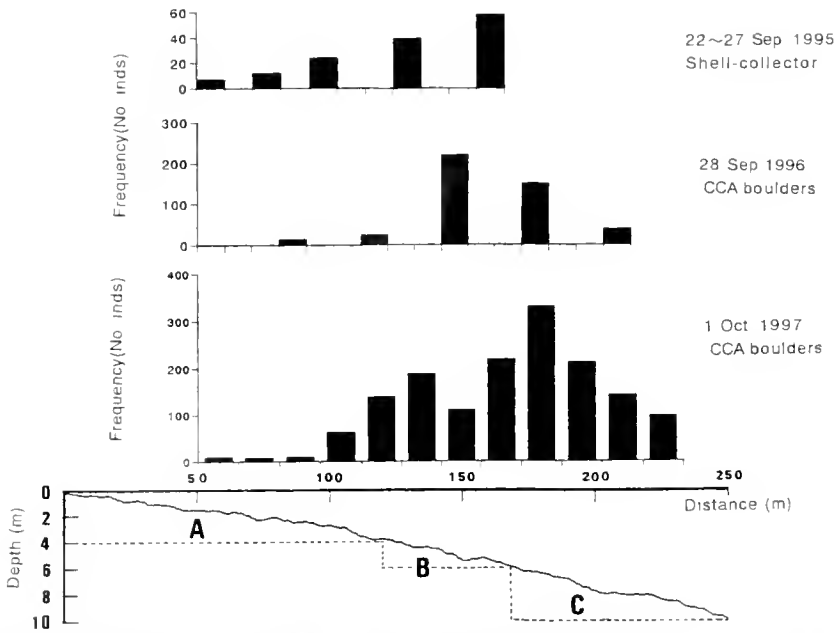

Figure 4. Vertical distribution of density of *Haliotis* post-larvae in numbers/m^2 along a transect normal to the coast at Site 1 in 1995, 1996 and 1997, with depth profile of the bottom and horizontal extent of Zones A, B and C.

Distribution of Juveniles

Length-frequency distributions of juvenile abalone in Zones A, B, and C for all sites combined (Fig. 11) show that the largest mean size and the highest densities of juveniles were in the *Eisenia* forest (A) and the lowest densities were in the CCA flats (C). The mean density of juveniles was 1.06/m^2 in Zone A, 0.83/m^2 in Zone B and 0.27/m^2 in Zone C. Mean densities in Zones A and B did not differ significantly (t = 1.3; NS) but did differ significantly between Zones B and C (t = 3.1; P, 0.01). Size distributions in Zones A and C differed significantly from those in Zone B (for AB and BC comparisons χ^2 = 119 and 35 respectively: $P < 0.001$). Mean shell lengths in the three zones were 79 mm, 46 mm and 62 mm respectively. The age distribution of juveniles in the three zones combined (Fig. 12) shows that the density of the 0+ and 1+ years classes was 6–7 times higher in Zone B than in the other zones. The 0+ and 1+ year classes combined comprised 6% of all abalone on Zone A, 49% in Zone B and 25% in Zone C. The age distributions in Zones A and C also differed significantly from that in Zone B (for AB and BC comparisons χ^2 = 486 and 123 respectively; $P < 0.001$).

A change in the ratio of the density of each year class in Zone A to the density of the same year class in Zone B (Fig. 13) indicates the likely direction of migration between the two zones assuming that there is no differential M between zones. The low ratios for the 0+ and 1+ year classes shows high settlement and retention of those year classes within the zone, and the sigmoid curve for older year-classes suggests strong initial migration of the 2+ year-class from Zone B to A levelling off in the older year-classes.

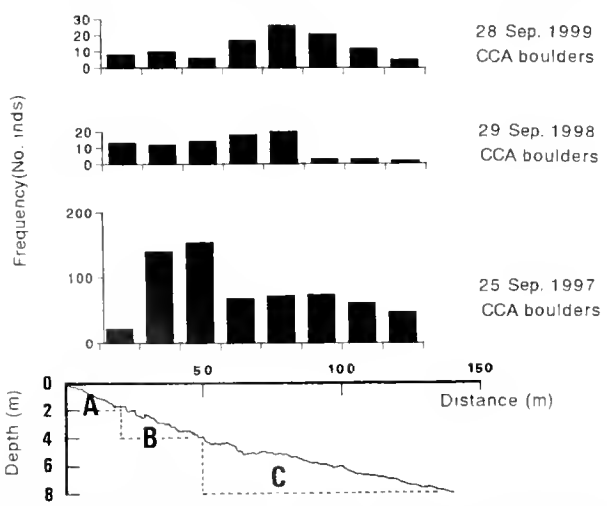

Figure 5. Vertical distribution of density of *Haliotis* post-larvae in numbers/m^2 along a transect normal to the coast at Site 2 in 1997, 1998 and 1999 with depth profile and zones as in Figure 4.

DISCUSSION

Post-Larval Distribution

This paper provides the first published account of the dynamics of settlement of *H. d. hannai*, survival of spat, and subsequent

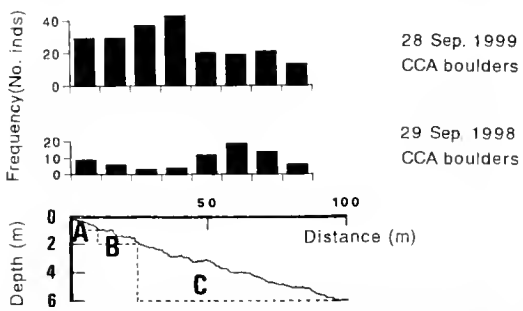

Figure 6. Vertical distribution of density of *Haliotis* post-larvae along a transect normal to the coast at Site 3 in 1998 and 1999 with depth profile and zones as in Figure 4.

movement of juveniles in relation to the near-shore habitats in north-east Honshu. Our earlier study (Sasaki & Shepherd 1995) examined larval dispersal in Kesennum and Samenoura Bays, and the vertical distribution of larval settlement in Kesennuma Bay. Larvae were advected shoreward by wind-driven on-shore currents and the highest density of settlers occurred on high energy coasts at 4–6 m depth. Larval densities declined sharply with increasing shelter within bays. Sasaki and Shepherd (1995) suggested that the preferred depth of settlement was fixed during the late veliger stage when highest larval concentrations were also found at 4–6 m depth.

The settlement of this abalone in Samenoura Bay (this study) follows the same pattern as in Kesennuma Bay, 120 km north (Sasaki & Shepherd 1995). The *Eisenia* forest habitat (Zone A) and adjacent habitats (B and C) are widest on exposed Pacific coasts and each zone narrows sharply with increasing shelter. The intensity of settlement is correlated both with the distribution of late veligers spatially and vertically in the water column (Sasaki & Shepherd 1995), and with the spatial extent of the *Eisenia* forest zone, which provides the source of algal food for this abalone (Taniguchi 1991). But why is the boundary zone the apparent preferred habitat for settlement of this abalone?

The other main herbivores in abalone habitat at our study sites are *Tegula lischkei, T. pfeifferi,* and *T. rustica* which all settle preferentially in Zone B and subsequently move into the *Eisenia* forest like *H. d. hannai* (R. Sasaki unpublished data). These *Tegula* species, as yet indistinguishable as post-larvae, settle at about double the density of *H. d. hannai* and may be competitors for diatoms preferred by the abalone. The habitat of *S. nudus* is coralline flats (Zone C). Further, the environmental cues which trigger epidemic spawning in *H. d. hannai* also trigger spawning of *Tegula* spp. and the sea-urchin *Strongylocentrotus nudus* (Sasaki & Shepherd 1995). We hypothesize that the CCA substratum is optimal for all four molluscs in the boundary zone but becomes less suitable with increasing depth. Seki (1997) found slow growth rates and high M of post-larval *H. discus hannai* in CCA habitat. CCA morphology varies according to the presence of an algal canopy, near-shore hydrodynamics and with depth (McShane 1996) and its suitability as a substratum for abalone post-larvae

also varies according to these factors and other local contingencies such as presence and abundance of predators. The dominant polychaete in CCA at our study sites is the detritus-feeding cirratulid *Dodecaceria concharum* (Hayashi et al. 1982) and we have no

evidence that they consume abalone spat as in McShane's experiments.

Survival

Our M values of 3.7–5.3/month according to the period examined are higher than our earlier values in Kesennuma Bay (1.4–2.7/month), but initial densities were ~900/m^2 compared with only ~200/m^2 in the former study. Shepherd (1998) and Shepherd et al. (2000) reviewed earlier studies on post-larval M and showed strong density-dependent M in the range 0.6–2.7/month; our present study is consistent with this hypothesis. But what is the mechanism for density-dependent M?

Our data suggest that starvation is a major contributing factor to the high M at our study site, and is how we summarize the evidence. First, the very high growth rates and low M on CCA cobbles show that CCA is the optimal substratum for settling post-larvae for the first five to seven days after settlement. Experiments by Daume et al. (1999a, 1999b) also favor this conclusion. The cessation of growth at ~450–500 μm thereafter suggest that food became limited and induced the increasing mortality that occurred from day eight to day 14. This is a critical phase in the life of a post-larval abalone, and diatoms are essential for further growth and survival (Kawamura et al. 1998, Daume et al. 2000). The highly skewed distribution of length-frequency data on dried boulders in the field experiment (Fig. 7) suggest that relatively few larvae grew beyond the size at settlement or, alternatively, that M of larger post-larvae was higher in comparison with natural boulders.

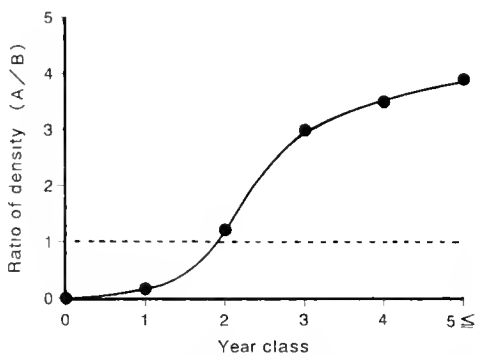

Figure 13. Plot of the ratio of density of each age class in the *Eisenia* forest (A) to the density of the same age class in the boundary zone (B).

Lastly, the apperance of atrophied post-larvae at modal sizes of 475–550 μm (Fig. 9) suggests that the high densities of post-larvae exhausted the natural diatom supply soon after the critical size when diatoms dominate the diet of post-larvae (Kawamura et al. 1998). In independent experiments with plankton trap-nets set at Site 1 in October and in other years, we have also recorded atrophied post-larvae of mean length 740 μm (SE 240 μm) as well as other small gastropods presumably washed off the substratum by wave turbulence. This suggests that starving post-larvae are susceptible to mortality from wave-shear as proposed by McShane (1996). Shepherd et al. (2000), in reviewing the evidence for density-dependent M of post-larvae, suggested that in southern Australian habitats, the carrying capacity of CCA boulders was ~100 post-larvae/m^2. From the results of this study and our earlier one we hypothesize a carrying capacity of <200/m^2 in terms of food availability on Miyago coasts. It is also possible that *Tegula* spp. may compete as post-larvae with post-larval abalone and so further reduce the carrying capacity of the habitat for abalone.

Distribution of Juveniles

The pattern of distribution of juveniles is initially similar to that of post-larvae, although in practice we found that highest juvenile densities occurred within the boundary zone (B) but just shoreward of the area of highest density of post-larvae. Because the depth of the *Eisenia* forest decreases with increasing shelter, the band of highest juvenile density is shallower in more sheltered waters.

What is the adaptive significance of shoreward migration of this abalone? Ino (1966) and Nie (1992) stated that this abalone migrated into shallow water before spawning, implying some adaptive advantage such as increased larval dispersal. If so, this behavior is analogous to the movement of other abalone species into the swell or into increased current flow (Shepherd 1986, Clavier & Richard 1984). While this may be true at our study site, the obvious explanation is that *Eisenia* and associated algae are a preferred food (Taniguchi 1991, Shepherd & Steinberg 1992). Hence movement to this habitat must be advantageous for growth and reproduction. A similar size-related migration by the related species *H. kamtschatkana* from deeper water where larvae settle into shallower kelp habitat is also recorded in Alaska and Canada (Sloan and Breen 1988, S. A. Shepherd unpublished data). Such migration is quite different from the aggregation and movement of spawning adults onto the highest points of reefs in shallow water for spawning (Breen & Adkins 1980, Stekoll & Shirley 1993, unpublished observations).

CONCLUSIONS

Our study has important implications for the management of the declining *H. d. hannai* fishery in north-east Honshu. Abalone larvae advect shoreward according to local hydrodynamic conditions and settle at densities that depend on coastal topography and the extent of suitable habitat. Post-larval densities of both this abalone and *Tegula* spp. are highest in the boundary zone between the near-shore *Eisenia* forest and the deeper CCA habitat. However, post-larval survival appears to be food-limited because significant numbers of post-larvae five to seven days old show an atrophied condition. This raises the possibility that the abundance of *Tegula* post-larvae in the same habitat may affect the survival of post-larval abalone.

With increasing age juvenile abalone migrate into the *Eisenia* forest which provides an abundant food supply for adult abalone. To achieve an understanding of the causes underlying the decline of the fishery, studies should now focus (a) on the relation between recruitment strength of abalone into the fishery and the extent of the boundary zone, and (b) the competitive relations between abalone and *Tegula* post-larvae.

ACKNOWLEDGMENTS

We thank Dr. K. Taniguchi (University of Tohoku) for his valuable advice on the algal flora at our study sites and for permission to use the data in Figure 2. Dr. T. Seki (National Research Institute of Aquaculture) gave helpful advice and encouragement. We thank Dr. Sabine Daume for improvements to the manuscript.

SUITABILITY OF AUSTRALIAN FORMULATED DIETS FOR AQUACULTURE OF THE TROPICAL ABALONE *HALIOTIS ASININA* LINNAEUS

D. JACKSON,[1,2] K. C. WILLIAMS,[2] AND B. M. DEGNAN[1,*]

[1]Department of Zoology and Entomology, University of Queensland, St. Lucia 4072, Australia; [2]CSIRO, Division of Marine Research, P.O. Box 120, Cleveland 1163, Australia

ABSTRACT The performance of *Haliotis asinina* Linnaeus fed four commercially available diets formulated for temperate Australian species was assessed relative to a natural diet of *Gracilaria edulis*. Parameters measured included growth in terms of total wet body weight (TWBW) and shell length (SL), survival, food conversion ratio (FCR), condition index (CI), and sexual maturation. The results of these measurements indicated that two of the formulated diets could be used for commercial culture of *H. asinina*. Nutritional and physical parameters of these diets were used in a multivariate regression analysis to identify variables that explained the most variation in growth between diets. Parameters that were selected by this analysis were the ratio of crude protein (CP) to gross energy (GE) and the rate that protein leached from the formulated diets. The resulting regression equation was highly significant in its explanation of the variation in growth ($P = 2.2 \times 10^{-6}$). To determine the quality of the dietary CP in each diet, the essential amino acid profile of each diet was compared to that of whole soft body tissue in *H. asinina*. Methionine seemed to be deficient in all of the diets. Animals fed *G. edulis* did not seem to suffer from a lack of n-3 PUFAs.

KEY WORDS: *Haliotis asinina*, formulated diet, growth, amino acid, fatty acid, sexual maturation, protein leaching

INTRODUCTION

Many abalone fisheries around the world are in decline (Hahn 1989a), and, as a result, research programs aimed at the efficient artificial production of a range of haliotid species are underway. One important aspect of such research is the identification of the nutritional requirements of commercially important abalone species (Fleming et al. 1996). This allows the formulation of cost-effective diets that provide a consistent and precise method of supplying the nutrients necessary for maximal growth. Diet formulations can also be easily modified as the nutritional requirements of an animal changes during development (e.g., postsettlement, growout, and broodstock diets).

Traditionally, the majority of abalone diet research around the world has focused on temperate species, because these form the majority of abalone exports worldwide (Hahn 1989a). However, recent research has indicated a growing demand for tropical abalone (Nateewathana & Hylleberg 1986, Singhagraiwan & Doi 1993, Jarayabhand & Paphavisit 1996). Jarayabhand and Paphavisit (1996) report that in Taiwan these smaller tropical species are preferred to the temperate species because of their size and delicate flavor.

The distribution, ecology, reproductive biology, and natural diet of the tropical abalone *Haliotis asinina* Linnaeus differ from Australian temperate species. *H. asinina* is found on intertidal coral reef flats throughout the Indo-Pacific (Gosliner et al. 1996); whereas, *Haliotis rubra* Leach and *Haliotis laevigata* Donovan are subtidal animals (Prince & Shepherd 1992) found on rocky temperate reefs. Populations of *H. asinina* on Heron Island (23°27′S; 151°55′E) spawn fortnightly in cue with lunar and tidal cycles from mid-October to mid-April (Counihan et al. 2001); whereas, temperate species in culture are artificially induced to spawn because of their relatively unpredictable and infrequent natural spawning patterns (Hahn 1989b). Temperate Australian abalone occur on reefs where macroalgae are relatively abundant (Dayton 1994); whereas, the abundance of frondose macroalgae on coral reefs is limited (Littler & Littler 1994). Sawatpeera et al. (1998) demonstrated that the gut contents of adult *H. asinina* collected from coral reefs of Samed Island, Thailand contained over 80% diatoms. These significant differences between temperate and tropical abalone suggest that diets formulated for temperate Australian abalone, *H. rubra* and *H. laevigata*, may not be suitable for *H. asinina*.

Research on tropical abalone nutrition is limited. Capinpin and Corre (1996) have investigated the growth rates produced by *H. asinina* fed a Japanese-formulated diet over 90 days, but performed minimal nutritional analyses on the diets used. Bautista-Tereul and Millamena (1999) also conducted a 90-day growth experiment and reported on the effects of dietary energy and protein on the growth of *H. asinina*, but not on the fatty acid (FA) profiles of the diets. These studies did not include a nutritional acclimatization period, and were run for only 90 days. Day and Fleming (1992) highlight the effects that previous diets may have on growth and recommend an initial period of nutritional acclimatization before any growth experiments, even for artificially produced animals that have a common diet history. Furthermore, they suggest that, in the case of *H. rubra*, a growth trial of less than 100 days will not be informative.

Here we report on the suitability of formulated diets that were produced for temperate Australian species (*H. rubra* and *H. laevigata*) for the culture of *H. asinina*. We determined: (1) the water stability of the diets; (2) rates of growth in terms of total wet body weight (TWBW) and shell length (SL) increase; (3) sexual maturation; (4) food conversion ratio; (5) dry feed intake; and (6) the condition index (CI) of the abalone after being fed these diets for 6 mo after a nutritional acclimatization period of 49 days. Growth rates promoted by the various diets are related to a range of nutritional parameters, including the crude protein (CP), total lipid (TL), gross energy (GE), fatty acid (FA), and essential amino acid contents of the diets fed.

MATERIALS AND METHODS

Diets

Samples of four formulated diets from two Australian abalone feed companies were obtained for comparison with a natural diet

*Corresponding author. E-mail: bdegnan@zen.uq.edu.au

of the red seaweed, *Gracilaria edulis*. Animals were fed nightly to satiation, and uneaten food was removed the following morning. This procedure was done only once on weekends. *G. edulis* was chosen as the reference diet, because *Gracilaria* species have been reported to promote high growth in *H. asinina* (Singhagraiwan & Sasaki 1991, Singhagraiwan & Doi 1993, Capinpin & Corre 1996, Bautista-Teruel & Millamena 1999, Capinpin et al. 1999).

Animals and Management

Juvenile *H. asinina* used in the following experiments were derived from spontaneous spawnings by wild broodstock collected from Heron Island, Great Barrier Reef, Australia (23°27′S; 151°55′E). Abalone at the start of the experiment ranged in SL from 11.8 mm to 23.4 mm (average 18.3 ± 2.76 mm) and TWBW from 0.40 g to 2.75 g (average 1.32 ± 0.577 g). Individuals were blot dried, weighed, measured, tagged, and assigned to an experimental unit. Abalone were distributed among replicates so that there were no significant differences in SL or TWBW. Each diet treatment was replicated six times, and consisted of a 1.7-L lidded plastic container (21 × 14 × 7 cm) housing four abalone. A "spare" replicate of each diet treatment was also maintained. Animals in these spare replicates were used to replace any that died during the experiment. This maintained a constant density of animals per experimental unit for the duration of the experiment. Filtered (10 μm) seawater was heated to 28°C and delivered to individual containers at a rate such that the entire volume was exchanged once every 3 min. Seawater was not recirculated. Abalone were maintained in a 12L:12D light cycle for the duration of the experiment. Abalone were acclimatized to their respective diet treatments before the first TWBW and SL measurement for 49 days to reduce the residual effects of accumulated body stores from previous natural diets.

Growth Data Collection

SL and TWBW measurements of every animal were made at four weekly intervals. The trial was run for 24 wk. Growth promoted by each diet treatment was expressed as the increase in SL and TWBW over 24 weeks. All animals were examined for the presence of gonad tissue from the third month of the experiment onward. If gonad tissue was present, its color was recorded, allowing the sex of individual animals to be determined. As animals were individually tagged, a statistical comparison between male and female growth rates was also made.

Condition Index

A simple CI was used to evaluate the health of each animal at the end of the experiment using the equation:

$$CI = {}^{SFBW}/_{TWBW} \times 100$$

where TWBW is the total wet body weight (g), and SFBW is the shell free body weight (g). SFBW was estimated by subtracting the shell weight (SW) from the TWBW. Because the animals used in the feeding trial were to be used in other experiments, SW was estimated indirectly according to the equation:

$$SW = 3 \times 10^{-4} \times SL^{2.3245}$$

where SL equals shell length. This relationship had an R^2 value of 0.99 and was derived from over 300 shell measurements.

Food Conversion Ratio

The food conversion ratio (FCR) of animals reared on each diet was estimated during wk 18 to 20. Each night the wet weight of diet added to each experimental unit was weighed to within 0.1 mg. Twelve h later, uneaten feed was collected by passing the entire contents of each experimental unit carefully through a 1-mm^2 filter to remove feces, and then through preweighed Whatmann filter paper. The wet feed was then vacuum filtered and dried at 105°C overnight. For each experimental unit, the nightly dry feed intake (DFI) was calculated as follows:

$$DFI = f_1 \times {}^{DM}/_{100} - ({}^{f_2 \times 100}/_{WS})$$

where f_1 is the wet weight (g) of feed added each night, DM is the percentage of dry matter for each diet, f_2 is the weight (g) of uneaten dried feed, and WS is the water stability (%) of each diet. Water stability was calculated as the dry weight retained after immersion in seawater for 12 h under conditions identical to those at which the growth experiment was conducted. The nightly DFI over the 2-wk period was summed to give the total food intake (TFI) for each replicate. TWBW measurements were taken at the beginning and end of the 2-wk period, allowing the FCR to be calculated as follows:

$$FCR = {}^{WG}/_{TFI}$$

where WG is the TWBW gain (g) over the 2-wk period.

Gonad Index and Histology

During the final TWBW and SL measurements the gonad index (GI) of each animal was ranked following the method described by Singhagraiwan and Doi (1992). At the end of the growth experiment, the gonads from the two most mature animals of each sex on each diet were dissected, fixed in Bouin's fixative for 6 days, and washed three times in 70% ethanol over 3 days. Gonads were then embedded in paraffin, sectioned at 6 μm on a Spencer 800 microtome and stained with hematoxylin and eosin. Representative digital photos were taken with an Olympus DP10 digital camera attached to a BX60 microscope.

Nutritional Analyses

Representative samples of each diet were analyzed, usually in triplicate, for nutrient composition. The dry matter of each diet was determined by drying at 105°C for 12 h. Ash content was determined by incinerating dried samples at 200°C for 2 h, and then at 550°C for 12 h. Nitrogen content was analyzed by the Kjeldahl procedure, and CP was estimated by multiplying the nitrogen content by 6.25. TL was extracted with chloroform-methanol using the method of Folch (Folch et al. 1957). Saponification and esterification of the TL extract was performed following a modified method of van Wijngaarden (1967). Two replicate extracts of each diet were analyzed on a Hewlett Packard GC for FA content. GE was measured with an IKA Labortechnik Calorimeter.

For amino acid analysis, six wild adult abalone, ranging in TWBW from 63.6 to 149.3 g and in SL from 63 to 100 mm, were shucked, and the foot and viscera were blended together into a homogenate before being freeze dried. Two replicates of each diet were freeze dried and finely ground using a mortar and pestle. Samples were hydrolyzed in 6 M HCl at 105°C for 24 h. Free amino acids were derivitized using phenylisothiocyanate and separated using high-power liquid chromatography (HPLC) on a C-18 column with detection at 254 nm. Instrumentation was a Bio-Rad

2800 solvent delivery system with a Bio-Dimension UV/Vis monitor, controlled by a Series 800HPLC and v2.30.1a software. To compare diets directly, each amino acid was expressed as a proportion of the corresponding amino acid in *H. asinina* whole soft body tissue.

Protein Leaching

The rate of protein leaching from each diet was measured by the Bradford micromethod of protein estimation (Bradford 1976) using the Bio-Rad protein assay kit. 100 mL of 10 μm filtered seawater was placed into a clean conical flask and a background reading (before addition of any diet) was taken in triplicate. Approximately 1 g of each diet was weighed to within 0.1 mg and added to a flask. Triplicate optical density readings were taken at exactly 30 and 60 min after the addition of a diet treatment and thereafter hourly for a further 6 h using a Hitachi U-2000 spectrophotometer. Flasks were gently vortexed (approximately 120 cycles/min) in a Ratek orbital mixer at room temperature to simulate the effects of water flow and physical disturbance. A control consisting of 100 mL of seawater was run in parallel to the dietary treatments. All treatments were replicated three times, and optical density readings were related to a standard curve constructed from 10 concentrations of bovine serum albumin dissolved in seawater. The total protein leached (i.e., the protein concentration after 7 h) was expressed as a percentage of the total protein added to the flask (calculated from the protein content of each diet and the weight of feed added to each flask). It was found that *G. edulis* could not be included in this experiment, because it interfered with the dye-binding reaction of the Bradford method, resulting in protein concentrations less than the control. Therefore, to be included in the multiple regression analysis (see below) it was assumed that *G. edulis* leached no protein over a 7-h period.

Statistical Analyses

All statistical analyses were performed on STATISTICA for Macintosh (Statsoft 1994). All datasets were tested for violation of the assumptions of homogeneity of variance, normality, and independence of errors before further analysis. Datasets that failed any one of these assumptions were transformed and re-analyzed. The effect of tank was tested for all analyses where appropriate and was never found to be significant. Where significant differences between diet treatments were detected by one-way analysis of variance (ANOVA), a Student's–Newman-Keuls test (SNK) was performed for *a posteriori* comparison of treatment means. Growth data were analyzed by comparing the total increase in SL and TWBW between diets for the entire duration of the trial by one-way ANOVA. TWBW data were square root transformed before analysis to satisfy the assumptions of normality, independence of errors, and homogeneity of variance. SL data did not require transformation. The effect of diet and sex on GI was tested by a Kruskal- Wallis ANOVA by ranks. A forward stepwise multiple regression analysis was used to determine the nutritional parameters that explained the most variability in TWBW growth. Variables included in this analysis were: CP, TL, GE, the ratio of CP to GE, and the rate that protein leached from the diets (this rate was assumed to be zero for *G. edulis*, see above). Those variables that produced an F ratio in excess of 1.0 were included in the regression equation, and the tolerance level was set at 0.01. The significance level for all statistical analyses was set at $\alpha = 0.05$.

RESULTS

Water Stability and Nutritional Composition of Diets

The water stability and nutritional composition of four formulated diets and *G. edulis* were analyzed (Table 1). Diets were arbitrarily labeled 1 to 4. Diet 4 was significantly ($P < 0.05$) more water stable than all other formulated diets. When compared on a dry matter basis to *G. edulis*, formulated diets had significantly ($P < 0.05$) higher CP (21.8–40.0 vs 16.4%), TL (4.1–5.7 vs 0.8%) and GE (18.7–19.4 vs 9.0 MJ/kg) contents, respectively. The ash content and CP:GE ratio of diet 4 was significantly lower ($P < 0.05$) than all other diets (4.8–5.4 vs 3.3% for ash and 17.0–20.8 vs 11.7 mg/kJ for CP:GE). The rate of loss of protein from each of the formulated diets was essentially linear over 7 h, but seemed to begin to plateau by the final measurement, most noticeably in diet 4 (Fig. 1). The total loss of protein (expressed as mg dissolved protein per mL of leachate per gram of feed) over 7 h ranged from 9.1 to 18.0 (Fig. 1), with diet 4 losing the least protein and diet 3 the most. However, when the total amount of protein leached was expressed as a percentage of the total available protein (a more meaningful measure because of the different protein contents of each diet), diet 1 leached the lowest proportion of its protein content (9.6%), and diet 4 leached the highest proportion of its protein content (13.4%). These differences were significant between all diets, except diets 3 and 4 ($P < 0.05$; see Table 1).

Amino Acids

Relative to the formulated diets, the essential amino acid (EAA) composition of *G. edulis* protein contained higher amounts

TABLE 1.

Water stability and gross nutritional composition of four formulated diets and *Gracilaria edulis* fed to *Haliotis asinina*.

	Water Stability (%)	Protein Leached (mg/kg CP)	Moisture (g/kg)	Ash (g/kg)	CP (g/kg)	TL (g/kg)	GE (MJ/kg)	CP:GE (g/MJ)
Diet 1	76.6 (0.67)^{a}	96 (2.0)^{a}	111 (0.18)^{a}	54 (0.7)^{a}	400 (3.7)	45 (3.9)^{a}	19.2 (0.11)^{a,b}	20.8
Diet 2	75.0 (0.15)^{a,b}	113 (1.6)^{b}	124 (0.25)^{b}	53 (0.3)^{a}	347 (0.4)	57 (1.3)^{b}	19.4 (0.09)^{a}	17.9
Diet 3	77.8 (0.09)^{b}	126 (1.7)^{c}	113 (0.16)^{a}	48 (2.3)^{b}	322 (6.4)	41 (0.8)^{a}	19.0 (0.10)^{a,b}	17.0
Diet 4	82.9 (1.32)^{c}	134 (4.3)^{c}	92 (0.12)^{c}	33 (0.2)^{c}	218 (5.8)	55 (1.2)^{b}	18.7 (0.07)^{b}	11.7
G. edulis	95.4 (1.70)^{d}	ND	890 (1.02)^{d}	59 (2.3)^{d}	164 (1.6)	8 (1.4)^{c}	9.0 (0.24)^{c}	18.2

Water stability is expressed here as the percentage of dry weight remaining after overnight immersion in seawater. Protein leached is expressed as the weight of dissolved protein per kg of CP after 7 h immersion in seawater. Moisture is expressed as the weight (g) lost after 12 h at 105 °C. Ash, crude protein (CP), and total lipid (TL) values are expressed as g/kg of dry diet. Gross energy (GE) is expressed as MJ per kg of dry sample. Numbers in parentheses are standard deviations of the mean. Values in the same column that share the same superscript letter do not differ significantly ($P > 0.05$).

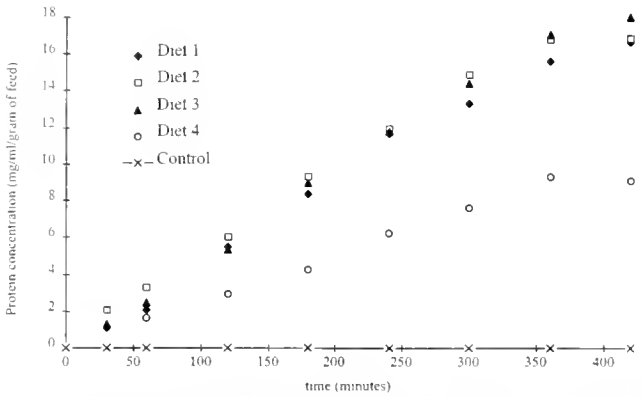

Figure 1. Rate of protein leaching measured in four formulated diets over 7 h. Values are expressed as milligrams of dissolved protein × mL of leachate^{-1} × gram of feed^{-1}. Error bars are omitted for clarity of presentation. The control consisted of three flasks of seawater treated in exactly the same way as the diet treatments.

of isoleucine, leucine, methionine, threonine, and valine and a lower amount of histidine (Table 2). Of the formulated diets, diet 4 contained the lowest amounts of all essential amino acids except for lysine (Table 2).

Fatty Acids

Large differences were found in the FA profile of *G. edulis as* compared with the four formulated diets (Table 3). The largest differences were between 20:4n–6 (53–79 times less abundant in the formulated diets) and 18:2n–6 (40–53 times more abundant in the formulated diets). Other large differences were seen for 18:3n–3, 20:1n-9 and 22:6n–3, which were less abundant and for 20:3n–6, which was more abundant in *G. edulis* as compared to the formulated diets. These differences culminated in total n–3 FAs being approximately five times higher in the formulated diets. Total n–6 FAs occurred at similar concentrations in all diets; whereas, saturated FAs (SFAs) were higher in *G. edulis* relative to the formulated diets. Differences in the FA profiles between formulated diets were less pronounced than those between *G. edulis* and formulated diets. The most obvious difference was with diet 4, which was higher in total n–3 and lower in total n-6 FAs compared to diets 1 to 3 (Table 3).

Feeding Study

Animals reared on *G. edulis*, diet 1 and diet 2 produced significantly (P <0.05) higher TWBW growth rates than animals reared on diets 3 and 4 (Table 4). *G. edulis* produced significantly (P <0.05) higher SL growth than all other diets, followed by diet 1, which was significantly higher than all the other formulated diets (P <0.05). Diet 2 produced significantly (P <0.05) higher SL growth than diets 3 and 4, which did not differ from each other (Table 4). No difference was detected between male and female growth in terms of TWBW and SL growth (data not shown). Although the cumulative monthly measures of TWBW and SL show a fairly linear growth rate over 24 weeks across all diets (Fig. 2), the monthly growth rates (Fig. 3) revealed a considerable amount of intermonthly variation. Most noticeable was the eleva-

TABLE 4.

Increase in total wet body weight (g) and shell length (mm), mean condition index, mortality rates, food conversion ratio, and nightly dry food intake of abalone reared on four formulated diets and *Gracilaria edulis* for six months.

	TWBW Growth	SL Growth	CI	Mortality	FCR	DFI

Total wet body weight (TWBW) growth data was square root transformed before any statistical analysis was performed, but values presented here are untransformed. Condition index (CI) measures are the weight of soft tissue (viscera and muscle) expressed as a proportion of the total wet weight (soft tissue plus shell weight). Mortality is expressed as the number of deaths recorded for each diet as a proportion of that recorded for *G. edulis*. Food conversion ratio (FCR) was calculated as the ratio of dry feed eaten to wet weight gained. Dry food intake (DFI) is the weight of dry food eaten each night, expressed as a percentage of wet body weight. Values in the same column that share the same superscript letter do not differ significantly. Numbers in parentheses are standard errors of the mean, except for FCR and DFI where they are standard deviations.

tion in growth over mo 2 to 4 relative to mo 0 to 2, followed by the subsequent decline over months 4 to 6.

Animals fed diet 1 had significantly higher ($P < 0.05$) condition indices than those reared on all other diets; whereas, animals fed diet 4 had significantly lower condition indices than those reared on all other diets (Table 4).

FCRs did not differ significantly between diet treatments (Table 4). However, the power of this ANOVA to detect a difference was very low (approximately 16%). FCRs for the formulated diets ranged from 1.4 to 1.8; whereas, that for *G. edulis* was 1.6. During the period of FCR measurement, abalone fed *G. edulis* ate significantly more ($P < 0.05$) than animals fed diets 1 and 3; whereas, those fed diets 2 and 4 did not differ from *G. edulis* in the weight of food eaten. Animals fed diets 1 to 4 did not differ significantly in the weight of food eaten (Table 4).

The results of the multivariate regression analysis identified two nutritional parameters that explained a significant proportion of the variation in growth observed: CP:GE ratio and the rate of protein leaching. Overall, the regression equation was highly significant ($P < 0.01$) with an R^2 value of 0.63 (Table 5). The CP:GE ratio carried the most weight in explaining growth with a beta coefficient of 0.55; whereas, the inverse relationship between protein leaching and growth had a beta value of −0.39. The normal probability plot of residuals revealed a very strong linear associa-

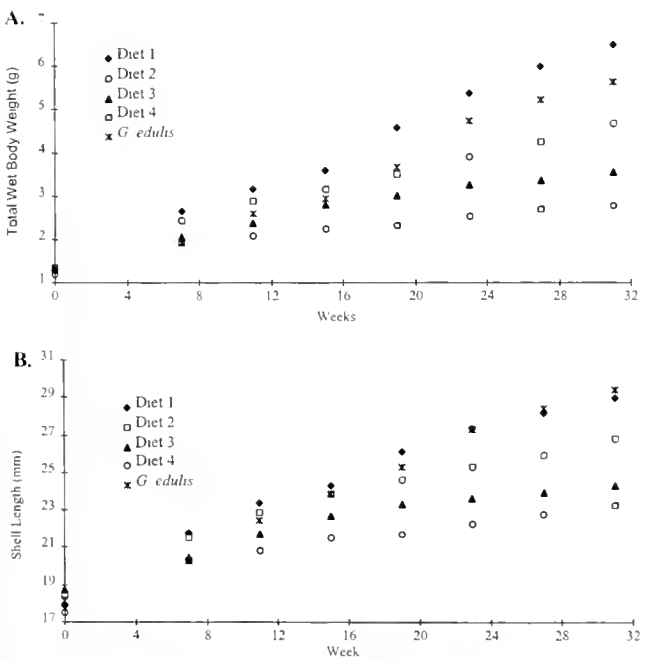

Figure 2. Average (n = 6) cumulative growth of abalone fed four formulated diets and *G. edulis* over 24 wk after a nutritional acclimatization period of 7 wk (shown as week 0 to week 7). Measures were taken every 4 wk. Growth was measured in terms of (A) total wet body weight and (B) shell length. Error bars are omitted for clarity of presentation.

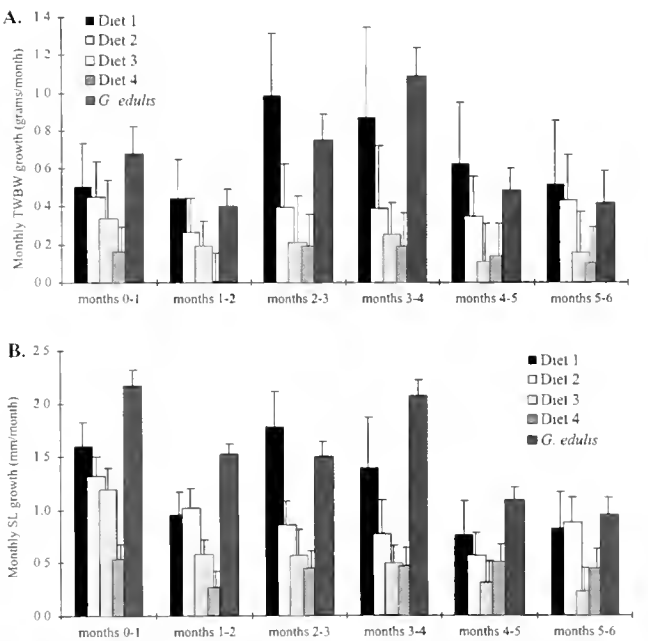

Figure 3. Average (n = 6) monthly growth rates of abalone fed four formulated diets and *G. edulis* over 24 wk after a nutritional acclimatization period of 7 wk. Monthly growth rates are presented in terms of (A) total wet body weight and (B) shell length. Error bars are the standard error of the mean.

TABLE 5.

Results of forward stepwise multivariate regression analysis.

Variable	Beta Coefficient	SE Beta	B coefficient	SE B	Tolerance	*P*-Value
CP:GE	0.55	0.13	0.09	0.02	0.83	0.0003
Protein leaching	−0.39	0.13	−0.04	0.01	0.83	0.006
Regression equation			Growth = 0.37 + 0.09 CP:GE − 0.04 Protein leaching			2.2×10^{-6}

tion, indicating that all variables were normally distributed. A scatter plot of observed versus predicted residuals revealed that a linear regression was a good description of the relationship between growth and the three selected variables. No outliers were detected.

Gonad Index and Histology

Males were significantly more mature than females by the end of the trial ($P = 0.029$). When separated by sex, the GI of females fed different diets did not differ significantly ($P = 0.23$); whereas, for males the effect of diet on GI was significant ($P = 0.015$); diet 1 produced the most mature males, followed in order by diets 2, 3, 4, and *G. edulis* (Table 6). The smallest animal with visible gonad tissue had an SL of 16.4 mm, weighed 0.92 g, was male, and had been fed diet 4 for 84 days.

When examined microscopically, all animals reared on *G. edulis* and diets 1 and 2 seemed to have healthy gonads when compared to gonadal sections of *H. asinina* taken by Apisawetakan et al. (1997) and Jebreen et al. (2000). Sections of gonads from animals reared on diets 3 and 4 showed evidence of substantial amoeboid cell activity and large areas of degenerated oocytes; animals reared on diet 4 seemed to be more affected than animals fed diet 3 (Fig. 4).

DISCUSSION

Growth Experiment

This study sought to compare the growth of *H. asinina* reared on commercially available Australian temperate abalone feeds relative to a *Gracilaria* diet, a genus of red algae known to sustain high growth in this haliotid (Upatham & Sawatpeera 1998, Bautista-Teruel & Millamena 1999, Capinpin et al. 1999). Comparing the growth rates achieved by *H. asinina* fed the commercial feeds to that of individuals fed *G. edulis* demonstrates that two of these formulated diets may be suitable for the aquaculture of *H. asinina* (Table 4 and Fig. 2). Although the highest SL growth was obtained on *G. edulis*, TWBW growth was not significantly different between *G. edulis*, and diets 1 and diet 2. From an aquaculture perspective, weight gain is considered to be more important than SL increase (see Fleming et al. 1996). Furthermore, the CI of animals reared on diet 1 (87.1%) was significantly higher than that of animals reared on *G. edulis* (85.0%), indicating that diet 1 produced healthy animals of a high product quality (Table 4).

TABLE 6.

Gonad index observations made at the end of the growth experiment.

	Diet 1	Diet 2	Diet 3	Diet 4	*G. edulis*	*P*-Value
Male GI	3	2	2	1.5	0	0.015
Female GI	0	1.5	1	1	0	0.225

Values are medians and range from 0 to 3, with 3 being fully mature. *P*-values were obtained from a Kruskal-Wallis analysis of variance (ANOVA) by ranks.

The diets and experimental conditions employed within this study produced growth rates lower than similar studies on *H. asinina*; Capinpin et al. (1999) recorded an SL growth rate of 60 mm/year (equivalent to 164 μm/day) with animals reared in sea cages and fed *Graciliaria bailinae*. Bautista-Tereul and Millamena (1999) achieved growth rates ranging from 222 to 247 μm/day over 90 days when 20 juvenile *H. asinina* (of a similar size to those used in the present study) were housed in large 60-L containers and fed either of three formulated diets. In the present study, *H. asinina* were reared in small (1.7 L) enclosures, which may have contributed significantly to the low growth rates (19–56 μm/day) when compared to these studies. Although the results are not directly comparable because of differing experimental conditions, Capinpin et al. (1999) found a significant density dependent effect on growth across four stocking densities: 43, 88, 130, and 175 abalone/m^2. The density used within this experiment equated to approximately 72 abalone/m^2, and implies that growth may have been affected by density. Furthermore, Mgaya and Mercer (1995) demonstrated a size grading effect on growth in *H. tuberculata* such that small abalone reared in the presence of large abalone did not grow as quickly as their size-graded counterparts. In our study, strict size grading did not occur. Growth may have been less variable and possibly higher had such a regimen been employed.

No significant differences were detected in the DFI by animals fed the formulated diets (Table 4), suggesting that differences in growth between these diets were attributable to nutritional factors rather than diet preferences (see Vandepeer *et al.* 1999). However, animals fed *G. edulis* ate significantly more than animals fed diets 1 and 3. Therefore, the possibility that animals fed *G. edulis* grew faster in terms of TWBW than animals fed diet 3 because of a higher food consumption cannot be ruled out.

Despite the short period over which FCR measurements were taken, the recorded values were low (1.4–1.8), and similar to those reported by Bautista-Tereul and Millamena (1999). The formulated diets used by these authors produced very high growth in juvenile *H. asinina* of a similar size to those used in the current study. Furthermore, Fleming et al. (1996) reviewed the food conversion efficiency (FCE) of seven diets formulated for temperate abalone by various feed manufacturers around the world and reported an FCR range of 0.77 to 3.33. The FCR values obtained in the present study compare favorably (Table 4).

All four formulated diets leached a considerable portion of their protein content when gently agitated at room temperature for 7 h (Fig. 1 and Table 1). The only other similar assay for abalone diets

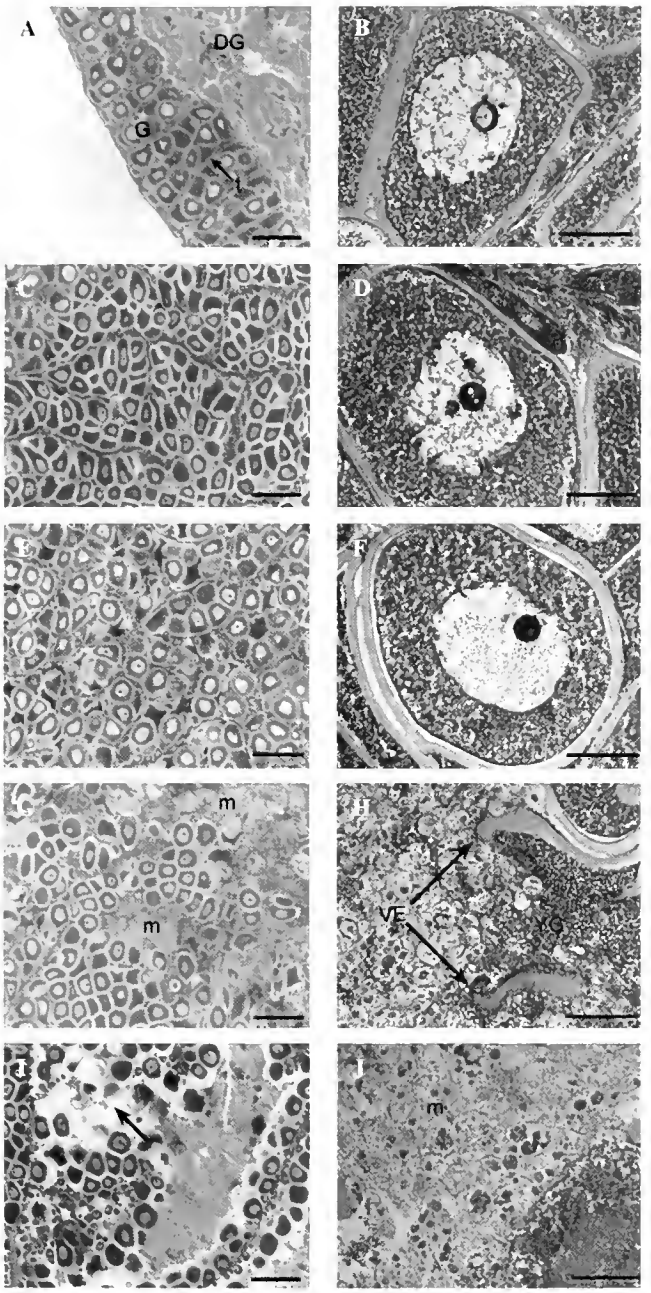

Figure 4. Representative ovary structures of *H. asinina* reared on a natural diet and four formulated diets. (A-B) Sections of ovary taken from an animal reared on *G. edulis* for 6 mo. Animals reared on *G. edulis* were not as mature as those reared on the formulated diets. This is reflected by the relatively thin layer of ovary that overlies the digestive gland. DG, digestive gland; t, trabeculae; G, Gonad. (C-D) Sections of ovary taken from an animal reared on diet 1 for 6 mo. Note the similarity in the over-all structure of the gonad in C, and in the size and shape of an individual oocyte and germinal vesicle in D. (E-F) Sections of ovary taken from an animal fed diet 2 for 6 mo. Note the similarities between diets 1 and G. edulis. (G-H) Sections of ovary taken from an animal fed diet 3 for 6 mo. Note the lack of over-all integrity of the gonad in G, with large populations of macrophages (m). In H, an oocyte that has had its vitelline envelope (VE) ruptured is undergoing phagocytosis by macrophages. Yolk granules (YG) are also evident. (I-J) Sections of ovary from an animal fed diet 4 for 6 mo. Note extensive voids left by degenerated gonad tissue (arrowhead) in I, and extensive macrophage activity in J. Scale bars in A, C, E, G, and I are 100 μm, and in B, D, F, H, and J are 10 μm.

(Viana et al. 1996) reported a leaching rate of 90.1 to 98.7mg/g over 12 h at 16°C, indicating that those diets were more protein-stable than those employed within the present study. The results of the protein leaching assay contradict the water stability results, because diet 4 (the most water-stable diet) leached the highest proportion of its protein; whereas, diet 1 (no different from the least water stable diet) leached the lowest proportion of its protein. This discrepancy between nutrient leaching and dry matter water stability has been noted by others (Viana et al. 1996, Edwards & Cook 1999).

The multiple regression analysis identified CP:GE and protein leaching rate as variables that explained a significant amount of the variation in growth between the five diets. The correct balance between energy and protein is essential for a diet to promote maximum growth (Fleming et al. 1996). Although CP:GE ratios are not as useful as digestible protein:digestible energy ratios (DP:DE), they were able to explain a significant amount of the variation in growth recorded in this study. The beta coefficients in Table 5 indicate the relative contribution of each variable to the regression equation. The standardized beta value of the CP:GE variable was higher than the protein leaching variable, indicating that CP:GE contributed the most toward the explanation of growth. The highest TWBW growth was achieved on diets *G. edulis* and diets 1 and 2, which had CP:GE ratios of 18.2, 20.8, and 17.9 MJ/kg, respectively. We expect that further research concerning the DP:DE ratio will allow the production of cheaper and more effective feeds (see Britz 1996, Britz & Hecht 1997, Fleming et al. 1996, Vandepeer et al. 1999). The different methods and ingredients used to bind a diet will presumably affect the rate that protein is lost from a diet. Because protein is essential for soft tissue growth in abalone and is an expensive component of a formulated feed, the efficiency with which a diet binds its protein could conceivably determine its over-all quality. The results of the multivariate regression analysis suggest that this is an essential characteristic of a formulated diet.

The two major differences in the FA content of *G. edulis* and the formulated diets lay in the amounts of 20:4n–6 and 18:2n–6 (Table 3). 20:4n–6 was 53 to 79 times more abundant in *G. edulis* than the formulated diets; whereas, 18:2n–6 was 40 to 54 times less abundant in *G. edulis*. Floreto et al. (1996) suggested that abalone may not be able to synthesize 20:4n–6 from the n–6 series of lower FAs and that it may be a nutrient that affects growth. This is supported by other workers (Dunstan et al. 1996, Mai et al. 1996, Uki et al. 1986). Although the percentage of 20:4n–6 in the formulated diets was much lower than in *G. edulis*, the higher measures of TL in diets 1 to 4 may have meant that this FA was adequately supplied.

18:2n–6 has been shown to enhance growth in other haliotids significantly (*H. discus hannai*, Floreto et al. 1996, Mai et al. 1996, and *H. tuberculata*, Mai et al. 1995). The obvious deficiencies of 18:2n–6 and total n–3 PUFAs in *G. edulis* may provide an explanation for the reduced growth rates noted in the present study in comparison to others studies on *H. asinina* that employed *G. bailinae* (see Bautista-Teruel & Millamena 1999, Capinpin et al. 1999). It could also partially explain the reduced growth rates noted during months 5 to 6 (Fig. 3A and B). It would be informative to analyze the FA profile of *G. bailinae* for comparison with *G.*

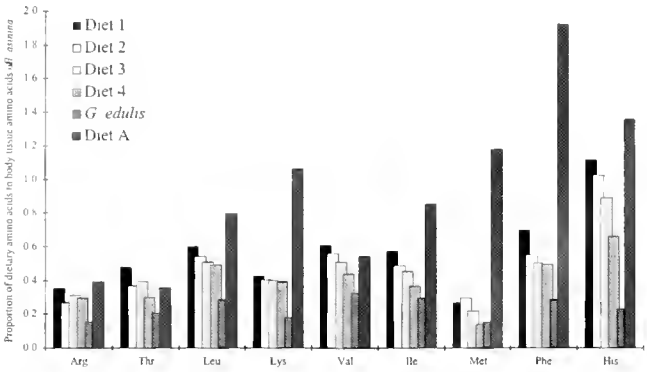

Figure 5. Essential amino acid profiles of 5 formulated diets and *G. edulis* (diet A was taken from Bautista-Teruel & Millamena 1999). The amount of each amino acid is expressed as a unitless proportion of the corresponding amino acid found in *H. asinina* soft body tissue.

edulis. It is also interesting to note that among the formulated diets, the amounts of 18:2n–6 in diets 1 and 2 (which promoted significantly higher TWBW growth) were higher than in diets 3 and 4.

Barneveld et al. (1998) concluded that Australian abalone feed formulators are oversupplying the lipid content of their feeds. Not only does lipid contribute to the energy content of a diet formulation (Fleming et al. 1996) affecting the DP:DE ratio, it may also inhibit the utilization of other nutrients (Barneveld et al. 1998). TL content was not detected by the multivariate regression analysis as being a nutritional parameter that affected growth. However, its putative inhibitory effect on nutrients (such as vitamins, minerals, and digestible energy) was not considered in this analysis. Diets 2 and 4 contained the highest amounts of TL. Furthermore, diet 4 contained the lowest CP content of the formulated diets. The low growth rate produced by diet 4 may be a result of the inhibitory effect of a high lipid inclusion on digestible protein. *G. edulis* contained a lipid concentration of 0.8% and produced high growth rates. This suggests that a diet with a blend of appropriate FAs may contain a minimal lipid content. The Japanese feed produced by the company Nihon Nosan Kogyo K.K. (NNKKK), which is reported to be a highly nutritious and well-balanced feed for abalone, contains a lipid content of 1.5% (Fleming et al. 1996), supporting evidence that abalone do not require a diet high in lipids.

Allen and Kilgore (1975) determined the essential amino acids required by *H. rufescens*. These 10 amino acids have since been assumed to be essential for other haliotid species (Mai et al. 1994, Knauer et al. 1995, King et al. 1996), and are assumed to be essential for *H. asinina* in the current study. The ideal ratio of amino acids in dietary protein has been shown to reflect the ratio of amino acids in the body tissue of fish (Wilson & Poe 1985). This approach to abalone diet formulation has been used in several studies (Knauer et al. 1995, reviewed in Fleming et al. 1996, King et al. 1996), although its accuracy when applied to abalone nutrition has not been rigorously tested. However, a comparison of the amino acid profile of the formulated diets and *G. edulis* to that of *H. asinina* soft body tissue seemed to explain some of the observed variation in growth between diets. The essential amino acid profiles of the five diets were compared by expressing each amino acid (g/kg) as a proportion of that found in the soft tissue of *H. asinina* (Fig. 5). Included in the comparison is the amino acid profile of a formulated diet (diet A) that was reported by Bautista-Tereul and Millamena (1999) to produce a very high growth (247 μm/day) in similar sized *H. asinina*. This diet was included to test the validity of this comparison. According to this method of comparison, a diet with consistent ratios of essential amino acids will provide adequate amounts of each residue; a diet with a flat profile, will be more balanced than a diet with any large fluctuations between residues. Such factors as the amount of protein in each diet, the feed intake, digestibility, and water stability will affect the over-all amount of each amino acid available to the abalone, and hence the height of each column. From Fig. 5, none of the diets within the current study had essential amino acid profiles that seemed to be very balanced. The essential amino acids methionine and arginine seemed to be limiting in diets 1 to 4 and *G. edulis*. A deficiency in arginine and methionine was reported by Mai et al. (1994) in six species of macroalgae, and also seems to apply to *G. edulis*. Lysine also seemed to be deficient in *G. edulis*. The relatively high concentrations of methionine, phenylalanine, and lysine in diet A as compared to diets 1 to 4 and *G. edulis* is obvious and may explain the high growth rates achieved by Bautista-Tereul

TABLE 7.

Essential amino acid profiles expressed relative to lysine for seven haliotid species.

Amino Acid	*H. asinina*	*H. discus*[a]	*H. iris*[b]	*H. midae*[c]	*H. tuberculata*[a]	*H. rubra*[d]	*H. rufescens*[e]

and Millamena (1999). However, the different experimental conditions between these two studies must be considered when comparing these growth rates.

When the essential amino acids of *H. asinina* are expressed relative to lysine, the profiles of all haliotids seem to be similar, except for higher amounts of threonine, valine, and methionine and lower amounts of phenylalanine *H. asinina* (Table 7). This supports the conclusions of previous comparisons between other species (reviewed by Fleming et al. 1996) and suggests that if diets formulated for temperate abalone can be supplemented with threonine, valine, and methionine, they will be suitable for *H. asinina*.

Gonad Index and Histology

The effect of diet on sexual maturation was not initially intended to be a measure of the nutritional quality of each of the diets investigated in this study. However, after some animals displayed gonad tissue early on in the trial, it was decided to make further observations. Although the effect of diet on gonad maturation, as assessed by a noninvasive method, was not statistically significant for females (Table 6), the size at which females on the formulated diets started to mature was smaller than females reared on *G. edulis*. The size at which animals started to mature was well below that reported by other workers (Singhagraiwan & Doi 1992, Capinpin et al. 1998); the smallest animal recorded with the first signs of gonad tissue was a male with an SL of 16.40 mm and weighing 0.917 g. Subsequent monitoring of individual abalone revealed monthly fluctuations in the presence and absence of gonad tissue (data not shown), indicating the ability of *H. asinina* to resorb germinal tissue. This was reflected in the results of the histological analysis. Female animals reared on diets 3 and 4 showed marked differences in the over-all gonad integrity when compared to those on diets 1, 2, and *G. edulis*. The lack of structure of gonad tissue among female animals on diets 3 and 4 (Figs. 4D and E) is reflected by the large populations of amoeboid cells evident in these gonads (Figs. 4I and J). In normal ovaries, amoeboid cells only proliferate after a spawning event and seem to be responsible for the degradation of unspawned mature oocytes (Jebreen et al. in press). Because of the random distribution of amoeboid cells and immature eggs within the ovaries of animals fed diets 3 and 4, it is assumed that this resorption of eggs is not a postspawning event, but is rather a response to either stress or malnutrition. Female animals reared on diets 1, 2, and *G. edulis* did not possess extensive populations of amoeboid cells in the gonads. There were no apparent histological differences in the gonads of male animals reared on different diets.

The precocious maturation by *H. asinina* maintained on formulated diets is an obvious concern for potential *H. asinina* farmers and feed formulators. Bautista-Teruel and Millamena (1999), achieved very high growth rates with *H. asinina* maintained on three formulated diet and noted no sexual maturation during the course of the 90-day experiment. Conceivably, a longer experiment would have seen reduced growth rates and yielded mature animals. This possibility is supported by Capinpin and Corre (1996), who found that all juveniles reared on a formulated feed and *G. heteroclada* were sexually mature at the end of a 120-day experiment. They attributed reduced growth rates toward the end of the experiment to a channeling of energy into gonad maturation. Fleming et al. (1996) suggested that the nutritional lipid requirement of abalone may increase during gonad development. Given the relatively high lipid content of the formulated diets tested within this study as compared to *G. edulis*, it is not surprising that female animals reared on the formulated diets were more mature than animals fed *G. edulis*. Ideally, feed formulations for "grow-out" diets should maximize somatic growth and minimize germinal growth. Further research in this area with more appropriate experimental designs (i.e., increased sample size and reduced handling stress) should yield a better understanding of the relationship between growth and reproduction in haliotids.

Conclusion

The results of this study indicate that *H. asinina* can be efficiently farmed on Australian diets formulated for temperate abalone. Efficient binding of nutrients into the diet to increase water stability, although retaining their biological availability for digestion still remains a challenge for feed formulators and seems to be an area of research that has not received the attention it deserves. The rates of protein loss from the formulated diets recorded in this study highlights the need for appropriate on-farm feeding strategies. Further research and development of these diets in terms of the DP:DE ratio, the amino acid requirements, and FA requirements will increase growth, making the culture of this species more profitable. On the basis of these results, *H. asinina* seems to be an ideal species for aquaculture within Australia; its highly frequent, synchronous and predictable natural spawning pattern (Counihan et al. 2001), very high meat to shell weight ratio (>85%), and high growth rate potential in culture (Bautista-Teruel & Millamena 1999, Capinpin et al. 1999) meet the major requirements for the economic production of any haliotid (Hahn 1989a).

ACKNOWLEDGMENTS

We thank Lina Daddow for expert histological advice and Maggie Barclay and Chris Wood for FA and amino acid analysis. This work was funded by a SPIRT grant to B. M. Degnan, K. C. Williams, and N. Preston.

THE PARTIAL AND TOTAL REPLACEMENT OF FISHMEAL WITH SELECTED PLANT PROTEIN SOURCES IN DIETS FOR THE SOUTH AFRICAN ABALONE, *HALIOTIS MIDAE* L.

T. A. SHIPTON AND P. J. BRITZ

Department of Ichthyology and Fisheries Science, Rhodes University, Grahamstown 6140, South Africa

ABSTRACT As protein is the most expensive nutrient to supply in abalone feeds, it is necessary to evaluate the relative performance of different protein sources in formulated diets. Fourteen diets were formulated to contain 34% crude protein and 6% lipid. These were fed to juvenile abalone, *Haliotis midae* (initial shell length: 10.6 ± 0.1 mm). Dietary fishmeal was substituted at 30, 50, 75, or 100% with plant protein concentrates, and the growth and nutritional parameters were recorded over a 180-day growth period. No significant differences were found in the growth rates between the control diet (100% fishmeal) and diets in which 30% of the fishmeal component had been replaced by either soy or sunflower meals, or torula yeast ($P > 0.05$). Substitution of 50% fishmeal with either soya meal or spirulina did not affect growth rates ($P > 0.05$). Replacement of either 75 or 100% of the fishmeal with plant protein sources had a significant affect on growth ($P < 0.05$). Pearson product moment correlations between dietary lysine levels and either growth rates or protein efficiency ratios revealed positive correlations ($r = 0.75$, $P < 0.002$; $r = 0.88$, $P < 0.0001$, respectively), suggesting that lysine may have been the first limiting amino acid in these diets. Carcass analysis revealed that dietary protein source had no significant affect on body composition ($P > 0.05$).

KEY WORDS: abalone nutrition, fishmeal replacement, plant proteins, *Haliotis midae*

INTRODUCTION

Increasing concern about the future supply and demand for fishmeal (Barlow 1989, Rumsey 1993) has increased efforts to reduce its use as the major protein source in commercial aquaculture feed formulations. The reduction of the fishmeal component in feeds has met with considerable success in a number of species, and suggests that its partial substitution with alternative protein sources need not compromise growth. The most notable success to date is illustrated by the channel catfish industry, where the substitution of fishmeal with soy, meat, and blood meals has reduced current fish meal inclusion rates to as low as 0–4% as compared with >30% in pre-1975 formulations (Stickney et al. 1996). Although the level of substitution has not been as dramatic in other sectors of the industry, it has been demonstrated that significant reductions in dietary fishmeal are possible. Among others, these sectors include the salmonids (Pongmaneerat & Watanabe 1992, Moyano et al. 1992), tilapias (Jackson et al. 1982, Lim 1989a), and shrimp (Lim 1989b).

With respect to abalone nutrition, a number of studies have compared fishmeal-based diets with other single protein formulations (Uki et al. 1985a, Uki & Wantanabe 1986, Uki & Watanabe 1992, Viana et al. 1993, Britz 1996), and although these studies give an indication of which proteins may have potential to become fishmeal substitutes, Fleming et al. (1996) reviewed the nutritional composition of twelve currently available commercial and experimental dietary formulations, and found that of the eight diets that contained fishmeal, all contained supplementary proteins. However, no indication of the effects that these alternative protein sources had on growth and nutritional indices is available. Nevertheless, considering the success of previous growth trials using single plant protein sources, and the fact that Haliotids are naturally herbivorous animals with a digestive and enzymatic physiology equipped for processing plant materials (Knauer 1994), the prospects for replacing dietary fishmeal with plant protein sources are promising. The aim of this study was therefore to determine the effects that the partial and total replacement of dietary fishmeal with locally available plant protein sources has on growth, nutritional indices, and body composition of juvenile *H. midae*. The protein sources chosen for investigation were: soy and sunflower meals, spirulina, torula yeast, and corn gluten meal.

MATERIALS AND METHODS

Experimental Animals and System

The experiment was conducted at the Port Alfred Laboratory using water drawn from the mouth of the Kowie River estuary on the Indian Ocean (33°45′S; 26°00′E). A 10,000 L semirecirculating system was employed. Water quality was maintained using biological filtration and the replacement of 25% of the system volume per day. A 12 light:12 dark photoperiod was used throughout the experimental period. Temperature and salinity were maintained at 20 ± 1°C and 35 ± 1 ppt, respectively. Animals were housed in 24 fiberglass experimental containers (30 × 50 × 26 cm, 39 L volume, four water exchanges per hour). Within experimental containers, three replicate groups of animals were housed in perforated 2-L plastic jars. Water flow through the jars was maintained by the use of airstones.

Juvenile hatchery-reared abalone (10.6 ± 0.1 mm shell length, 0.26 ± 0.01 g weight) were used in the experiment. Before experimentation, the animals were fed exclusively on a fishmeal-based artificial diet (34% crude protein, 4.5% lipid) and acclimated to the experimental system for a 1 mo period. Three replicate groups of 30 abalone were assigned to each dietary treatment, and placed in the experimental system according to a randomized block design. The duration of the experiment was 180 days. Whole body wet weight and shell length measurements were taken at monthly intervals throughout the experimental period. Weight was recorded to the nearest 0.01 g using an electronic balance and shell length to the nearest 0.01 mm using vernier calipers. Before these measurements were taken, the animals were starved for a 24-h period to ensure that their last meal had been processed and did not affect the animal's weight. A 10% (w/w) solution of magnesium sulfate was used to anesthetize the animals during the measurement process.

Animals were fed daily at 1700 h, and the feed consumed over the experimental period was recorded and corrected for leaching. Correction factors for total solids leached were determined for each diet by placing 4 g of feed in a control container containing

no abalone and placing it in the aquaria for a 12-h period. Total solids leached were calculated as dry weight loss over this period. Feed conversion ratios (grams dry feed consumed /grams wet weight gain) and protein efficiency ratios (grams wet weight gain/ grams protein consumed) were calculated for all treatments. Feed consumption and condition factors for all replicate treatments were calculated according to Britz (1996).

Dietary Formulations

Thirteen experimental diets were formulated to contain 34% crude protein, 4.5% lipid; a fourteenth diet containing 34% LT-fishmeal and 4.5% lipid was used as a control (Table 1). Formulations between experimental diets varied such that the fishmeal component of the control diet was substituted at either 30, 50, 75, or 100% with the selected plant protein sources. The diets were bound using agar according to the method described by Knauer (1994). In summary, 20 g agar was boiled in 1,200 mL water for 30 sec and allowed to cool to 45°C. The agar was then mixed with 80 g of dietary mixture, spread into a flat sheet 0.5-cm thick and allowed to set at room temperature. Once set, the diet was cut into squares (0.5 × 0.5 cm), oven dried at 60°C for 24 h and stored frozen at −20°C until required.

Carcass and Dietary Analysis

Proximate analyses of the dietary treatments and the abalone at the beginning and end of the experimental period were undertaken. Although triplicate 5-g samples of feed were used to determine the proximate composition of the dietary treatments; thirty animals at the start of the experiment and five animals from each replicate at the end of the experimental period were used to determine the proximate composition of the abalone. The abalone were initially frozen at −20°C for subsequent analysis. On defrosting, the animals were weighed and shucked, and the soft body material was homogenized using an Ika Turrax T25 homogenizer. With the exception of lipid, the proximate composition of both abalone and the diets were measured according to the standard methods of the AOAC (1984). Thus, crude protein was determined as total Kjeldahl nitrogen (N × 6.25), ash as the residue following the combustion of samples at 550°C for 12 h, and moisture by oven drying to constant weight at 104°C. Lipid was determined by the chloroform/ methanol extraction method (Folch et al. 1957), and the nitrogen-free extract was estimated from the difference.

Statistical Analysis

Growth rates were determined as the slopes of the natural log-transformed weight data. The slopes of the growth models were compared using analysis of covariance (ANCOVA) followed by a one-tailed F-test (Zar 1984). One-way analysis of variance and Student's–Newman-Keul's multiple comparison procedure were used to determine significant differences in feed consumption, condition factors, food conversion ratios (FCR), and protein efficiency ratios (PER) between dietary treatments, and, in addition, the effect of dietary treatment on the proximate composition of the abalone at the end of the experimental period. Comparisons between the essential amino acid profiles of the dietary treatments and the whole soft tissue of *H. midae* were undertaken using Pearson product moment correlations. In addition, Pearson product moment correlations were used to determine the strength of association between growth rates, protein efficiency ratios, and the levels of individual essential amino acids across all dietary treatments.

RESULTS

The partial and total replacement of dietary fishmeal with the alternative protein sources significantly affected abalone growth over the experimental period (Tables 2 and 3). Although five of the

formulations produced growth rates that were not significantly different to the control, the remaining eight formulations produced significantly lower growth rates. Growth rates and increases in abalone weight over the experimental period ranged between 1.09 to 1.41% body weight/day^{-1} and 600 to 1,230% respectively. FCRs and PERs ranged from 0.80 to 1.25 and 2.15 to 3.75 respectively.

With respect to the control diet (100% fishmeal), only torula yeast significantly improved feed conversion at both the 30 and 50% fishmeal substitution levels ($P < 0.05$, Table 2). However, although a 30% substitution of fishmeal with torula yeast did not significantly affect growth, at 50% substitution, growth was significantly lower than the control ($P = 0.00027$, Table 3). With respect to protein efficiency, a 30% substitution of fishmeal for torula yeast significantly improved efficiency ($P < 0.05$), but at a 50% substitution level, protein efficiency did not differ significantly from the control. In addition, consumption rates did not differ significantly between the control and the diets containing either 30 or 50% torula yeast.

In comparison with the control, the inclusion of sunflower meal at 30% or soy meal at either 30 or 50% did not significantly affect growth rates ($P > 0.016$, Table 3). Nevertheless, the inclusion of corn gluten meal at either 30 or 50% or sunflower meal at 50% produced significant reductions in growth rates ($P < 0.016$, Table 3). In comparison with the control diet, feed conversion was significantly improved when soy meal was used at the 30% substitution level ($P < 0.05$, Table 2) but did not differ significantly at a 50% level of substitution. In contrast, the opposite was found to be the case when either sunflower or corn gluten meals were used as substitutes. In both cases, a 30% fishmeal substitution produced an insignificant reduction in feed conversion ratio. At the 50% substitution level, feed conversion was further reduced, and in both cases, found to be significantly lower than control ($P < 0.05$). With respect to protein efficiency, inclusion of either soy, sunflower, or corn gluten meals produced a significant reduction in efficiency at both levels of inclusion. It is, however, interesting to note that at the 30% fishmeal substitution level, there were no significant differences in the protein efficiency ratios between the three protein sources. However, at the 50% substitution level, the protein efficiency ratios of the sunflower and corn gluten formulations were significantly lower than the soy meal formulation. At the 30% fishmeal substitution level, the consumption rates of these diets were higher than those observed for the control; however, it was only when inclusion rates were increased to 50% that they were significantly higher than the control ($P < 0.05$). One exception was the diet containing corn gluten meal, where a comparison with the control diet produced no significant difference in consumption rates ($P > 0.05$). As respective consumption rates and final body weights were generally found to increase and decrease across all the diets in which fishmeal had been substituted at either 30 or 50% with soy, sunflower, or corn gluten meals, a Pearson product moment correlation was performed between the consumption rates and final body weights to determine whether consumption rates were related to animal size. No significant correlation was found ($r = -0.42$, $P > 0.05$, $n = 7$); thus, it seems that differences in animal size cannot adequately account for the observed consumption rates. Differences in consumption rates may therefore be attributed to dietary factors.

The results using spirulina as a partial fishmeal replacement, demonstrated that a 50% substitution of fishmeal with spirulina produced neither a significant reduction in growth rate ($P > 0.0125$, Table 3), nor a significant reduction in feed conversion ratio (P

* Whole body wet weight.

Different alphabetic superscripts within a column indicate significant differences between treatments for the parameter concerned. Growth rates are expressed as the slopes of the log-transformed weight data × 100. See Table 3 for ANCOVA describing significant differences between growth rates.

NS: Not significant.

*: Significant.

Growth models expressed as the natural log of the weight (y in grams) as a function of time (× in days) for the abalone fed the 16 experimental diets. Superscripts next to the F-values indicate which models were compared (n = number of values in model, r^2 = coefficient of determination, df = degrees of freedom, P = significance). To avoid accumulated error, significance was denoted at 0.0166 for three model comparisons, and 0.0125 for four model comparisons.

> 0.05, Table 2). Furthermore, although the animals fed this diet consumed significantly more feed than those animals fed the control diet ($P < 0.05$, Table 2); protein efficiency was significantly reduced ($P < 0.05$), indicating less efficient protein utilization. It is interesting to note that in the four diets containing the soy meal/sunflower meal combinations and fishmeal or spirulina at either 25 or 50% inclusion; feed conversion and protein efficiency were greater in those diets containing the fishmeal component as opposed to the spirulina. Nevertheless, a comparison between the diets containing spirulina or fishmeal at the 25% inclusion level, revealed that there were no significant differences between the feed conversion or protein efficiency ratios ($P > 0.05$, Table 2). However, at the 50% fishmeal or spirulina inclusion level, feed conversion, and protein efficiency were significantly reduced in those animals fed the spirulina-based diets ($P < 0.05$, Table 2). A comparison between the consumption rates revealed that at the 50% inclusion rate, those animals fed the spirulina-based diet consumed significantly more than those fed the fishmeal-based diet; however, at the 25% inclusion rate, consumption rates did not differ significantly.

Comparisons between the control and the diets containing the soy/sunflower combinations with fishmeal at either 25 or 50%, revealed that both formulations produced significant reductions in growth rates ($P < 0.00001$, Table 3), feed conversion, protein efficiency, and consumption ($P < 0.05$, Table 2). Nevertheless, it is interesting to note that between these formulations, no significant differences were found between either growth rates or the nutritional indices ($P > 0.05$, Tables 2 and 3).

To determine whether the dietary essential amino acid balance had an effect on growth and protein utilization by the abalone, a preliminary analysis using Pearson product moment correlations between the essential amino acid profile of the soft body tissues of *H. midae*, and the calculated essential amino acid profiles of the dietary treatments was undertaken (Table 4). The coefficients (r) from these correlations indicated that, with respect to the amino acid balance of the commercial formulation, and with the exception of those diets containing corn gluten, the amino acid balances of all the dietary treatments produced equal or closer approximations to the balance of amino acids found in the soft body tissues of the abalone. Secondary analyses, using Pearson product moment correlations were performed between the dietary/abalone EAA correlation coefficients and either the respective growth rates or the protein efficiency ratios. Because no significant correlations were observed ($P > 0.05$, Table 5), it can be assumed that, in this

Comparison between dietary essential amino acid profiles and the essential amino acid profile of abalone are presented as the correlation coefficients between the dietary and abalone EAAs (r). Amino acid values are presented as a percentages of protein (dry weight).

The amino acid profiles of *H. midae*, spirulina, and torula yeast were taken from Britz (1995). The fishmeal amino acid profile was supplied by 999 Esbjerg Fiskeindustri, Denmark, and those of soy meal, sunflower meal, corn gluten, and maize taken from NRC 1993. Semolina was determined by the Department of Poultry Science, University of Natal, SA

study, dietary essential amino profiles could not be used to predict potential feed utilization by the abalone. In contrast, Pearson product moment correlations between the levels of individual dietary essential amino acids and either the growth rates or protein efficiency ratios (Table 5), revealed that dietary lysine levels were significantly and positively correlated to both growth and protein efficiency (growth rate: $r = 0.75$, $P < 0.002$; PER: $r = 0.88$, $P < 0.0001$). Furthermore, although leucine was found to be negatively correlated to the growth rate ($r = -0.68$, $P = 0.003$), and histidine positively correlated to protein efficiency ($r = 0.67$, $P < 0.05$), the other essential amino acids were not significantly correlated with either growth or protein efficiency ($P > 0.05$).

TABLE 5.

Pearson product moment correlations (r) between either the dietary essential amino acids or the correlation coefficients (r) between dietary/abalone EAA profiles, and growth rates and protein efficiency ratios.

	Factor			
Amino acid	**Growth rate**		**Protein efficiency ratio**	
Arginine	$r = -0.05$	$P > 0.05$	$r = -0.42$	$P > 0.05$
Histidine	$r = 0.41$	$P > 0.05$	$r = 0.67$	$P < 0.05$
Isoleucine	$r = -0.38$	$P > 0.05$	$r = -0.48$	$P > 0.05$
Leucine	$r = -0.69$	$P < 0.01$	$r = -0.46$	$P > 0.05$
Lysine	$r = 0.75$	$P < 0.002$	$r = 0.88$	$P < 0.0001$
Methionine +cystine	$r = -0.46$	$P > 0.05$	$r = -0.17$	$P > 0.05$

Tryptophan	$r = 0.23$	$P > 0.05$	$r = -0.14$	$P > 0.05$
Valine	$r = -0.12$	$P > 0.05$	$r = -0.36$	$P > 0.05$
Correlation coefficients (r) between dietary and abalone EAA profiles	$r = 0.41$	$P > 0.05$	$r = 0.09$	$P > 0.05$

The body composition of the abalone at the end of the experimental period revealed that diet did not significantly affect the protein, lipid, carbohydrate (nitrogen-free extract), ash, or moisture levels in the soft body tissues of the animals ($P > 0.05$, Table 6).

Although condition factors were found to reduce in all treatments over the experimental period, at the end of the experiment, there were no significant differences in condition factors between the control diet and the experimental diets ($P > 0.05$, Table 2). The exceptions being those diets in which 50% of the fishmeal was substituted with either sunflower meal or corn gluten meal, and, in addition, those diets containing the mixture of soy and sunflower meals in combination with 50% fishmeal or 25% spirulina. In these diets, condition factors were found to be significantly reduced with respect to the control diet ($P < 0.05$).

Mortality of the abalone was low, ranging from 0–4.4%, and was attributed to the small animal size and the consequent susceptibility to damage caused by handling stress during weighing and measuring. There was no evidence of disease in any of the replicates.

DISCUSSION

Without exception, the substitution of dietary fishmeal with plant protein sources increased consumption rates in the abalone. However, because feed consumption may be affected by a number of factors, it is difficult to determine causality. Among others, factors that have been shown to affect consumption in poikilo-

TABLE 6.

Proximate composition (%) of the soft tissue of the abalone at the end of the experimental period.

Diet	Protein (%) ($n \times 6.25$)	Lipid (%)	Nitrogen-free extract (%)	Ash (%)	Moisture (%)

Spirulina/soy meal/sunflower meal 25:37.5:37.5 (%)	51.0[a]	5.3[a]	29.9[a]	13.8[a]	77.2[a]
Fishmeal/spirulina 50:50 (%)	55.2[a]	5.4[a]	26.4[a]	13.0[a]	76.4[a]

With the exception of moisture, all values are expressed on a dry weight basis. Different alphabetic superscripts within a column indicate significant differences between treatments for the parameter concerned ($n = 5$, $P < 0.05$). Initial values for the abalone at the start of the experimental period were: protein—52.6%; lipid—4.1%; ash—15.2%; nitrogen-free extract—28.1; moisture—75.6% ($n = 30$).

therms include dietary energy density (Lee & Putman 1973, Weisberg & Lotrich 1982), and feed attractiveness and palatability (Harada et al. 1996).

If it is assumed that animals eat to satisfy their energy requirements (Smith 1989), it is reasonable to suggest that the differences in digestible energy across the dietary treatments provide an explanation for the observed consumption rates. It is possible that high levels of indigestible carbohydrates present in the plant protein sources may have reduced the dietary digestible energy densities. Thus, as the animals adjust their feed intake to satisfy their energetic requirements, they consume more of the fishmeal/plant protein diets that contain less available energy than the fishmeal-based diet. However, as it has also been demonstrated that dietary protein source may affect feed consumption in Haliotids (Uki & Watanabe 1986, Viana et al. 1994), the effect of differential attractiveness and palatability between protein sources cannot be discounted as factors that may have affected consumption.

The efficacy of soy meal as a partial fishmeal replacement has been well documented in fish (Reinitz 1980, Jackson et al. 1982, Watanabe et al. 1992), and although it has been incorporated into a number of formulations for Haliotids (Fleming et al. 1996), this is the first detailed information suggesting that it is a viable fishmeal replacement for use in diets for *H. midae*. Although protein efficiency was reduced at both the 25 and 50% substitution levels, growth rates were not significantly affected. Increasing dietary EAA deficiencies or lower bioavailability of nutrients may explain this reduction in protein efficiency. Although a number of studies have demonstrated that amino acid supplementation can improve nutritional indices in soy-based diets for salmonids (Dabrowska & Wojno 1977, Rumsey & Ketola 1975); methionine has been found to be deficient in soy-based formulations for Japanese eel (Lovell 1989) and carp (Murai et al. 1989). Therefore, it is probable that at the higher inclusion level, the soymeal-based diet may have been deficient in EAAs, and in particular methionine. However, it is not possible to verify whether this was the case until both the essential amino acid requirements of the species, and the availability of the amino acids in the soy and fishmeal have been established.

The growth and nutritional indices using the sunflower meal as a fishmeal replacement demonstrate that it has good potential for future use in formulations. Although feed conversion increased and protein efficiency reduced with respect to the control, the higher consumption rates may have improved growth rates, which, at the 30% fishmeal substitution level was not significantly different from the control. However, the reduction in growth and protein efficiency that became apparent when the inclusion level of the sunflower was increased from 30 to 50% may have been attributable to either a reduction in digestible protein or energy, or imbalances in essential amino acids. Although there is no information concerning the effects of sunflower meal in diets for Haliotids, there have been a number of studies with fish. Using rainbow trout, Sanz et al. (1994) cited imbalances between leucine and isoleucine as the primary factor reducing protein efficiency both in their study and an additional study carried out previously by Tacon et al. (1984). It is well documented that a leucine/isoleucine imbalance has a negative impact on growth and nutritional indices in fish (Harper et al. 1970, Hughes & Rumsey 1983, Robinson et al. 1984). However, until more detailed information regarding the essential amino acid requirements of abalone is available, it is not possible to determine whether this was the case in this study.

The combination of soy and sunflower meals as a partial fishmeal replacement significantly affected both feed conversion ratio and protein efficiency. These indices were respectively higher and lower than the control indicating poorer dietary utilization of the feed, which, with the exception of the 50% corn gluten substitution, produced the lowest growth rates in the study. Notwithstanding gross differences in digestible energy between the diets, these reductions in nutritional indices were probably caused by a combination of factors previously discussed when either the soy or sunflower meals were tested individually. It is, however, interesting to note that when the fishmeal component was completely removed and replaced with spirulina, there was an improvement in the growth rates. Not only does this suggest that spirulina is a viable fishmeal replacement—a result confirmed by the growth and nutritional indices obtained using the 50:50 fishmeal/spirulina

formulation—it also suggests that, as more information concerning the dietary requirements of the abalone and the availability of nutrients from plant protein sources becomes available, the complete removal of the fishmeal component may become a viable proposition.

The substitution of fishmeal with torula yeast produced some of the best growth rates and nutritional indices in the study. This was most apparent at the 30% fishmeal substitution level where the diet out-performed all the alternative formulations. The high apparent protein digestibility coefficient of the torula yeast (83.4% pers. obs.), combined with the high protein and feed efficiency suggests not only high availability of the protein source to the animals, but that it contains a well-balanced essential amino acid profile that supports good growth in this context. Nevertheless, at the 50% substitution level, the growth and nutritional indices were reduced with respect to the 30% substitution level. As consumption rates between the two formulations were not significantly different, this reduction in efficiency was probably caused by an imbalance of EAAs at the higher torula yeast inclusion level.

The results using the corn gluten meal suggest that it has potential as a fishmeal replacement at levels below 30%. Comparable studies with fish have indicated that inclusion levels between 20–30% dietary protein are viable, and do not have a negative impact on growth and feed efficiency (Gropp et al. 1979, Alexis et al. 1985, Robaina et al. 1997, Regost et al. 1999). However, in comparison with other protein sources, reduced feed efficiency and growth at higher inclusion levels (>30%) have been related to its poor essential amino acid profile, and, in particular, low lysine levels (Robaina et al. 1997). This may account for the results in this study in which both feed conversion and protein efficiency were reduced at the 50% inclusion level.

Although Pearson product moment correlations between the dietary and abalone EAA profiles revealed a large variation in correlation coefficients ($r = 0.70–0.97$, Table 4), Pearson product moment correlations between the r-values and the respective growth rates or protein efficiency ratios revealed no significant correlations (Table 5). Therefore, it appears that the balance of dietary EAAs was not a good predictor of either growth or protein utilization in the abalone. In contrast, when similar correlations were performed between growth, protein efficiency, and the levels of individual dietary EAAs (Table 5); the levels of dietary lysine were significantly and positively correlated to both growth rates and protein efficiency. Thus, although the bioavailability of the EAAs was not taken into account in this study, it can be concluded that, as opposed to the dietary EAA profile, dietary lysine levels provide a better indication of which protein sources will promote growth and protein efficiency. Furthermore, the positive correlations between dietary lysine levels and growth and protein efficiency suggest that lysine may have been the first limiting amino acid in these diets.

In conclusion, the results suggest that the potential to replace fishmeal with plant protein sources in commercial diets for *H. midae* is promising. However, although the commercial application of the torula yeast- and spirulina-based diets may be restricted by current high raw material costs from South African suppliers (respectively 340% and 250% higher than LT-fishmeal), the low raw material costs associated with the soy and sunflower meals make these protein sources particularly attractive to commercial feed formulators (respectively 60 and 75% lower than LT-fishmeal). Nevertheless, this study should be viewed as a preliminary investigation into the partial and total replacement of fishmeal; and that, before determining the optimal protein mixtures required to optimize growth at the least cost, a considerable amount of further research is required. In particular, the digestibility of essential amino acids and energy from the protein sources must be determined, the EAA requirements of the abalone, and the optimal dietary digestible protein: energy ratio. Only then can formulations be designed, which will optimize growth and feed utilization through the delivery of the required essential amino acids and appropriate digestible energy.

THE USE OF STIMULANTS AS AN AID TO WEAN FISHERY CAUGHT BLACKFOOT ABALONE (*HALIOTIS IRIS*) TO ARTIFICIAL FOOD

VICTORIA J. ALLEN,* ISLAY D. MARSDEN, AND NORMAN L. C. RAGG

Department of Zoology, University of Canterbury, Private Bag 4800, Christchurch, New Zealand

ABSTRACT Abalone use a combination of tactile and chemosensory feeding cues to detect suspended seaweed in their natural environment. However, in a commercial situation, adult abalone (*Haliotis iris*) caught for broodstock or pearling, show reluctance to start feeding on stationary artificial food. If they cannot be induced to feed, they may lapse into a starvation phase that can last several weeks. Subtidal adult *H. iris* (125 mm shell length) were collected during autumn, winter, spring, and summer from Banks Peninsula, Canterbury and held at Pendarves Abalone Farm Ltd. (South Island, New Zealand). Abalone were divided randomly into two groups. One group was offered a commercial pellet diet together with small quantities (0.03–0.05g dry weight L^{-1}) of suspended seaweed particles (*Gracilaria* spp.) to test its potential as a tactile phagostimulant. The other group (nonstimulant control) were supplied with the same commercial diet without the algal stimulant Each group consisted of three replicate vessels containing three individuals. Abalone behavioral responses and ingestion rates were monitored in both groups over a 3-wk period. Abalone in the stimulant experiment exhibited a typical feeding posture almost immediately, were more alert, and engaged in a greater range of feeding activities than the abalone that had been supplied with commercial food only. Those abalone without access to the algal stimulant remained either quiescent or alert in most seasons. Feeding activity of abalone in the stimulant treatment was significantly higher ($P < 0.05$) as compared with abalone from the nonstimulant control for all seasons except winter. Also, abalone consumed significantly more artificial food when tactile stimulants were present during autumn and winter. However, ingestion rates seemed highly sensitive to both season and acclimation time. Within each season, there was a consistent trend of increasing ingestion rate during the third week of the experiment, and this was most discernible in the stimulant treatment.

KEY WORDS: *Haliotis iris*, stimulant, artificial food, behavior, New Zealand abalone

INTRODUCTION

The commercially valuable New Zealand abalone, *Haliotis iris* Martyn, locally known as paua, is the main species of abalone harvested (Hooker & Creese 1995) and more recently, cultured in New Zealand (Clarke & Creese 1998). In addition to animals caught by the fishery for immediate processing, adult *H. iris* (≥125 mm shell length) may be taken to land-based holding facilities for later sale or, more critically, use in aquaculture as broodstock or for pearling.

Newly fished abalone are inevitably stressed by handling and air transport, and a holding system must, therefore, permit initial recovery and subsequently promote the growth and conditioning of gonads or allow abalone to become suitably physiologically robust to withstand the implanting of pearl nuclei. It is a major challenge to provide a suitable food source that will be accepted by the abalone throughout this period. Abalone are macroalgivores (Wee et al. 1992), using a combination of tactile and chemosensory stimuli to detect suspended and attached seaweed in their natural environment (Fleming 1995). Adult *H. iris* are largely sedentary, favoring exposed rocky substrata and feeding on drift seaweed detected by the cephalic and epipodal tentacles and subsequently trapped by the anterior foot or shell margin (Poore 1972a). Few algal harvesting permits have so far been granted for the commercial collection of seaweed in New Zealand (Schiel 1997), forcing farmers to rely upon artificial pellet feeds (certain artificial diets are also favored by pearl farmers for the resulting desirable nacre properties). Although nutritionally robust and relatively stable in seawater (Fleming 1995), the dense artificial pellets are unable to simulate the dynamic motion of neutrally buoyant seaweed fragments (Fleming et al. 1996). In the absence of the tactile stimulus of moving algae, captive *H. iris* will usually lapse into a starvation phase, taking up to 6 wk to commence feeding on pellets (pers. obs.); during this time, abalone inevitably suffer a loss of condition and may die.

Qualitative observations have suggested that the addition of small quantities of seaweed particles to a tank with suitably dynamic water movement will illicit a feeding response from adult *H. iris*, stimulating the abalone to graze upon static feed pellets that would otherwise be ignored on the tank bottom. This experiment is designed to characterize and quantify the nature of the abalone's response to the presence of a suspended tactile stimulant (dried *Gracilaria* spp. fragments). Seasonal variability in the feeding behavior of abalone is well documented (Poore 1972a,b, Shepherd 1973, Marsden & Williams 1996, Donovan & Carefoot 1998), hence the trials were repeated at 3-mo intervals over 1 yr and season treated as a fixed variable in subsequent analyses.

MATERIALS AND METHODS

Collection and Holding of Abalone

Adult *Haliotis iris* ≥125 mm shell length were collected using SCUBA from a depth of 6–10 m from a rocky reef within Whakamoa Bay, Akaroa Heads, New Zealand (43°53′S, 172°53′E). Collections were made once each season beginning in autumn (11 May 1999) and including winter (30 August), spring (4 November), and summer (22 December). The abalone were transported overland, in damp air at 5°C, to the Pendarves Abalone Farm Ltd., Canterbury, New Zealand.

Abalone were tagged and individual wet weight and shell length were recorded. Three animals were randomly assigned to each experimental vessel, an opaque 40-L tank receiving five exchanges h^{-1} of unfiltered seawater at ambient temperature (10–16°C), pH 8.2 ± 0.2, salinity 32 ppt.

Experimental Design

Two dietary treatments were examined. The first simply offered the abalone static pellets of artificial feed, while the second in-

*Corresponding author. E-mail: vjaqua_n2@yahoo.co.nz

cluded *Gracilaria* spp. fragments suspended in the water column as a tactile stimulant. There were three replicate vessels for the stimulant treatment and the control group. Behavioral responses of abalone were quantified in both groups for an initial 10-h period, and ingestion rates were measured at 3-day intervals for 3 wk.

Tanks were covered with black polyethylene sheeting to provide total darkness for the initial 96 h after stocking, providing the abalone with an undisturbed 4-day recovery period from handling and transportation. On day 5, the covers were removed and the tanks siphoned clean. To three tanks were added 3 g of preweighed, dry artificial food (Abfeed™, Sea Plant Products, South Africa), these are referred to as the nonstimulant treatment or control. A further three tanks were supplied with 3 g Abfeed, plus 1.5 g of dried, mulched *Gracilaria* spp. particles (stimulant treatment) equivalent to 0.03–0.05 g L^{-1}. The tank inflow jet was positioned to suspend the *Gracilaria* spp. particles in the water column and leave the Abfeed pellets static on the tank floor.

Behavioral Responses

Abalone behavior was observed and recorded over a 10-h period beginning at approximately 1 PM and finishing at 11 PM. A photoperiod of 12 h light/12 h dark was maintained with lights being turned off at 6 PM. Abalone were observed at night under red light. Abalone behavior was divided into the following categories:

1. quiescent (shell clamped, cephalic, and epipodal tentacles retracted);
2. alert (shell slightly raised, epipodal, and cephalic tentacles extended);
3. locomotion (crawling);
4a. feeding on artificial pellets;
4b. feeding on *Gracilaria* spp. particles; and
5. active feeding posture (shell and foot raised, anterior lobes of foot and tentacles extended and waving).

Abalone were examined every 15 min and their behavior recorded. At the end of the 10 h period, nylon lids were placed on the tanks to minimize light-shadow disturbance. For the purpose of statistical analysis, behavioral responses were combined into feeding (categories 4a, 4b, and 5) or nonfeeding behavior (1–3).

Ingestion Rates

Tanks were cleaned and food and stimulant replaced every 3 days following the completion of the behavior assessment. Cleaning consisted of the inflow being turned off; all solid material was then siphoned from the bottom of the tank and collected on GF/C filter paper. The solids were rinsed in fresh water, and all identifiable food particles were isolated from the *Gracilaria* spp. and feces were then dried at 55°C for 24 h and weighed. Artificial feed was also stocked to a control tank containing no animals, the proportion of initial weight lost was used as a correction factor to compensate for passive leaching; in this way a correction factor was determined for each season using weight change over a 3-day period. Biomass-specific ingestion rates were calculated for each group of abalone during each 3-day feeding period using the following equation:

$$I = \frac{[(W_I \times C_{summer}) - W_F] \div 3}{B} \cdot 100$$

Where ingestion rate, I (percentage biomass ingested per day), is determined from W_I and W_F, the initial and final dry weight of artificial food over a 3-day feeding period corrected for C, the season-specific leaching correction, and standardized by biomass of abalone in the tank B.

Abalone ingestion rates were calculated over 3 wk for each seasonal sample, but this was extended to 4 wk in winter because of low rates of food intake.

Statistical tests were performed using Statistica™ 5.1 (StatSoft Inc., USA).

RESULTS

Behavioral Responses

During all four seasons, the abalone tended to be largely inactive (categories 1 and 2 on Fig. 1), spending less than 10% of the time moving about the tank (category 3). The presence of the algal stimulant had little effect upon the amount of time engaged in each

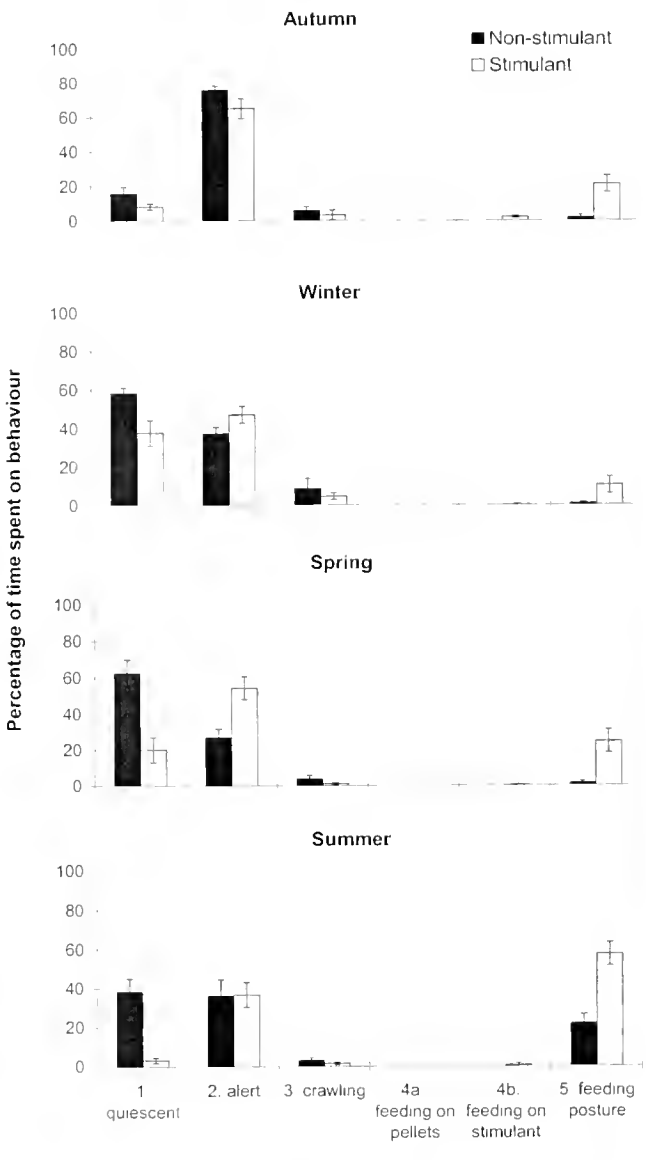

Figure 1. Seasonal time budgets for *Haliotis iris*, behavioral categories recorded over a 10-h period in the presence (Stimulant) or absence of algal stimulant (Nonstimulant). n = 9 individuals per treatment. Graphs show mean ± SE.

nonfeeding activity during autumn and winter (Fig. 1). However, abalone receiving the stimulant treatment spent relatively little time clamped and unreceptive during spring and summer (20.1 ± 7.0% and 3.3 ± 1.3%, mean ± SE, respectively) as compared to their nonstimulant counterparts (62.6 ± 7.2% and 38.5 ± 6.6%).

A two-way analysis of variance (ANOVA) was used to examine the effects of stimulant presence and season upon the amount of time devoted to feeding activities (categories 4a, 4b and 5). Both the stimulant ($F = 54.24$, $P < 0.001$) and season ($F = 21.99$, $P < 0.001$) had a significant effect on the duration of the feeding response, with no interaction between the two factors ($F = 1.13$, $P = 0.342$). Tukey's "Honest Significant Difference" pairwise comparison found the feeding activity of animals in the stimulant treatment was significantly higher ($P < 0.05$) than nonstimulant for all seasons except winter. Within each treatment, summer feeding activity was significantly higher than all other seasons. Nonstimulant abalone that exhibited virtually no feeding behavior between autumn and spring spent 22.0 ± 5.0% (mean ± SE) of their time in a feeding posture in summer. In contrast, abalone from the stimulant treatment spent 57.0 ± 6.0% of their time in this posture, as compared to 17.0 ± 3.5% throughout the rest of the year. With the exception of isolated instances, where stimulant particles were successfully captured by the abalone, all feeding activity during the initial 10-h observation period was limited to a receptive posture rather than actual ingestion.

Ingestion Responses

Abalone consumed significantly more artificial food when tactile algal stimulants were present during autumn and winter (ANCOVA, $F = 4.763$, $P = 0.035$, and $F = 7.650$, $P = 0.008$, respectively). It must be noted, however, that winter trials were extended for a fourth week because of very low ingestion rates. No significant differences were detected between stimulant and nonstimulant treatments in spring ($F = 2.397$, $P = 0.130$) and summer ($F = 2.159$, $P = 0.150$). Ingestion rates seemed highly sensitive to both season and acclimation time (Fig. 2). Despite erratic abalone consumption rates during autumn and very low initial rates in winter and spring, a consistent trend of increasing ingestion rate occurred during the final week of all of the seasonal experiments. This was most discernible in the stimulant treatment. A similar potential trend in summer may have been obscured because of a pump failure during the final 3 days of monitoring.

Because the ingestion response attributable to the presence of stimulants seemed to become more pronounced over time, the final 3-day ingestion data from each season were considered to be the most representative predictor of long-term feeding responses. Statistical analysis (two-way ANOVA) found that both treatment ($F = 3.4$, $P < 0.001$) and season ($F = 14.6$, $P = 0.002$) had a significant effect upon final ingestion rates; there was no significant interaction. A least-significant difference post hoc comparison of means (95% CI) found final ingestion rates were significantly higher in the presence of stimulants in autumn (0.13 ± 0.01% biomass d^{-1} in stimulant, 0.07 ± 0.007% biomass d^{-1} in nonstimulant), but no significant difference for any other season. An examination of seasonal effects alone, based upon final ingestion rate, ranked autumn significantly higher than summer, which was, in turn, significantly higher than winter and spring, which were similar.

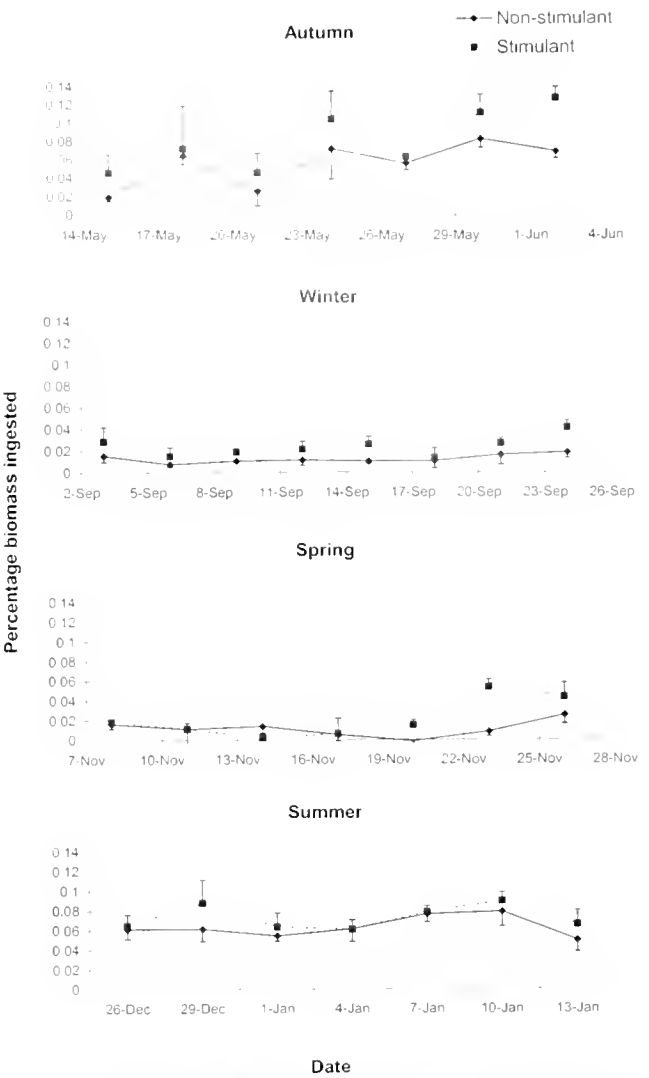

Figure 2. Seasonal ingestion rate of *Haliotis iris* provided with an artificial diet in the presence (Stimulant) or absence of algal stimulant (Nonstimulant). Graphs show mean + or −SE.

DISCUSSION

To understand the responses of wild abalone following capture and transfer to an artificial situation, such as a commercial facility, it is important to understand their feeding mechanisms and behavior. Initially thought to be browsing herbivores, haliotids tend to be largely sedentary except when food is scarce (Poore 1972a,b). Adult *H. iris* consume a wide range of seaweeds (Tunbridge 1967), feeding predominantly on drift algae in most localities (Schiel 1992). *Haliotis ruber* Leach and *H. laevigata* Donovan, when exposed to sufficient water flow, raise the front of their shells to catch drift seaweed with their foot instead of grazing on benthic algae (Shepherd 1973). It was noted that this posture also occurred in the absence of drift algae. Hingham et al. (1998) also described the behavior whereby abalone were observed to form two "hands" with their foot and grasp food as it moved past, detected by contact with the epipodal tentacles. Poore (1972a) noted that *H. iris* responded to drift seaweed in the same way.

Abalone use both chemosensory and tactile cues to detect food in the wild. Crofts (1929) observed that the cephalic, mantle, and epipodal tentacles appreciate even slight chemical changes in the water and that in all the tentacles, the sense of touch is particularly acute. The cephalic and epipodal tentacles play an important role in investigating the environment and guiding the abalone around their habitat (Crofts 1929, Upatham et al. 1998) and also respond to such tactile stimuli as drifting algal fronds and particles. The sensitivity to such stimuli is attributable to the cluster of sensory cells that reside beneath the epithelium on the tentacles, lips, anterior edge of the foot, and mantle edge (Luchtel et al. 1997). According to de Vlieger (1968), the optimal stimulus for positive thigmotaxis (during creeping as well as when exploratory movements are carried out) is a nonmoving object occasionally met by the foot (e.g., food pellet). This results in the withdrawal of the tentacle or foot followed by a full tentative exploration of the initial stimulus (de Vlieger 1968). Abalone in both the control and algal stimulant treatments were observed to touch and feel around the edge and over the whole pellet with their foot after they had physically encountered it (they usually bumped into it, then stopped to explore). Some abalone crawled over the pellets after exploring them, but no attempt at ingestion was made. Hence, contact with the food pellets seemed to elicit a positive thigmotactic response but did not stimulate a feeding response in freshly caught *H. iris*.

Abalone were regularly observed in a typical feeding posture in the tanks where stimulants were provided; however, this same feeding posture was also observed in the nonstimulant tanks, especially in summer. These abalone were found directly under the water in-flow with their shells raised and feet extended, corroborating the view taken by Shepherd (1973), who suggested that water movement is an important environmental factor affecting the feeding of those species that feed on algal drift. The increased tendency to adopt a feeding posture accounted almost entirely for the significantly elevated level of feeding behavior of *H. iris* in the stimulant treatment. Abalone consistently spent less time in the unreceptive quiescent/clamped state when stimulants were present (Fig. 1). Because clamping is usually regarded as an escape response in haliotids, this behavior may be considered a reaction to an unfavorable environment. In the presence of stimulants, the amount of time spent quiescent seemed closely related to water temperature. The same observation was found for *H. kamtschatkana* Jonas (Donovan & Carefoot 1998) and may reflect metabolic limitation rather than an avoidance response. It is interesting to note that captive adult *H. iris* do not share the wild population's tendency to increase foraging (crawling) rate in response to hunger (Poore 1972a, Donovan & Carefoot 1998), nor to the presence of stimulants, locomotion tending to be limited to negative phototactic response only (pers. obs).

The ingestion rates of *H.iris* feeding on a commercial pellet diet support the initial hypothesis that, with the addition of a tactile algal stimulant, abalone would be encouraged to feed on the artificial food and increase the ingestion rate. In all the trials; however, ingestion rates varied over time. Feeding rates were low or erratic for the first 2 wk of captivity, then increased steadily toward the end of each trial (Fig. 2.). This pattern occurred sooner and was better defined in the stimulant treatment than in the nonstimulant control. Ingestion rates increased up to 50% in autumn and winter and slightly less in spring and summer. The improvement in dietary intake of abalone in the presence of the stimulant usually began after 9–12 days and was consistently later in nonstimulant abalone, typically taking 15–18 days (Fig. 2.). Extended trials using a larger sample of individuals to establish the steady-state ingestion rates of abalone when fully acclimated to captivity and artificial food would be valuable in determining the long-term role of seaweed particles as a phagostimulant.

Differences in abalone ingestion rate between the four seasons can be attributed in part to elevated water temperature, which can increase metabolic rate and subsequently feeding rate (Marsden & Williams 1996). Hence, although it might be predicted that feeding rates should be higher during summer than in the autumn, food consumption may be affected by other metabolic demands, including the abalone reproductive cycle. *Haliotis iris* from the collection site are known to spawn during the autumn (March to May) (Poore 1972b); hence, increased food intake may be neccessary to support rapid gonad development (gonad condition was not examined to minimize handling stress). Some apparent inconsistency in the ingestion data may also have been caused by the collection times within each season. Autumn, winter, and spring collections were made relatively late because of the uncompromising dive conditions, and an early collection was made in summer to exploit favorable sea conditions.

Applied nutritional research on abalone has focused upon the use of attractants and chemical feeding stimulants. Harada et al. (1996) tested various novel ingredients, including herbs and spices for their attracting ability and Sakata and Ina (1992) used different algal methanol extracts to study the feeding behavior of young *H. discus*. Also, attempts have been made to design a neutrally buoyant feed that simulates algae in the culture tank (Fleming et al.1996), and more recently, the role of water movement in stimulating abalone feeding has become recognized (Hingham 1998). The results from the present study suggest that tactile algal particles could provide an additional stimulant, complementing those already described.

In conclusion, the addition of *Gracilaria* spp. particles to the water of a tank containing newly collected field specimens of *Haliotis iris* immediately stimulates a positive feeding response. This subsequently shortens the period to first acceptance of artificial feed and seems to stimulate elevated ingestion rates. The nature of these responses; however, is highly seasonal and may be subject to a period of acclimation during which the feeding response can change. It is suggested that this aspect be examined further using a larger sample size and individuals of a range of shell lengths. Also, investigations into the effects of tactile phagostimulants on ingestion and subsequent meat, gonad, and nacre development may assist the future development of the abalone culture industry.

ACKNOWLEDGMENTS

We thank Pendarves Abalone Farm Ltd. for research space and facilities and the staff, including N. Williams, B. Williams, and C. Stanger for technical support and constructive advice. D. Bradshaw, D. Tattle, and R. Bishop assisted with the collection of wild abalone. We also thank J. and J. Bradshaw for transport and access to Whakamoa Bay, and D. Bradshaw for discussion and comments on the manuscript. This research was undertaken as part of a Graduate Research in Industry Fellowship (awarded to V. Allen) funded by the Foundation for Research, Science, & Technology in New Zealand.

COMPARATIVE PERFORMANCES OF JUVENILE *HALIOTIS ROEI* FED ON ENRICHED *ULVA RIGIDA* AND VARIOUS ARTIFICIAL DIETS

SAM J. BOARDER[1]* AND MUKI SHPIGEL[2]

[1]*Fremantle Maritime Centre, 1 Fleet St., Fremantle, Western Australia, 6160;* [2]*Israel Oceanographic and Limnological Research, National Center for Mariculture, P.O. Box 1212, Eilat, Israel*

ABSTRACT Growth rates of juvenile *Haliotis roei* fed inorganically enriched *Ulva rigida* were compared with growth achieved on various artificial diets. Juvenile abalone (20–40 mm SL) were collected from reef platforms off the Perth (Western Australia) metropolitan area and assigned to one of seven different dietary treatments. All diets were fed *ad libitum* (3% bw day $^{-1}$) every second day, and growth rates were quantified over a 3-mo period. Specific growth rate (SGR) for both shell length and whole body weight indicated that growth of abalone fed enriched *U. rigida* was not significantly different ($P > 0.05$) to growth achieved from the best performing artificial diets.

A 96-h salinity stress test was also conducted on all treatments to assess the effects of diet on stress resistance. Diet significantly effected survival at 20‰, with the *U. rigida* fed animals exhibiting decreased tolerance to hypo-osmotic conditions ($P < 0.05$). This may have been caused by an interference with the cell volume regulatory mechanisms normally utilized by *Haliotis* spp.

Enrichment of wild *U. rigida* increased the algal protein content from 11.4 ± 2% (dry weight) to 32.2 ± 1.5%, perhaps partially explaining the difference in performance between this and other abalone feed trials utilizing *Ulva* spp. Results indicate that enriched *U. rigida* is a suitable feed for *H. roei*, providing similar growth to that achieved from several commercially available diets.

KEY WORDS: abalone, *Haliotis roei*, *Ulva rigida*, nutrition, salinity tolerance

INTRODUCTION

The main constituents of aquaculture effluent are ammonia and phosphate, with ammonia known to be the main contributor to marine eutrophication when added to an oligotrophic marine environment (Dosdat et al. 1995, Wu, 1995, Lemarie et al. 1999). Many shore-based aquaculture facilities utilize sedimentation ponds to remove particulate matter but ignore dissolved inorganics such as ammonia (NH_3/NH_4^+) and phosphate (PO_4^{3-}) because of the difficulty of their removal from high volumes of water. Use of macroalgal biofilters has been shown to remove a large proportion of the dissolved nitrogen from aquaculture effluent when integrated into intensive fish culture systems (Neori 1996, Shpigel et al. 1996a). Species of sea lettuce (*Ulva* spp.) have been shown to remove up to 90% of dissolved nitrogen from aquaculture effluent (Neori et al. 1998). Research in Israel has also shown that culture of *Ulva* spp. in nutrient-rich waters increases their protein content from 11–13% to over 35% of the dry weight (Shpigel et al. 1999). This enriched *Ulva* has been shown to provide good growth rates for *Haliotis tuberculata* (Neori et al. 1998, Shpigel et al. 1999), and *Haliotis discus hannai* (Corazani & Illanes 1998, Sbpigel et al. 1999). Aquaculturists may be enticed to adopt effluent treatment procedures more readily if shown that enriched *U. rigida* can also be used as a feed for abalone species.

Stress tests have previously been used as an assessment of general health or vigor in several aquatic species (Dhert et al. 1990a; Dhert et al. 1990b, Briggs 1992, Boarder & Maguire 1998, Samocha et al. 1998). Abalone are osmoconformers and possess only limited osmoregulatory capabilities; thus, the effects of salinity fluctuations directly affect internal ionic composition (Brix 1983, Somero & Bowlus 1983). It has been shown previously that dietary history can directly effect resistance to low salinity in abalone (Boarder & Maguire 1998).

This trial was conducted to assess the suitability of enriched *U. rigida* as a feed for *Haliotis roei* and to compare growth rates of this diet with growth rates on various artificial diets.

MATERIALS AND METHODS

H. roei were collected from limestone reef platforms in the Perth metropolitan area in March 1999. Abalone were gently removed from the reef top and immediately placed into aerated seawater for transport. All animals were tagged (Hallprint Pty Ltd, FPN shellfish tags), and then randomly distributed into 28 trial tanks after being weighed to the nearest 0.01 g (whole wet body weight; WWBW), and measured with manual calipers (0.1 mm accuracy). The initial mean length and weight of the abalone were 31.9 ± 4.3 mm and 6.17 ± 2.28 g (mean ± SE) ($n = 560$).

Trial System

Abalone were kept in rectangular 27-L plastic aquaria with artificial grass strips above the water line to prevent abalone from climbing out of the tanks. Twenty abalone were allocated to each trial tank (four replicates per diet), and all 28 tanks were arranged randomly in relation to experimental diet. The system was flowthrough and used a seawater bore as the water source. All tanks were individually aerated. The flow rate to each tank was maintained at 1 L min^{-1} and checked weekly. Water quality parameters (dissolved oxygen [DO], pH, and temperature) were randomly measured during each feed with systematic analyses made in each tank weekly.

Diets

Diets used in this trial are listed in Table 1. All artificial diets were commercially available (with the exception of the FRDC2 control diet), and enriched *U. rigida* was grown in high nutrient water (5 g N m^{-2} day^{-1}; 0.6 g P m^{-2} day^{-1}) on inorganic nutrients (NH_4Cl and Na_2HPO_4) in accordance with Shpigel et al. (1999). The abalone were fed 3% bw/day, which is in excess of requirements for greenlip abalone, *H. laevigata* (Tom Coote 1999 pers. comm.). Tanks were cleaned by siphon every second day. Feed rates for *U. rigida* were calculated on a dry weight basis. This was based on enriched *U. rigida* possessing a water content of 84%. The control diet, known as the FRDC2 formulation, was made available by the Fisheries Research and Development Council

TABLE 1.

Artificial diets used.

6	Deakin Diet—*Marine Feeds*	——
7	Diet 7—confidential	——

Note: feed manufacturers are listed in italics.

(FRDC). The dry ingredients included fishmeal, soyflour, semolina, sodium alginate, and $CaCO_3$. The Deakin diet (Diet 6), and Adam and Amos (Diet 2) diet, were both commercially available within Australia. Haliogro (Diet 5) was from New Zealand, and AB-feed (Diet 4) was from South Africa. It should be noted that none of the diets used in this trial was specifically formulated for *H. roei*.

Analysis of U. rigida

Proximate analysis of *U. rigida* was undertaken throughout the trial to quantify moisture, ash, protein (nitrogen × 6.25), fat, and carbohydrate levels. Moisture content was determined by gravimetric weight loss on heating the samples to a constant weight at 105°C (Association of Official Analytical Chemists [AOAC] method number 950.46B). Ash was determined by gravimetric weight loss on ashing the samples in a muffle furnace at 550°C (AOAC method number 920.153). Analysis of nitrogen content utilized the Kjeldahl method (AOAC method number 928.08), and fat/lipid levels were determined via acid hydrolysis and solvent extraction (AOAC method number 950.54).

Consumption Analyses

Consumption was assessed twice during the trial by manually siphoning uneaten feed from tanks. Consumption was estimated by relating the dry weight of the uneaten food to the known dry weight of the feed provided. Consumption data were corrected for dry matter weight loss attributable to leaching by leaching all diets over a 48-hr period and drying to a constant weight. Consumption estimates involved the collection of all uneaten food before cleaning on the second day of the feed/clean cycle, through manual siphon onto 100-μm mesh screen. Collected feed was carefully washed onto a circular filter mesh for drying and weighing. Feed was dried at 55–60° C for a period of 2 days before weighing.

Salinity Stress Test

A 96-h stress test for over-all health was conducted to assess the effect of diet on abalone health. Salinities for the stress test were derived from a preliminary assessment of salinity tolerance for *H. roei* and the limited literature regarding salinity tolerances of abalone (Nakanishi 1978, Mgaya & Mercer 1994, Jarayabhand & Paphavasit 1996, Boarder & Maguire 1998). Abalone were held in PVC cages (see Harris et al. 1997) and acclimatized in full strength seawater for 4 days (Boarder & Maguire 1998). Twelve abalone were randomly assigned to each cage. Upon acclimation, one cage from each diet was suspended vertically within an aerated 1,000-L tank of a particular salinity. Salinities used were 35, 25, and 20‰, and each salinity was replicated twice. Cages were checked every 4 h for 96 h by lifting the cage clear of the water and gently shaking. Abalone no longer attached to the cage and nonresponsive to touch on the mantle were classified as mortalities. Animals responsive to touch and not attached to the cage were recorded as detachments and returned to the cages.

RESULTS

Growth

Specific growth rate (SGR) was significantly affected by diet, as measured by either whole weight ($P < 0.05$) or by shell length ($P < 0.01$). Growth rates for *H. roei* fed inorganically enriched *U. rigida* (D3) were not significantly different (Tukey's test, $P > 0.05$) to growth achieved from the best performing artificial diets. The abalone grew best on the Adam and Amos (D2) diet for both length and weight (SGR-L = 0.161 ± 0.004; SGR-W = 0.495 ± 0.2). However, growth was not significantly higher than on the FRDC2 (SGR-L = 0.139 ± 0.006; SGR-W = 0.371 ± 0.035), *U. rigida* (SGR-L = 0.142 ± 0.010; SGR-W = 0.379 ± 0.040), or AB-feed (SGR-L = 0.131 ± 0.006; SGR-W = 0.4113 ± 0.014) diets. This is shown in Figures 1 and 2, respectively.

Consumption Analyses

Consumption rate was significantly affected ($P < 0.01$) by diet for both consumption assessments. The two consumption analyses were also significantly different from each other ($P < 0.01$), as shown in Figure 3. Diets 2, 5, 6, and 7 were all observed to be less water stable than Diets 1, 3, and 4 after 2 days within the treatment tanks.

Salinity Stress Test

Abalone held in full strength seawater and 25‰ salinity exhibited 100% survival at the conclusion of the 96-h trial, with the exception of abalone fed on Diet 3, which exhibited 92% survival over the same period in 25‰. Detachment rates for both of these salinities were negligible for all diets at the higher salinities.

Diet significantly affected survival at 20‰ ($P < 0.05$). No abalone fed Diet 3 (enriched *U. rigida*) survived in 20‰ after 96-h (Fig. 4). Survival was significantly the same for all other diets (Tukey's test $P > 0.05$), with an average survival of 40.28 ± 4.33%.

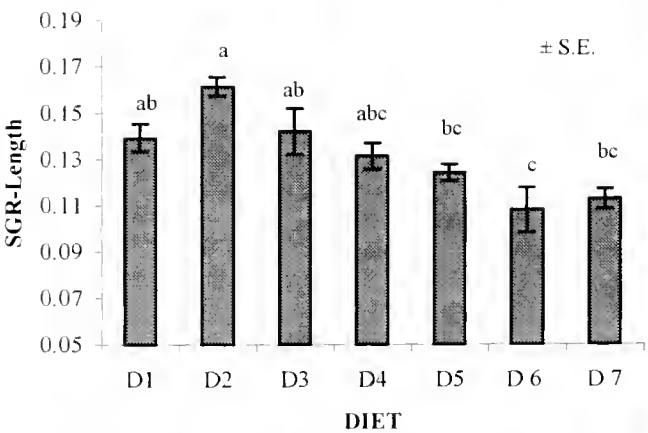

Figure 1. Effect of diet on specific growth rate for length (mm) for juvenile *Haliotis roei* ($n = 4$). *Note*: Diets sharing the same letters are not significantly different (Tukey test, $P > 0.05$).

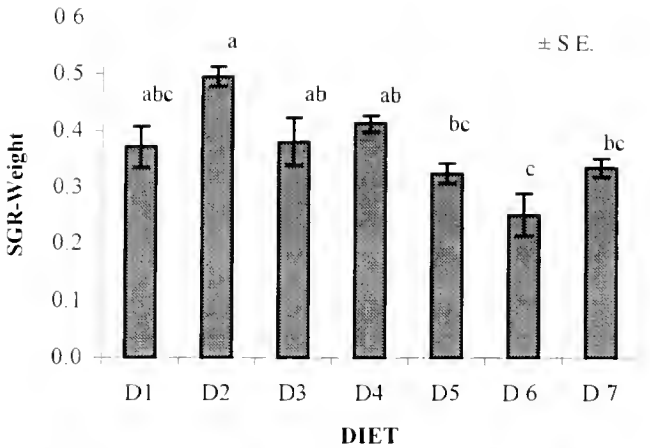

Figure 2. Effect of diet on specific growth rate for weight (g) for juvenile *Haliotis roei* (n = 4). *Note*: Diets sharing the same letters are not significantly different (Tukey test, P > 0.05).

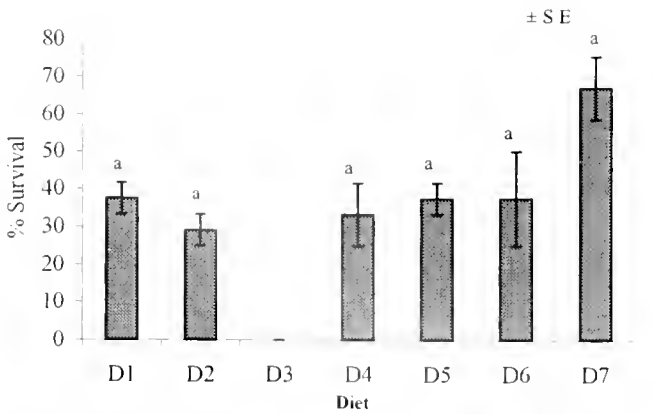

Figure 4. Effect of diet on survival after 96 h at 20% salinity for juvenile *H. roei* (n = 2; 12 abalone per replicate). *Note*: Diets sharing the same letters are not significantly different (Tukey test, P > 0.05).

Diet 3 was not included in the analysis of variance (ANOVA) because of zero variance caused by 0% survival. Mortality on Diet 3 was also observed earlier than all other diets (Table 2). Fifty percent of all animals fed enriched *U. rigida* died after 68 h, as compared with an average of 9.73 ± 2.06% for abalone fed other diets over the same time period. Most other diets reached 50% mortality after approximately 85 h, almost 20 h later than the *U. rigida*-fed abalone (Table 2). Abalone fed Diet 3 were also observed to detach earlier than those on other diets.

DISCUSSION

Growth rates of *H. roei* fed enriched *U. rigida* were not significantly different from growth rates achieved on the three best performing artificial diets ($P > 0.05$). Previous growth trials with *Ulva* spp. as a feed for abalone species have used "wild" *Ulva* spp. or *Ulva* spp. that had not been enriched (Mai et al. 1994, Mai et al. 1996, Simpson & Cook 1998). These growth trials have shown the effectiveness of *U. rigida* as a feed to be totally dependent on the abalone species to which it is being fed. Mai et al. (1996) found that although wild *U. lactuca* was a "moderately good diet" for *H. tuberculata*, it was the worst of five diets for *H. discus hannai*. Corazani and Illanes (1998) showed that *H. discus hannai* grew significantly faster on *U. rigida* than on other macroalgal diets, and the authors recommend juvenile abalone of this species be fed a diet of *Ulva* spp. in combination with an artificial diet. They felt that the artificial component of the diet was a supplement to the *Ulva* spp. and should be fed at levels no higher than 1% of total body weight day^{-1}.

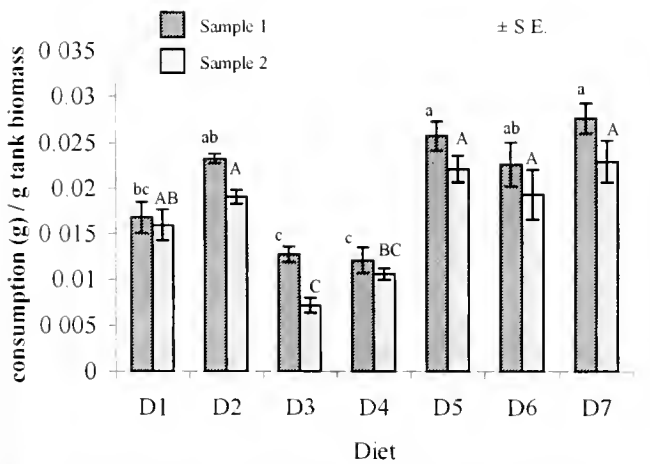

Figure 3. Effect of diet on consumption rate (grams dry feed consumed/gram tank biomass) for juvenile *Haliotis roei* at two separate sampling times (n = 4). *Note*: Diets sharing the same letters are not significantly different (Tukey test, P > 0.05).

Simpson and Cook (1998) investigated the growth of *H. midae* grown on various natural algal diets. They found that after 4 mo on trial diets, abalone fed on a diet of wild *Ulva* sp. were significantly shorter in shell length than abalone fed on most other macroalgal diets. *Ulva*-fed animals were also found to have the lowest wet weight to shell length ratios. However, when the animals were fed *Ulva* as a proportion of a mixed diet, they exhibited excellent growth rates, suggesting that *Ulva* provided essential nutrients not found in the other algae fed.

The increase in protein content of *U. rigida* observed within this trial is supported by previous research in which *Ulva* spp. have been used as macroalgal biofilters (Tenore 1976, Neori 1996, Shpigel et al. 1996a, Shpigel et al. 1996b). In the current trial, wild *U. rigida* was found to have a protein content of 13% (% dry weight), compared with 32.2 ± 1.5% (% dry weight) for *U. rigida*, which had been enriched on inorganic nutrients. The high protein content throughout the trial could explain the differences observed between the growth achieved on wild *Ulva* spp. in other research and the growth achieved within this trial *U. rigida*. Fleming (1995) found that the intake of digestible nitrogen directly influences the growth rates of *H. rubra*. This suggests that nitrogen may be a limiting factor for growth in *Haliotis* spp. Britz and Hecht (1997) support this view by stating that maximum growth can only be achieved when sufficient protein, in the correct proportions of amino acids, is supplied in the feed. Shpigel et al. (1996a; 1999) state that the good growth of *H. tuberculata* and *H. fulgens* when fed enriched *U. lactuca* was attributable to a consistent supply of high protein diet.

The consumption results in this study do not adequately reflect the trends observed within the tanks. Some diets were observed to be more water stable than others, and thus were easier to fragment upon siphoning for collection. Diets 1 and 4 (FRDC2 and

TABLE 2.

Effects of diet on time (hours ± SE) taken to reach 50% mortality for Juvenile *H. roei* held at 20‰ saline (n = 2; 12 abalone per replicate).

Diet	1	2	3	4	5	6	7
LS_{50} Time @ 20‰	84 ± 4^{ab}	86 ± 2^{a}	68 ± 4^{b}	82 ± 2^{b}	88 ± 4^{a}	86 ± 2^{a}	>96

Note: Diets sharing the same letters are not significantly different ($P > 0.05$).

AB-feed) were both extremely water stable within the tank and, thus, held together well through the siphoning collection process. Diets 2, 5, and 6 (Adam & Amos, Haliogro and Deakin) were less water stable, but were still firm after 2 days. These diets fragmented when they were siphoned, as did Diet 7, which was very soft after 2 days within the tanks. The data were potentially biased against Diets 1, 3, and 4 because of the fragmentation of other diets causing some loss of material during analysis. This would have reduced the amount of feed actually collected; thereby, increasing the apparent consumption. Differences in the various diets' water stability may be attributable to the diets having being formulated for colder water species.

Stress determination for aquatic animals usually involves a quantitative evaluation of a variable that is directly affected by the stressor. The application of an environmental stress allows for an assessment of general health or vigor for animals from different treatments. Salinity stress tests have been used previously to determine the quality of prawn post larvae (Briggs 1992, Samocha et al. 1998), fish larvae (Dhert et al. 1990a, Dhert et al. 1990b) and the effects of diet on abalone robustness (Boarder & Maguire 1998). Boarder and Maguire (1998) found that dietary vitamin levels directly determined the survival of *H. laevigata* at 23‰ salinity. Animals fed on twice the normal dietary inclusion level of vitamin mix exhibited over 90% survival after 96 hours, as compared with approximately 50% survival for animals fed the normal dietary vitamin level.

The poor survival at 20‰ for abalone fed *U. rigida* within this trial may be attributable to the osmoregulatory mechanisms utilized by *Haliotis* spp. rather than a general lack of health. Abalone species are known ionic conformers; therefore, blood osmolality and ionic concentration closely resemble those of the external environment (Somero & Bowlus 1983). The ability to regulate cell volume is also an important ability in soft-bodied osmoconforming marine animals (Tarr 1976, Burton 1983), because this prevents cells from rupturing upon exposure to low salinities. Cell volume regulation within some osmoconforming mollusks is controlled by organic solutes, such as amino acids (Burton 1983, Mai et al. 1994). At low salinities, amino acids are excreted from the cell along with osmotically obligated water, thereby restoring cell volume (Pierce & Amende 1981). Pierce and Amende state that there is a possibility that the physiological response of osmoconforming mollusks to low salinity may be directly related to their ability to maintain and control a large intracellular free amino acid pool.

The most important free amino acids for cell volume regulation (dependant on abalone species) are taurine, glycine, alanine, and proline, with an emphasis on taurine (Burton 1983). Biosynthesis of the amino acid taurine from methionine is known to occur in gastropod mollusks (Mai et al. 1994). Mai et al. (1994) found that the levels of taurine in the viscera of *H. discus hannai* were significantly lower in abalone fed wild *U. lactuca* than abalone fed on all other diets. The authors also found that the viscera methionine levels within the abalone fed *U. lactuca* were extremely high, indicating some physiological inhibition in the biosynthesis of taurine from methionine. Toxic substances contained within *U. lactuca*, as detailed by Borowsky and Borowsky (1990), were thought to cause this inhibition. Johnson and Welsh (1985) found that an exudate excreted from *U. lactuca* killed 100% of estuarine crab larvae within 24 h. The authors also report that the bactericidal and fungicidal properties of *Ulva* spp. exudate have been known for some time.

Because taurine is one of the most important amino acids for cell volume regulation, inhibition of taurine production from methionine could significantly affect the cell volume regulation ability of abalone fed solely on *Ulva* spp. The comparatively good growth observed in *H. roei* fed *U. rigida* within this trial indicates that there was no feeding inhibition caused by antinutritional compounds or toxic substances contained within the seaweed. Fleming (1995) found that antinutritional compounds within some algal species did not prevent preferences for algae containing high levels of digestible nitrogen. This suggests that, although the abalone fed on enriched *U. rigida* were capable of good growth, they were not capable of adequate cell volume regulation when exposed to hypo-osmotic conditions because of a lack of taurine within their free amino acid pool. It is important to note that all other health parameters (including growth) were excellent for abalone fed solely on enriched *U. rigida*.

The results of this trial indicate the salinity tolerance of *H. roei* to be between 25 and 20‰. This correlates closely with the limited literature on *Haliotid* salinity tolerances, which indicate short-term survival is possible at salinities around 20‰ (Singharaiwan et al. 1992, Jarayabhand & Phapavisit 1996, T. McCormick 1997 pers. comm., Boarder & Maguire 1998). The 96-h LS50, the salinity at which 50% of the test animals survive after 96 h, is relatively close to 20‰ for *H. roei*. Most diets displayed 50% survival at just under 96 h within this trial. This compares with only 10% survival after 96 h for *H. diversicolor supertexta* juveniles transferred from 35 to 20‰ at similar temperature (Chen & Chen 2000).

In conclusion, enriched *U. rigida* is a suitable feed for *H. roei*, producing comparable growth rates to several commercially available manufactured feeds. Diet directly affects survival of abalone under hypo-osmotic stress, and *U. rigida* may impair the ability to cope with this stress by affecting cell volume regulatory mechanisms.

ABSTRACT Bioenergetics (food ingestion, absorption, growth, respiration, ammonia, and mucus production) of the warm-water abalone *Haliotis fulgens* and the cold-water species *H. tuberculata* were studied under summer and winter conditions in the Gulf of Aqaba. Individuals of 38–45 mm shell length and 7–11 g whole live weight were fed *Ulva lactuca* and *Gracilaria conferta*. Food ingestion was greater in summer but not sufficient to overcome the high maintenance, resulting in low (*H. fulgens*) or no (*H. tuberculata*) growth in summer. Growth for *H. fulgens* and *H. tuberculata* during winter was 0.10 ± 0.05 mm/d and 0.09 ± 0.02 mm/d and 0.02 ± 0.01 and 0.03 ± 0.01 g DW/d, respectively. Respiration rate and ammonia excretion were greater in summer for both species. In summer, *H. tuberculata* had greater food absorption than *H. fulgens*, and the reverse was found in winter. Mucus secretion was only 1–9% of the energy budget. In winter, growth accounted for the majority of the energy budget of both species and in summer, respiration and ammonia were the main components. Overall, *H. fulgens* seems to be most suited to year-round conditions found in the Gulf of Aqaba.

KEY WORDS: abalone, bioenergetics, *Haliotis fulgens*, *Haliotis tuberculata*

INTRODUCTION

Nonindigenous species must have certain characteristics if they are to be successfully cultured in a new environment. In particular, candidates for aquaculture must be acclimated and problems identified quickly. It is essential to know the degree of compensation possible to environmental change and to understand how they function in their natural environment. An energy budget relates the growth of an animal to its physiological condition and is one way to understand the basic biology of an animal and observe its energy partitioning for maintenance and growth in the new environment.

Previous research has shown that *Haliotis fulgens* and *H. tuberculata* are suitable for culture in warm-water environments (Shpigel et al. 1996a, Shpigel 1996b). However, comparison of the performance of these two species and description of the process by which ingested food is utilized for maintenance and growth is not known for warm seawater conditions. Growth and production characteristics can be measured using energy budget parameters. Food consumption, feces egestion, respiration, ammonia excretion, and mucus secretion are essential elements in an abalone energy budget (Peck et al. 1987, Barkai & Griffiths 1988, Donovan et al. 1998). Nutrient relationships are also useful in understanding an energy budget and indicate the role of digestive characteristics in energy utilization. Food absorption and food conversion efficiencies have been used in other invertebrates to indicate interactions between metabolism and production (Lawrence 1975, Bayne et al. 1975).

H. fulgens is a warm-water species found in seawater of 12–23°C (Hahn 1989) but tolerates temperatures up to 28°C for short periods (Leighton et al. 1981). *H. tuberculata* is a cold-water species found in seawater of 5–18°C (Mgaya 1995) but shows accelerated growth when cultured in seawater near 20°C (Koike et al. 1979, Shpigel et al. 1996a). *H. fulgens* and *H. tuberculata* are benthic, motile to semisessile subtidal species relying on drift and attached macroalgal communities for food. The objective of this study was to determine the status of *H. fulgens* and *H. tuberculata* by measuring energy budget parameters in summer and winter.

*Corresponding author

METHODS

Two species of abalone, *Haliotis fulgens* and *H. tuberculata*, were studied for two seasons, winter and summer. Individuals of 38–45 mm shell length and 7–11 g whole live weight were selected from cultured populations at the National Center for Mariculture in Eilat, Israel. Incoming seawater was filtered by sand and cartridge filtration to 1 μ. Seawater temperatures were 24–28°C and 20–22°C in summer and winter, respectively. Dissolved oxygen was always near saturation, and salinity was 41 ± 1 ppt. Ambient photoperiod was 14 h of light in summer and 11 h of light in winter. Animals were held in glass aquaria of 25 L. For each species, five replicate aquaria held 10 individuals per season. Abalone were selected randomly from two aquaria for respiration, ammonia, feces, and mucus measurements. Individuals were used only once for metabolic measurements. Three aquaria per species were used to determine feeding and growth rates. These individuals were not used for physiologic measurements. A preliminary energy budget including ingestion, assimilation, respiration, ammonia production, feces, mucus secretion, and growth was prepared showing the allocation of energy in joule/g DW/day in summer and winter.

Somatic Growth (G)

H. fulgens and *H. tuberculata* were measured at the start and finish of each seasons' experiments to determine daily growth increments. Growth was measured as the change in shell length (mm) and whole dry weight (g) during the summer interval, 7 July to 5 October 1995, 93 days, and the winter interval 12 December 1995 to 5 March 1996, 83 days. Specific growth rate was calculated for weight (g) and length (mm) as [(*ln* mean final abalone dry weight (length) − *ln* mean initial abalone dry weight (length))/days per experimental period] * 100. Growth as change in energy content (joule/g DW/day) was calculated for the energy budget using the dry tissue weight of the abalone.

At the beginning of the study, samples of each *H. fulgens* and *H. tuberculata* were weighed to the nearest 0.001 g, measured to 0.01 mm, and dried at 60°C for 7 days to determine whole wet weight/dry weight ratio of the abalone. The dry tissue/dry shell ratio was calculated after drying. The dried abalone tissue was

combusted in a Parr semimicro bomb calorimeter using benzoic acid as a standard to determine gross energy content (joule/g DW).

Consumption (C)

The abalone were fed *Ulva lactuca* and *Gracilaria conferta ad libitum* at a ratio of 3:1. Food introduced to the abalone and uneaten food removed was blotted on paper toweling to remove excess moisture. Dry food ingestion was measured over 1-wk intervals four times each season. Algae held in aquaria without abalone had no significant weight change. Feed ingestion was calculated directly as the difference between algae added and removed from the aquaria.

The protein content, dry and ash weight of the algae were measured each season. Dry and ash weights were determined by drying to a constant weight at 60° C followed by incineration for 24 h at 550°C. Crude protein was measured using the Kjedahl method and multiplying *n* by 6.25. The gross energy content (cal/g DW) of *U. lactuca* and *G. conferta* was determined by combustion in a semimicro bomb calorimeter using benzoic acid as a standard.

Gross food conversion efficiency was calculated using the food ingested in terms of energy as (mean final joule/g DW–mean initial joule/g DW)/ (mean joule/g DW food consumed/abalone/season) × 100. The dry matter content of the abalone tissue was used for food conversion efficiency. Net food conversion efficiency for joule/g DW/day was calculated using the food absorbed.

Feces (F) and Absorption Efficiency

Feces were collected by placing individual abalone in a 1 L conical tank with a 1 mm mesh floor. The water containing the feces was filtered onto the dried, preweighed GFC filters, dried at 60°C for 24 h. Dry feces were incinerated for 3 h at 450°C in muffle furnace. The dry and ash weights were used to calculate the organic content of the feces.

The absorption efficiency was calculated by the indirect method of Conover (1966): $U' = F' - E'/(1-E')(F')$, where U′ is the absorption efficiency, and F′ and E′ are the concentrations of organic matter in the food and feces, respectively.

The energy expended in feces egestion was calculated from the food absorption values. The gross energy values of *H. tuberculata* feces, 2,817 cal/g dry weight, determined by Peck et al. (1987) were used for our energy budget calculations.

Respiration (R)

A 720-mL round, Perspex respiratory chamber with a magnetic stirrer submersed in a flowthrough seawater bath was used to measure oxygen levels every minute until 50% oxygen saturation was reached. Test Point® software was used to measure the incoming mg O_2/L with an accuracy of 0.01 mg O_2/L. Each respiration determination lasted for approximately 3 h. Measurements were made during the day and night. Results are presented per 24 h. Five chambers were run concurrently. Respiration measurements were made over 2-wk intervals each season. Night respiration was completed between 2300 to 0200 h. Day respiration was completed between 1100 to 1400 h. For the energy budget, the daily oxygen consumption, mg O_2/g DW/day was calculated from the day and night rates. Oxygen consumption was converted to energy using 3.47 cal/mg O_2 (Bayne et al. 1975).

Ammonia (U)

In separate tests, individual abalone were placed in respiration chambers. Seawater collected from the chambers was analyzed with a Technicon II Autoanalyzer giving μM NH_4^+/h/abalone. Ammonia was analyzed following filtration through HCl washed Whatman GF/C filters according to the modified oxidation procedure of Neori et al. (1996). Three 1-mL aliquots were collected from each abalone. For the energy budget, a mean daily ammonia excretion rate μM NH_4^+/g DW/day was calculated for day and night. Conversion factors used to calculate energy equivalents of ammonia excretion were μ18 M ammonia/μg ammonia and 0.0249 joule/μg ammonia (Bayne et al. 1975). Samples were collected during the night and day as for respiration measurements. Each test lasted 2.8 to 3.5 h.

Mucus (M)

Individual abalone were moved to clean aquaria without feed and with low aeration for 48 h. The abalone were removed, and the walls of the aquaria were cleaned with a spatula. The mucus from the aquaria water and walls were collected on preweighed, dried, GF/C filters. The filters were rinsed with distilled, deionized water to remove salts, and dried at 60° C. Mucus samples were pooled for all aquaria per species. The caloric value of mucus used was 5,439 cal/g dry weight (Peck et al. 1987).

Energy Budget

An energy budget was calculated for *H. fulgens* and *H. tuberculata* during summer and winter based on joule/g DW abalone/day using food ingestion (C), somatic growth (G), respiration rate (R), ammonia excretion (U), feces egestion (F), and mucus secretion (M) as parameters. The scope for growth, all maintenance energy (respiration, ammonia, mucus, and feces) subtracted from the total absorbed energy (A) (Widdows et al. 1989) was also calculated.

Statistics

Somatic growth, respiration, ammonia production, dry feed ingestion, organic content of the feces, and total organic absorption were compared between species and between seasons by Student's *t*-test. All mucus samples were pooled to give one value per species per season. Specific growth rates for dry weight and shell length were calculated from means resulting in one value per species per season.

RESULTS

The whole wet weight (g)/whole dry weight ratio for *H. fulgens* and *H. tuberculata* are 0.47 ± 0.3 and 0.43 ± 0.2, respectively (n = 20 in each sample). The dry tissue/dry shell ratio is 0.36 ± 0.07 and 0.33 ± 0.3 for *H. fulgens* and *H. tuberculata*. The caloric content of dry tissue is 4,848 cal/g DW and 4,600 for *H. fulgens* and *H. tuberculata*, respectively.

Somatic Growth (G)

In summer, *Haliotis fulgens* had a greater increase in shell length than *H. tuberculata,* but there were no significant differences (Table 1). At the end of the summer interval, *H. tuberculata* lost weight as compared to *H. fulgens*, which showed a slight weight gain. The mean weight loss of *H. tuberculata* resulted in significant differences between species in this measurement of somatic growth. In winter, shell length and dry weight increase were significantly greater for *H. tuberculata* than *H. fulgens*. Somatic growth was greater for both species in winter than summer (Table 2). The specific growth rates (SGR), daily changes in DW, and shell length reflected the growth pattern seen from direct

growth measurements (Table 3). Energy used for growth was greater in winter than in summer.

Consumption (C)

Dry feed ingested/g DW abalone/day was significantly greater for *H. tuberculata* than *H. fulgens* during both seasons (Table 1). Neither species had significantly different feed ingestion rates when compared between seasons (Table 2). Gross food conversion efficiency was greatest for *H. tuberculata* in the winter, followed by *H. fulgens* in the winter, *H. fulgens* in the summer, and least efficient in *H. tuberculata* during summer months (Table 3).

Algal protein content was greater in winter than summer ($t = -2.5052$, df = 12, $P = 0.028$, $t = -8.483$, df = 12, $P = 0.005$) for *Ulva lactuca* and *Gracilaria conferta*, respectively. Caloric values were not significantly different between seasons (Table 4).

Organic absorption was significantly different between species in both seasons. *H. tuberculata* had a higher food absorption rate than *H. fulgens* during summer, and the reverse was true in winter. The organic content of both algal species was the same, 70%, and did not change with season (Table 2). Food absorption in *H. tuberculata* in winter was the lowest found in this study.

Feces (F)

The organic content of the feces was significantly greater for *H. fulgens* in winter and for *H. tuberculata* in summer. The organic content of the feces was significantly greater for *H. tuberculata* in winter than summer. Organic content of the feces had an inverse relationship with the organic absorption (Tables 1 and 2).

Respiration (R)

H. fulgens and *H. tuberculata* had greater respiration rates in summer than winter. There were no significant differences in win-

ter, but *H. tuberculata* had a greater rate than *H. fulgens* in summer. For both species, respiration was similar for day and night measurements, except for *H. tuberculata* in the summer, where night respiration was greater (Table 5).

Ammonia (U)

Ammonia excretion rate was significantly greater for *H. tuberculata* than *H. fulgens* in summer. There were no significant differences between species in winter. When compared between seasons, *H. tuberculata* had a greater rate in summer than winter, and there were no significant differences in the ammonia excretion of *H. fulgens* between seasons (Tables 1, 2).

Ammonia excretion was similar during day and night measurements, except for *H. tuberculata,* which showed a higher rate during the summer night samples (Table 6).

Mucus (M)

Mucus collected from all aquaria per species per season was pooled. Mucus secretion was 0.004, 0.001, 0.003, and 0.001 g DW/abalone/day for *H. fulgens*-summer, *H. tuberculata*-summer, *H. fulgens*-winter, and *H. tuberculata*-winter, respectively.

Energy Budget

For both species and seasons, 83–94% of the assimilated energy was accounted for, except *H. tuberculata* in the summer, where 70% of the total energy intake was measured (Fig. 1). Because of higher feed ingestion rates in summer, total energy ingested was greater than in winter. In the summer, *H. tuberculata* responded to warm seawater conditions by high respiration rate and ammonia excretion. *H. fulgens* had the highest mucus secretion rate overall, particularly during summer.

The scope for growth was greater in winter than summer. Although *H. tuberculata* would have been expected to show growth rates similar to *H. fulgens* in the summer by the scope for growth calculation, this species lost weight and showed a slight increase in shell length.

DISCUSSION

The energy budget published for *H. tuberculata* (Peck et al. 1987) was done in its normal range and offers valuable insight to our results. *H. fulgens* has very little basic biological information published, thus we were unable to make any direct comparisons of metabolic and nutritive characteristics.

In general, the food ingestion increased in summer for both species. As expected, the energy expenditures in body processes of *H. fulgens* and *H. tuberculata* also intensified during the summer. Additional energy was available from the food ingested, but most of this was used for maintenance. The significant difference in responses of *H. fulgens* and *H. tuberculata* may result from the seawater temperatures tested here: 20–26°C.

H. fulgens is a relatively warm-water species and has shown accelerated growth for short periods at 28°C (Leighton 1981). *H. tuberculata* has maximal growth at temperatures near 20°C (Mgaya 1995, Shpigel et al. 1996a) and negative growth at 26°C (Shpigel et al. 1996b). On an annual basis, *H. fulgens* had greater growth in shell length (22.1 vs. 18.5 mm/y), and *H. tuberculata* has greater growth in whole dry weight (10.6 vs. 9.0 g/y). The growth rates found here may not represent maximal performance of *H. tuberculata,* because higher growth rates were found between

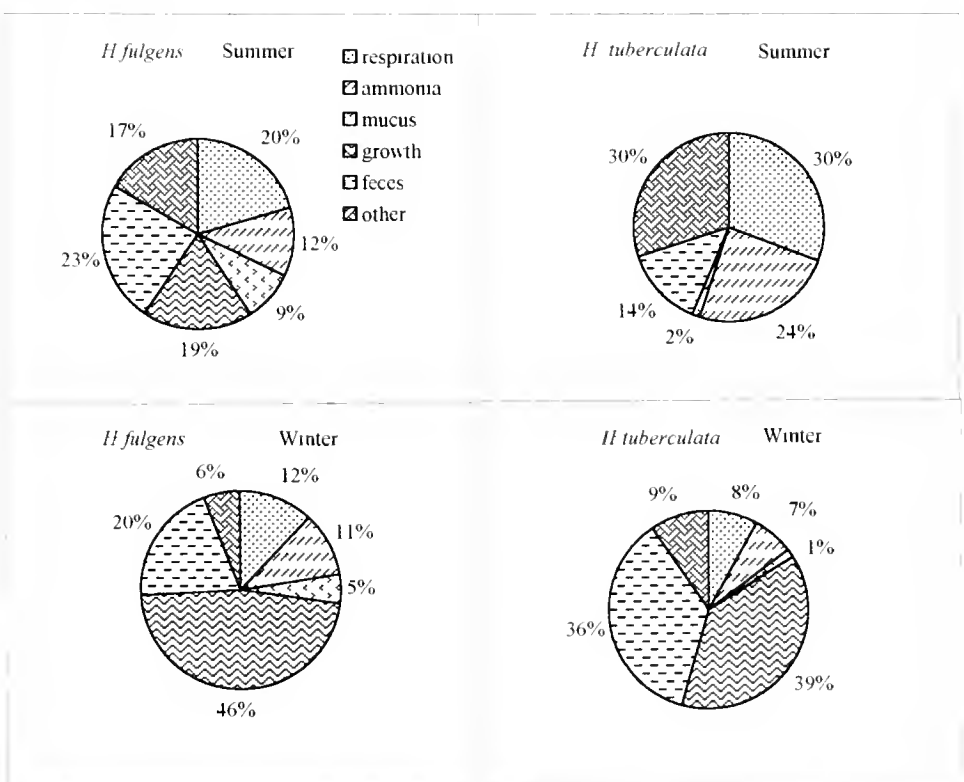

Figure 1. Energy budgets for *Haliotis fulgens* and *H. tuberculata* for summer and winter. Values are percentage of total energy ingested; other is energy not accounted for.

March and May (Neori et al. 1998), a time of year we did not study.

Fuller understanding of growth of these two species in a warm-water environment is shown in the scope for growth. The negative summer values indicate stress and reflect the high use of body reserves used for maintenance metabolism in both species. Other evidence of stress in *H. tuberculata* is demonstrated by the negative growth found in the energy budget. In contrast, *H. fulgens*, continued growing at a lower rate in the higher seawater temperatures recorded in summer months.

Mortalities observed during the decrease in seawater temperatures (Shpigel et al. 1996b) may result from the stressed condition of the *H. tuberculata* at this time. *H. tuberculata* may deplete stored body reserves of glycogen (Bennett & Nakada 1968) during summer. This combined with the additional stress of temperature change may explain these mortalities. The negative scope for growth found for *H. fulgens* may approach the lethal limit but seems less severe for this species.

Respiration is a useful and sensitive measure of daily energy expenditure. The stress of the higher seawater temperatures increased respiration rates. The solubility of oxygen changes little in the temperature and salinity range used in this study (Dejours 1988), but the ability of the abalone to cope with the seasonal environmental changes and maintain their metabolism was compromised. The higher rates of respiration relative to food intake found at temperatures between 24 and 26°C limited growth of both species. This relationship is also shown in the gross and net food conversion efficiencies that are lower for both species in summer.

The quality of the food is also important. Increased food ingestion in summer was probably more related to temperature than the slightly lower protein content of the algae in summer. The energy content may be more important in determining feed ingestion rates than protein (Shpigel et al. 1999). Energy content of *U. lactuca* and *G. conferta* was not significantly different between seasons.

The protein content of the algae fed here was consistent throughout the study and is higher than natural algal diets used in other studies. Cultured *U. lactuca* and *G. conferta* contains >20% protein, as compared to <11% found in natural populations (Peck et al. 1987, Barkai & Griffiths 1988, Shpigel et al. 1996b, Donovan et al. 1998). The elevated protein content seems to sustain growth in *H. fulgens* in summer and winter and provides adequate nutrition for significant growth of *H. tuberculata* in winter.

Organic absorption was significantly greater for *H. tuberculata* in winter than summer, again reflecting this species' ability for production in temperatures around 20°C. Seasonal variation in organic absorption is known for other invertebrates (McBride et al. 1998). The organic absorption of *H. fulgens* did not change significantly with season, again suggesting that this species is well adapted for production in seawater between 20–26°C.

The gross feed conversion efficiency indicates the efficiency with which the abalone utilizes the ingested energy for growth. Gross and net food conversion efficiencies were greatest for *H. tuberculata* during winter, because growth was high, and food ingestion and absorption were low, as compared to summer months, when growth was negative, and food ingestion was high. As with other measurements, the gross and net food conversion efficiency of *H. fulgens* were similar in summer and winter. The food conversion efficiencies were higher in winter for both species, showing more energy was available for growth and less was used for maintenance.

Mucus production was lower than other abalone energy budgets, between 1–9% of the total energy, as compared to 16–27% (Peck et al. 1987, Barkai & Griffiths 1988), except for *H. kamtschatkana* in winter, where mucus secretion contributed 4% of the total energy budget (Donovan et al. 1998). Two factors may contribute to the low mucus secretion values found here. First, *H. fulgens* and *H. tuberculata* move very little in culture condition at the National Center for Mariculture (pers. observ.). This is similar to the low activity found in *H. kamtschatkana* in winter (Donovan et al. 1998). Second, other studies determined mucus secretion by subtraction, and we calculated it by filtration. The combination of low activity of abalone in our study and our method of collection may have contributed to this difference

The scope for growth during winter months was similar for both species, reflecting their comparable growth rates. Although *H. tuberculata* lost weight during summer, their weight gain was greater on an annual basis than *H. fulgens*. Although not studied here, survival of *H. fulgens* seems to be greater than *H. tuberculata* because of seasonal seawater temperature changes (Shpigel et al. 1996b), adding more weight to the argument for pursuing culture of this species in a warm-water environment.

In conclusion, the energy budgets of *H. fulgens* and *H. tuberculata* provide a good indication of the animals' response to the culture environment. The mean seawater temperatures experienced by each species in its natural range strongly influenced expenditures of energy, resulting in low growth and high maintenance during summer and high growth and low maintenance in winter. In all factors measured, *H. fulgens* seems better adapted to the year-round culture conditions tested and would seem to be the most suitable species overall for culture in the Gulf of Aqaba.

SPAWNING INDUCTION OF YELLOWFOOT ABALONE, *HALIOTIS AUSTRALIS* USING CHEMICALS AND GANGLIONIC SUSPENSIONS

NURUDDIN M. J. KABIR,[1,*] MIKE F. BARKER,[1] PHILIP V. MLADENOV,[1] AND BRIAN E. NIVEN[2]

[1]Department of Marine Science, University of Otago, Dunedin, New Zealand; [2]Department of Mathematics and Statistics, University of Otago, Dunedin, New Zealand

ABSTRACT A two-step experimental approach (*in vitro* and *in vivo*) using serotonin (5-hydroxytryptamine), dopamine (3-hydroxytyramine), prostaglandin E_2, deionized water, filtered seawater, cerebral (CG) and pleural-pedal (PPG) ganglionic suspensions as inducers of the spawning of *H. australis* were tested. A total of 88 laboratory conditioned abalone (n = 6–10 per treatment) with fully ripe gonads were used. Filtered seawater caused spawning in 100% of females and 67% of males and 50% of females and 25% of males injected with serotonin (10^{-3} M) spawned. Prostaglandin E_2 did not induce the release of gametes. Fifty percent of females injected with dopamine (10^{-3} M) spawned a small number of eggs, while the males did not respond. Males did not respond to injection of any kind of ganglia, and 20% of females spawned a few eggs in response to CG and PPG from females. Forty percent of females spawned in response to PPG from males. Injection of deionized water caused no weight changes; whereas, filtered seawater caused a reduction in weight. Prostaglandin-treated animals gained weight on the second day but lost weight over subsequent days. Only females gained weight in the dopamine treated group, but both males and females gained weight in the serotonin-treated group. With ganglionic injections, males treated with CG or PPG from males gained more weight than their female counterparts, and the females treated with CG or PPG from females gained more weight than males. The increase in mean body weight of animals was followed by a swelling and softening of the ovaries, possibly because of increased water content in the ovaries. It seems likely that uptake of water in the ovary is a physiological precursor to spawning.

KEY WORDS: *Haliotis australis*, spawning, ganglionic extracts, other neurotransmitters

INTRODUCTION

The control of spawning is essential for the efficient use of hatchery facilities and to the success of an aquaculture operation (Hahn 1989). Artificial induction of spawning allows the production of larvae over a longer period than would be possible relying solely on natural spontaneous spawning. Several methods of artificial induction of spawning in abalone have been tried over the years, some have been successful and others of limited use. Commonly used methods to induce broodstocks of abalone to spawn include immersion in ultraviolet (UV) irradiated or hydrogen peroxide (H_2O_2) treated seawater for several hours (Kikuchi & Uki 1974, Morse et al. 1977). Both of these methods seem to induce spawning by a similar mechanism; that is, generation of hydroperoxy free radicals, $HOO^{\cdot}$, or peroxy diradicals, $^{\cdot}OO^{\cdot}$, in the seawater that activate the natural enzymatic synthesis of prostaglandins in the abalone (Morse et al. 1977), although the active molecule is produced differently (Hahn 1989). Prostaglandins, as well as some amines produced by nerve cells, are considered to play an important role in spawning in other molluscs as well (Khotimchenko & Deridovich 1991).

The yellowfoot abalone, *H. australis*, is the preferred species for New Zealand abalone farmers who want to produce cocktail size (60–70 mm) abalone for export, because the color of the foot makes them more acceptable on international markets (Moss 1998). The abalone reaches sexual maturity at about 70–90 mm (Poore 1972) and can be conditioned to ripeness in the hatchery by holding at constant temperature and *ad libitum* feeding (Moss 1998, Kabir et al. 1999). With the abalone aquaculture industry expanding worldwide, the demand for regular production of high-quality larvae is increasing. Existing methods for spawning broodstock are often unreliable, species specific, and frequently result in the spawning of poor quality eggs leading to high larval mortality in cultures (Moss 1998, pers. observ.). Spawning induction of *H. australis* by the H_2O_2 method resulted in an overall spawning rate of 17% for males and 10% for females (Moss 1998), which is very poor.

The present study aimed to investigate the effectiveness of different chemicals, neurotransmitters, and ganglionic extracts on the spawning induction in *H. australis*. Another objective was to identify a suitable solvent for the preparation of solutions of chemicals or ganglionic homogenates, because there was evidence that the most commonly used solvent, seawater, itself caused spawning in other abalone species (Anon 1990). We also wanted to identify neurotransmitters, which may trigger egg maturation in this species.

MATERIALS AND METHODS

Abalone Collection and Conditioning

Yellowfoot abalone, *H. australis*, (length 84.44 ± 1.07 mm, weight 111.32 ± 4.13 gm, mean ± SE) were collected from Warrington Beach in the Blueskin Bay area of the Otago coast of New Zealand and conditioned at 15°C for 150 days (effective accumulative temperature ≥ 1,400°C-days) in the holding facilities of a commercial abalone farm at Warrington. They were fed an artificial diet, Makara (Promak Technology, New Zealand), *ad libitum* and exposed to a 12-h dark and 12-h light photoperiod. Throughout the conditioning period, gonadal development was evaluated subjectively and classified into four levels of gonad index from 0 (unripe) to 3 (gravid) (Ebert & Houk 1984). Most of the abalone reached the gravid stage after the conditioning and were spawnable.

Trial 1: Oocyte Maturation Assays

Samples of gonad, haemocoel fluid, and cerebral (CG) and pleural-pedal (PPG) ganglia from ripe, unspawned, and spawned

*Corresponding author.

males and females of *H. australis* were collected, frozen in liquid nitrogen, and stored at −80°C. Ganglia were warmed slowly and homogenized on ice in 1.0 mL of 0.2 μm filtered seawater per 10 ganglia using a glass-to-glass tissue homogeniser. Gonads were also homogenized, and the homogenates were centrifuged (8,000 rpm, 20 min), and the supernatant was used for the assay.

One fully gravid female from the conditioned stock was dissected, gonad removed, and macerated. Small pieces of gonad, together with free oocytes were placed in wells of a tissue culture dish and exposed to the different treatments (different gonad extracts, hemocoel fluids, cerebral and pleural-pedal ganglionic extracts, hydrogen peroxide, fresh seawater, and deionized water) with three replicates per treatment. Oocytes were monitored continuously using an inverted microscope for any evidence of the occurrence of germinal vesicle breakdown (GVBD), extrusion of polar bodies, and change in shape.

Trial 2: Effects of Freshwater and Seawater Injection on Induction of Spawning

Twenty-four gravid abalone (3 males and 3 females per treatment) were kept individually in 2.0-L containers with individual water flow. One group was not treated and used as a control; whereas, other groups were: (1) sham injected everyday for 3 days; (2) injected with filtered (0.2 μm) seawater; and (3) injected with deionized water. The latter two treatments were injected once per day over 3 days (1 mL/abalone) into the hemocoel posterior to the head region using a TERUMO® needle 26G × ½" (0.45 × 13 mm).

Trial 3: Effects of Serotonin, Dopamine, and Prostaglandin E_2 on Induction of Spawning

Twenty-four gravid abalone (4 males and 4 females per treatment) were kept individually in 2.0-L containers with individual water flow and monitored as described above. Serotonin (5-hydroxytryptamine), dopamine (3-hydroxytyramine), and prostaglandin E_2 (Sigma Chemicals, St. Louis, MO) at a concentration of 10^{-3} M for serotonin and dopamine, and 10^{-5} M for prostaglandin E_2 were injected once per day over 3 days (1 mL/abalone) into the hemocoel posterior to the head region. These doses were selected based on the reports in other molluscs (Martinez et al. 1996). Solutions were made using deionized water as a solvent.

Trial 4: Effects of Different Ganglionic Suspensions on Induction of Spawning

Forty fully gravid abalone (5 males and 5 females for each treatment group) were used and maintained as described above. Each treatment group was injected with: (1) cerebral ganglia from males (CGM); (2) cerebral ganglia from females (CGF); (3) pleural-pedal ganglia from males (PPGM); or (4) pleural-pedal ganglia from females (PPGF). Ganglia were collected from the fully ripe wild yellowfoot abalone and were frozen in liquid nitrogen and stored at −80°C. Before use, the ganglion were thawed and homogenized on ice with deionized water in a glass-to-glass tissue homogenizer at a concentration of one ganglia per 0.1 mL of solution. The homogenates were injected once a day over 3 days, at a dose of 0.1 mL per abalone. This dose was selected after Yahata (1973), where he diluted one ganglion per 0.1 mL and injected into the abalone.

Spawning activity was monitored continuously, and the weight of the abalone was measured at 24-h intervals. The response was recorded as positive when gametes were released. The quality of the gametes was monitored microscopically.

Handling of the Abalone

All the abalone used for the trials were subjected to gentle detachment from the tank, inversion on blotting paper to drain branchial water, weighing, and return to the respective containers. The weight for each abalone was recorded at the start and every 24 h up to the end of the experiment. The weight of the abalone was standardized considering the initial weight for the treatment group as 100%.

Statistical Analyses

The spawning results are treated as a logistic regression with the treatment and sex as factors using the regression model: proportion of spawning = exp (y) / [1+ exp (y)] + binomial error, where y = constant + treatment effect + sex effect. It assumes that the probability of spawning for individual abalone is constant. The models are found to fit the data adequately, and the results are considered significantly different if $P < 0.05$.

RESULTS

Trial 1: Oocyte Maturation Assays

The oocytes were irregular in shape when placed in the wells but became spherical within 20 min. Afterward, no change in shape, motile response, or release of polar bodies was observed for any of the treatments and replications.

Trial 2: Effects of Freshwater and Seawater Injection on Induction of Spawning

Filtered seawater caused spawning in all females and two out of three males. One female spawned in the control group. There was no spawning in other treatment groups (Fig. 1). Analysis of deviance (Table 1) indicated that treatments have a significant effect on spawning ($P < 0.05$) with the spawning by the filtered seawater differing from others. The sex had no significant effect ($P > 0.05$). Filtered seawater resulted in a loss of body weight; whereas, deionized water caused no weight change. Based on this result, deionized water was used as a solvent for further preparation of chemicals and ganglionic suspensions.

Trial 3: Effects of Serotonin, Dopamine, and Prostaglandin E_2 on Induction of Spawning

Serotonin-injected animals gained weight over time, and two females and one male spawned (Fig. 2). Two out of four females treated with dopamine spawned a small number of eggs and gained weight; whereas, no males responded and lost weight. Prostaglandin E_2 did not induce the release of gametes, and the treated abalone gained weight on the second day but lost weight over subsequent days. Analysis of deviance (Table 1) indicated that treatments have a significant effect on the spawning ($P < 0.05$) with the spawning by serotonin differing from others. The sex had no significant effect ($P > 0.05$).

Trial 4: Effects of Different Ganglionic Suspensions on Induction of Spawning

Only one out of five females spawned a few eggs in response to CGF and PPGF, and two out of five females spawned with

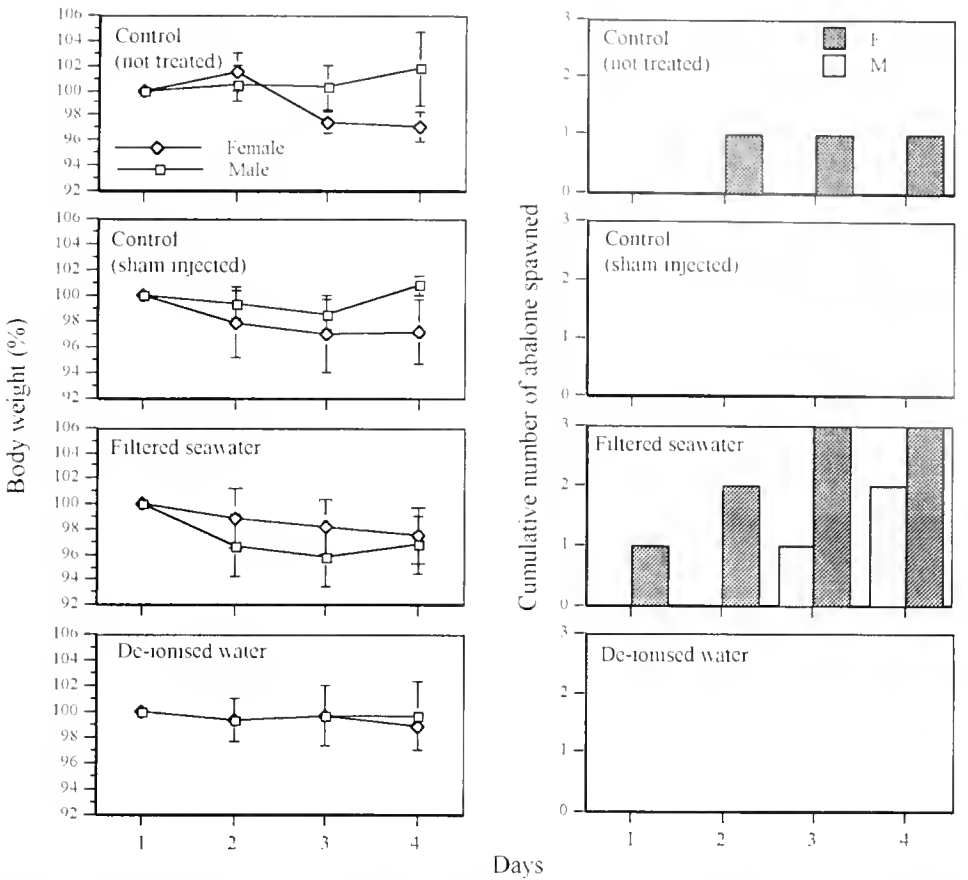

Figure 1. Changes in the mean body weight (± SE) (from a standardized initial mean weight of 100%) and cumulative spawning records of *H. australis* with different treatments.

PPGM. Abalone injected with CGM did not spawn (Fig. 3). Males treated with CGM and PPGM gained more weight than their female counterparts, and females treated with CGF and PPGF gained more weight than males. Analysis of deviance (Table 1) indicated that treatments have no significant effect on the spawning ($P > 0.05$), but the sex had significant effect ($P < 0.05$), with females differing significantly from the males.

DISCUSSION

Water temperature is considered as the main exogenous factor that regulates the reproductive cycle in many marine gastropods (Webber 1977, Hahn 1989). The process used to induce gonad ripeness and spawnability in adult abalone requires a number of exogenous and endogenous factors. The most common method to

TABLE 1.

Trial4	+Sex	0.0003	3	1.0000	6.2731	1	0.0123*

Nonsignificant P value for the "goodness of fit" confirms the model fits adequately. "Chi square test for term" indicates the effect of treatments and sex on spawning and is considered significantly different if $P < 0.05$ (marked with asterisks).

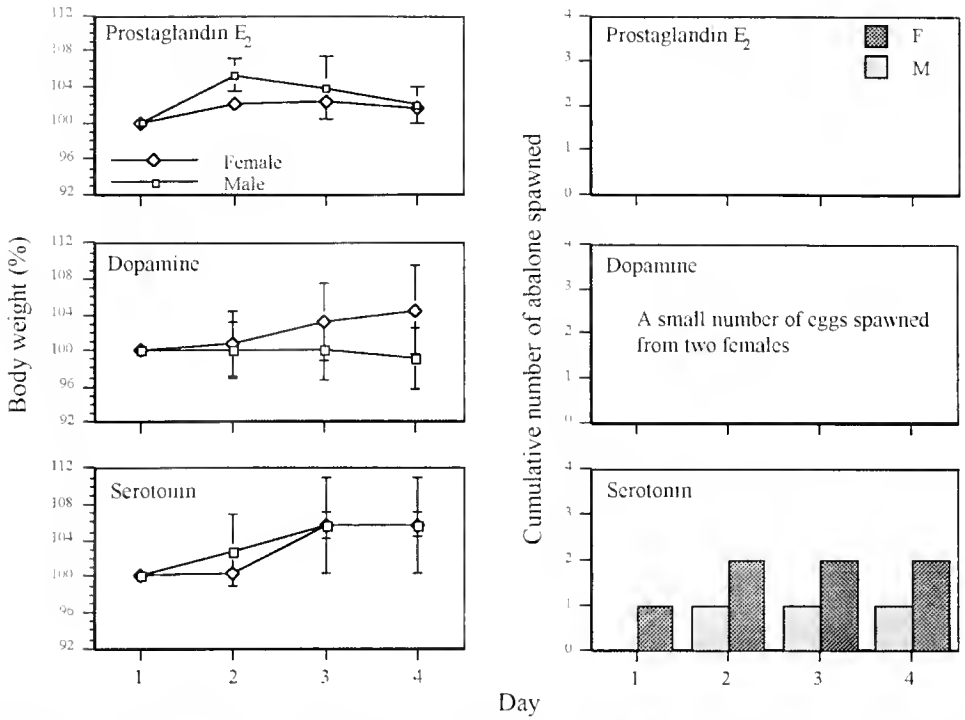

Figure 2. Changes in the mean body weight (± SE) (from a standardized initial mean weight as 100%) and cumulative spawning records of *H. australis* with different chemicals.

bring abalone into a ripe condition for breeding is to provide adults "with good living conditions (tailored to the ecology of the particular species) and *ad libitum* feeding" (Hahn 1989). The effect of temperature on abalone reproduction has been quantified in *H. discus hannai* (Uki & Kikuchi 1984) and *H. australis* (Moss 1998, Kabir et al. 1999). Our previous study (Kabir et al. 1999) showed that 21 wks of conditioning at 15°C (EAT ≥ 1,400°C-days) with *ad libitum* feeding induces gonad ripeness into a fully mature stage. Moss (1998) also reported 21 wks of conditioning at 15°C temperature was required for full gonad growth and initiation of spawning in *H. australis*, but this time may be reduced to 14 wks if the animals are held at 18°C water temperature. For the present experiment, the abalone were reared at 15°C for 21 wks following the result of Kabir et al. (1999). After conditioning, the gonad was bulging across the shell with a rounded tip at the end of a conical appendage; the ovary was brown to blue-gray, and the testis was milky white to creamy in color.

Oocytes treated with either ganglionic extract, hemocoel fluid, gonad extracts, or chemicals did not produce any motile responses or show any release of polar bodies. Saleuddin et al. (1983) reported that the freshly isolated oocytes from the ovotestis of *Helix aspersa* (Mollusca) showed amoeboid movement when treated *in vitro* with the extract of cerebral ganglia. They postulated that this form of induced motility might be associated with ovulation. On the other hand, Coggeshall (1972) suggested that ovulation in *Aplysia* is caused by the muscle contaction brought about by egg-laying hormone. Mature oocytes in the abalone do not undergo germinal vesicle breakdown until spawning is induced, and the oocytes are squeezed out of the gonad by the rapid contraction of the columnar muscle (Hahn 1990). In the present study, the inactivity of the oocytes may be attributable to the failure of oocytes to have matured sufficiently and they were, therefore, not ready for ovulation, or the isolation procedure caused invisible damage (chemical) to apparently healthy looking oocytes (Saleuddin et al. 1983). Another possibility is that the donor *H. australis* (from where the gonad, ganglia, and hemocoel fluid were collected) were not sufficiently mature and lacked the required amount of hormone to induce the oocytes. The exact mechanism of ovulation in abalone requires further investigation.

A preliminary study showed three out of five blackfoot abalone, *Haliotis iris*, spawned when a filtered seawater injection was used as a control. This prompted us to investigate the use of seawater as a control or its use as a solvent to homogenize different ganglia or other chemical solutions for the spawning experiment of *H. australis*. In the present experiment, injection of filtered seawater into the hemocoel caused spawning that is significantly different from other treatment groups ($P < 0.05$). Injection of 3.7% calcium chloride, sterilized or filtered seawater into the head and foot of *H. discus hannai* has also been observed to cause spawning (Anon. 1990). Yahata (1973) did not observe any spawning when 0.6% NaCl solution was injected into *Nordotis discus*, but it resulted in weight loss in the abalone. Thus, it seems that seawater or other salt solutions often induce spawning in *H. australis* and other abalone perhaps by stimulating the nervous systems. Therefore, we must be cautious in selecting a solvent to homogenize ganglia or to prepare other chemical solutions for spawning experiments with abalone.

The use of neurotransmitters and other chemicals in induction of spawning in molluscs (Vélez et al. 1990, Ram et al. 1993, Martinez et al. 1996) and of abalone (Morse et al. 1977) has been reported. Serotonin has been shown to be one of the most effective spawning inducers in some molluscs (surf clam Hirai et al. 1988, scallop Matsotani & Nomura 1982, China clam Alcazar et al. 1987, and giant clam Braley 1985). Therefore, the release of serotonin may play a role in abalone spawning. Prostaglandins (PG) have been suggested to be involved in the release of gametes

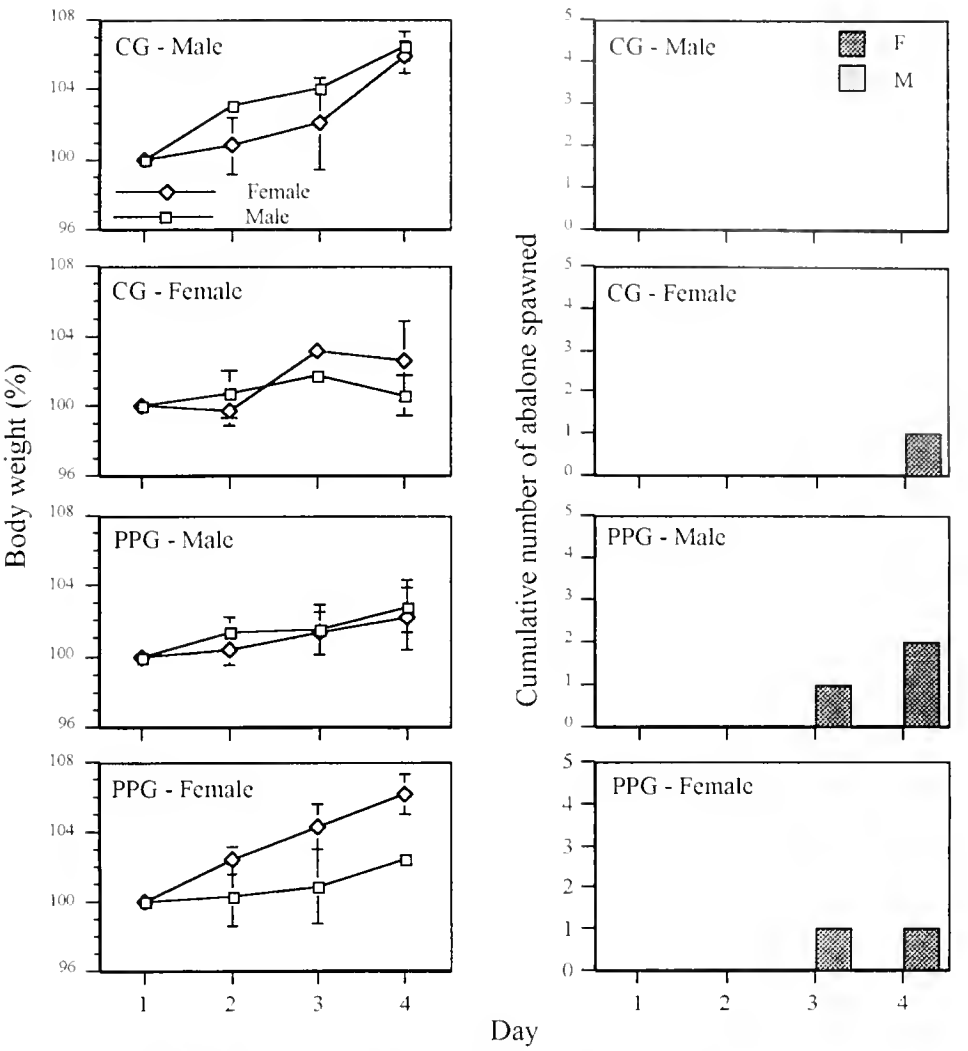

Figure 3. Changes in the mean body weight (± SE) (from a standardized initial mean weight of 100%) and cumulative spawning records of *H. australis* with different ganglionic suspensions.

(Morse et al. 1977). They showed that the ultraviolet (UV) irradiation of seawater or addition of hydrogen peroxide (activator of prostaglandin synthesis) to seawater induced spawning in male and female red abalone, *H. rufescens*. They were also able to induce spawning by adding the vertebrate hormone prostaglandin E or F (3×10^{-12} M) to the water. These hormones induced spawning in 38 to 47% of gravid abalone. Martinez et al. (1996) used 2×10^{-6} to 2×10^{-8} M prostaglandin E_2 for the spawning of scallop, *Argopecten purpuratus*. Kunigelis and Saleuddin (1986) reported that introduction of nanogram quantities of PGE_2 into the female genital opening of mated *Helisoma* increased the number of egg masses and the number of eggs per mass. The intrahemocoelic administration of thousand-fold higher concentration of PGE_2 failed to induce spawning. They postulated that the action of prostaglandin is localized and hormonally mediated. The failure of spawning by PGE_2 injection in this experiment supports the findings of Kunigelis and Saleuddin (1986), but a dose response experiment with different administration protocol in *Haliotis* sp. is essential to evaluate its role in abalone spawning.

In the present experiment to test the effect of ganglionic extracts, the treatments had no significant effect on spawning ($P >$ 0.05) Injections of crude homogenates of the cerebral ganglia into ripe females did not induce full spawning in ripe *H. discus hannai* (Yahata 1973). In their experiment, two out of five abalone injected with CG homogenates spawned a small amount of clustered eggs; however, there was a considerable gain in the mean body weight from an increase in water uptake without any noticeable change in the ovary. Hahn (1989) postulated that A-cells from cerebral ganglia of probably regulate vitellogenesis in females, but this ganglion does not contain a factor that is involved in the induction of spawning. Yahata (1973) also found that the injection of pleural-pedal and visceral ganglia crude homogenate into female *H. discus hannai* caused a large swelling and softening of the ovary and spawnings after two injections. Therefore, these ganglia may produce and release factors that induce spawning in abalone. Histological examination of the PPG showed several cell types producing abundant neurosecretory material that seemed to vary in relation to the reproductive cycle (Hahn 1990). The handling stresses (such as detaching, injection, and weighing) of the abalone on spawning were not evaluated in the present experiment. A recent study showed that handling for weighing may produce 7 to 17% weight reduction in adults of *H. iris* (Ragg et al. 2000). An

increase in body weight was observed in the present experiment with ganglionic suspensions and other neurotransmitters. These increases in the body weight may be caused by the increased uptake of water in the ovary, which indicates that the uptake of water by the gonad may be essential to bring about spawning (Yahata 1973).

The weak or almost no response of the ganglionic extracts in the spawning of *H. australis* in the present experiment raises a number of issues. First, the maturity of the animals from where the ganglia were collected must be examined. The abalone were collected from Warrington Beach, and those with bulging gonad above or near the shell edge were taken. Abalone with such bulging gonads are considered to be fully ripe (Ebert & Houk 1984), but this does not provide information on the oocyte maturation stage. It could be possible that in the wild population, abalone with fully developed gonads may not necessarily be spawnable and lack factors in the ganglia that are responsible for spawning. Second, the abalone that were injected came from the conditioned stock (1,400 C-days). It has been shown histologically that after such conditioning period oocytes become fully grown, and the abalone are spawnable (Kabir et al. 1999). Thus, the abalone used in this experiment were well gravid. Third, the dose of the ganglia (i.e., 1 ganglion per 0.1 mL = 1 injection) was selected following the protocol of Yahata (1973). This dose may not be effective for this species. Therefore, it requires further investigation with the ganglia to be collected from conditioned individuals and employed with different doses and combinations.

ACKNOWLEDGMENTS

We are grateful to Mr. Roger Bartlett, Executive Director of Abalone South Ltd., New Zealand for providing space on his farm and technical support. We thank two anonymous referees for constructive review of the manuscript. Thanks to Mr. Taka Kai, who translated the Japanese papers. REPRODUCTIVE PERFORMANCE INDICES BASED ON PHYSICAL CHARACTERISTICS OF FEMALE BLACKLIP ABALONE *HALIOTIS RUBRA* L.

MAGDALENA LITAAY* AND SENA S. DE SILVA

School of Ecology & Environment, Deakin University, 3280 Victoria, Australia

ABSTRACT Selection of abalone broodstock from the wild is often based on external appearances. The criteria used are size, color, and shape of the gonad. However, animals selected on external appearance are known to vary in egg fertilizability, hatching rates, and larval survival. The present study was instigated to develop easily useable indices, based on physical characteristics, for assessing the potential reproductive performance of female abalone. Analysis was conducted on wild-caught, artificially propagated blacklip abalone *Haliotis rubra* L., obtained from Australian coastal waters (142°15′; 38°21′S). Females were spawned using a combination of the desiccation and the UV irradiated methods and shell characteristics; length (SL), width (SW), height (SH), and total weight (W) of the spawners were determined. The fertilized eggs from each spawn were incubated, hatched, and larvae were reared separately in a flow-through system. The criteria used for assessing reproductive performance were fecundity, fertilizability, hatchability, and pre-settlement survival. The results show that fertilizability was positively correlated to hatchability and larval survival ($P < 0.01$). Furthermore, shell physical characteristics and weight can be used as predictors of reproductive performance. Accordingly, a number of polynomial regressions incorporating SL, SW, SH, W, and egg characteristics to fertilizability, and SL and W to fecundity, were developed.

KEY WORDS: blacklip abalone, *Haliotis rubra*, broodstock assessment, shell characteristics, reproductive performance

INTRODUCTION

Abalone (*Haliotis* spp.) is commercially exploited for its valuable meat and shell. Long-term exploitation of this group has resulted in the depletion of wild stocks in many areas of the world. To fulfill the high demand and because abalone take a long time to reach marketable size in the wild, culture of abalone has become a viable alternative to fishing wild stocks.

Australia is one of the main exporters of wild-caught abalone, contributing about 60% to world production. It is now in a prime position to become a world leader in the production and export of cultured abalone (Flemming & Hone 1999).

In abalone culture, wild-caught broodstock are used extensively. Before this study, the suitability and selection of broodstock from such wildstock has been based on the external appearances of mature animals. The main criteria used in such selection are size, color, and shape of the gonad. However, animals selected based on these criteria are known to vary widely in reproductive performance.

The present study attempts to develop suitable indices for broodstock assessment based on the physical characteristics of female blacklip abalone. It is expected that this will provide a method for performance estimation and will contribute to knowledge on broodstock selection in abalone aquaculture. Accordingly, this paper is based on the results of the spawning of 8 and 11 female blacklip abalone, *Haliotis rubra* L. in the spawning season of 1997 to 1998 and 1998 to 1999, respectively. Furthermore, in the 1999 to 2000 spawning season, the results of five females spawned were used for validation of the models developed based on observations in the previous spawning seasons.

MATERIALS AND METHODS

Spawning

Broodstock were obtained from coastal waters (142°15′E; 38°21′S) during the spawning seasons of 1997 to 1999 and 1998 to 1999. Spawning was conducted during the routine spawning operations of Southern Ocean Mariculture, Port Fairy, Victoria, Australia. To reduce stress, except for total weight, all physical characteristics of females used in the present studies were recorded after spawning. Spawning was triggered by using a combination of desiccation and the UV irradiated methods (Kikuchi & Uki 1974). Spawning was conducted using a flow-through system (velocity of 100 mL min^{-1}). In this study, to eliminate the influence of males, sperm from a number of males were pooled together, and females were spawned individually.

Spawned eggs and sperm were immediately separated from the spawners with a siphon, washed with 1μ of UV-treated seawater of 35‰ salinity, and the spawned eggs were concentrated into a known volume of clean seawater. The water containing the eggs was gently stirred to ensure a homogenous distribution of eggs through water column, and three subsamples were taken for estimating fecundity. Artificial fertilization was effected by mixing known numbers of newly released eggs with appropriate numbers of fresh sperm at an approximate ratio of 5 sperm/egg. Incubated eggs and larvae from each female were kept separately. The hatching stage was run using a static system, and hatched larvae were transferred into rearing containers soon after hatching. Larval rearing was done using a flow-through system (velocity of 80 mL min^{-1}), for 5 days with the extent of presettled larvae being determined by formation of the third tubule on the cephalic tentacle (Hahn 1989). Hatchery procedures followed that described elsewhere (Hone et al. 1997).

Parameters

Such parameters as physical characteristics of adults, number of eggs (fecundity), diameter of eggs, fertilizability, hatchability, and presettlement survival were recorded for 19 female blacklip abalone. Physical features including shell length (SL), shell width (SW), shell height (SH), and total weight (W) of each female spawner were recorded. Shell measurements were made with a Vernier caliper (to the nearest 0.05 mm). Conventional measurements of the shell used in this study are shown in Figure 1. Weight was recorded using a scale (to the nearest 0.01 g), and egg diameter was measured using an eyepiece graticule with a compound

*Corresponding author. E-mail: magdalen@deakin.edu.au

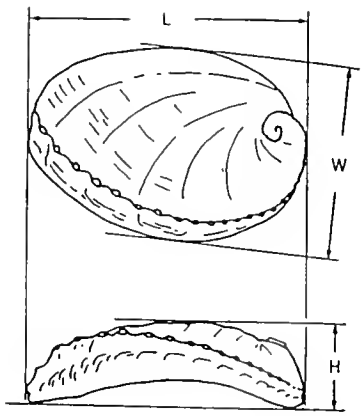

Figure 1. Conventional shell measurement of length (L), width (W), and height (H). (Mgaya & Mercer 1994).

microscope (to the nearest 0.5 μ). At least 150 eggs from each spawned female were measured, and means for individual females were used in regression analysis. Fertilizability was estimated by determining the number of fertilized eggs in a subsample of 1 mL taken after mixing eggs and sperm. For each spawner, five such subsamples were used, and the mean was determined. Similarly, hatchability and larval survival were estimated.

Fecundity is the total number of eggs produced by an individual female.

$$\text{Fertilizability (\%)} = \frac{\text{Total number of fertilized eggs}}{\text{Total number of eggs produced}} \times 100$$

$$\text{Hatchability (\%)} = \frac{\text{Total number of hatched larvae}}{\text{Total number of fertilized eggs}} \times 100$$

$$\text{Larval survival (\%)} = \frac{\text{Total number of survived larvae}}{\text{Total number of hatched larvae}} \times 100$$

Statistical Analysis

Scatter plots were used to observe the distribution of the data. Statistical relationships between physical characteristics and each of the reproductive performance indicators were explored using the software package Minitab version 12.1. The relationships then tested for, between parameters, were linear, curvilinear and the second- and third-order polynomial.

TABLE 1.

Physical characteristics of female abalone spawned (19) and the mean (±SE) of fecundity, fertilizability, hatchability, and larval survival from the spawning seasons 1997/98 and 1998/99.

Parameters	Mean (SE)	Range
Shell length (mm)	128.97 (1.70)	120.05–141.50
Shell width (mm)	103.64 (1.80)	90.95–121.00
Shell height (mm)	40.35 (1.52)	29.65–52.35
Total weight (g)	383.81 (19.51)	274.37–598.52
Fecundity (10^6)	3.51 (0.43)	0.54–5.92
Fertilizability (%)	91.36 (1.73)	70.47–97.30
Hatchability (%)	87.54 (1.21)	75.73–96.87
Larval survival (%)	79.41 (1.69)	66.00–88.41

RESULTS

Female Physical Features and Reproductive Performance

The legal size limit for wild-caught Victorian blacklip abalone is 120 mm. The mean (± SE), the range of the different physical features, and reproductive performance criteria of the 19 female abalone used in the study are given in Table 1.

Relationships of Shell Characteristics to Reproductive Criteria

The potential statistical relationship of the shell characteristics to the female reproductive criteria; namely, fecundity, fertilizability, hatchability, and larval survival, were explored. The resulting relationship, in the form of a correlation matrix, is given in Table 2. It was evident that only shell width and total weight were positively correlated to hatchability. None of the other shell characteristics, when individually considered, were correlated to any of the reproductive criteria in the study. Similarly, multiple regression analysis incorporating shell characteristics did not result in a statistically significant relationship to performance predictors.

It is also clear from Table 2 that fertilizability was positively correlated to hatchability ($r = 0.64$, $P < 0.01$) and to larval survival ($r = 0.65$, $P < 0.01$). Also, hatchability was positively and linearly correlated to larval survival ($r = 0.55$, $P < 0.05$) (Table 2).

TABLE 2.

Correlation matrix of relationships of female blacklip abalone physical characteristics to the different indices of reproductive performances ($N = 19$).

	SL	SW	SH	W	Fc	Ft	Ht	Sv
SL	1.00	0.82**	0.50*	0.81**	0.06 NS	0.08 NS	0.44 NS	0.17 NS
SW		1.00	0.54*	0.91**	0.06 NS	0.25 NS	0.52*	0.39 NS
SH			1.00	0.47*	0.26 NS	−0.28 NS	0.02 NS	0.09 NS
W				1.00	0.04 NS	0.14 NS	0.46*	0.26 NS
Fc					1.00	−0.15 NS	−0.28 NS	−0.03 NS
Ft						1.00	0.64**	0.65**
Ht							1.00	0.55*
Sv								1.00

TABLE 3.

Correlation matrix, partial coefficients of the combinations of physical characteristics to the indices of reproductive performance of female blacklip abalone (n = 19).

	Fecundity	Fertilizability	Hatchability	Larval Survival
SL/SW	0.82***	0.83***	0.77***	0.83***
SL/SH	0.50*	0.55*	0.55*	0.50*
SL/W	0.81***	0.81***	0.76***	0.81***
SW/SH	0.54*	0.65**	0.62**	0.55*
SW/W	0.91***	0.91***	0.88***	0.90***
SH/W	0.47*	0.53*	0.51*	0.46*

Significance level is indicated as $P < 0.001$ (***) $P < 0.01$ (**), $P < 0.05$ (*). For legends, see Table 2.

Hatchability (Ht) can be predicted by using performance indicator fertilizability (Ft), and its relationship is best described by the equation, Ht = 35.1 + 0.575 Ft (R^2 = 0.89, $P < 0.001$). The relationship between fertilizability (Ft) and larval survival (Sv) is described by the equation Sv = 7.4 + 0.802 Ft (R^2 = 0.73, $P < 0.001$). Furthermore, hatchability (Ht) can also be applied to estimate survival (Sv), and their relationship is described by the equation, Sv = −0.272 + 1.22 Ht (R^2 = 0.79, $P < 0.001$).

The regression relationships between different combinations of shell characteristics and reproductive performance indicators are given in Table 3. Partial correlation coefficients indicated that combination of SL/SW and SW/W are strongly correlated to fecundity, fertilizability, hatchability, and larval survival (in all cases $r > 0.77$, $P < 0.001$). A combination of SW/SH was also found to be significantly correlated to fertilizability ($r = 0.65$, $P < 0.01$) and to hatching rate ($r = 0.62$, $P < 0.01$), but was less significantly correlated to fecundity ($r = 0.54$, $P < 0.05$) and to larval survival ($r = 0.55$, $P < 0.05$).

However, none of the above relationships were linear. Shell characteristic; length, height, and width bear a quadratic relationship to fertilizability (Table 4). On the other hand, relationships between weight to fertilizability are best described by a cubic function. The quantitative relationships between female physical characteristics (SL, SH, SW, W) and fertilizability, and the relationship between SL and W and fecundity are shown in Table 4.

The quantitative relationships between shell length and total weight to fecundity are illustrated in Figure 2. The fecundity (Fc) of blacklip abalone was also related quadratically to length (SL) and total weight (W). Their relationships are best described by the following equations.

$$Fc = -622.238 + 9.492\ SL - 0.0359\ SL^2 (R^2 = 0.59, P < 0.01)$$

$$Fc = -26.628 + 0.147\ W - 1.67E\text{-}04\ W^2 (R^2 = 0.66, P < 0.01)$$

Egg Quality and Reproductive Performances

Egg quality in terms of yolk diameter and the ratio between yolk and total diameter could also be used as a predictor of fertilization (Figs. 3, 4). The relationship between yolk diameter (YD) and fertilizablity (Ft) is best described by the equation Ft = −9028.77 + 97.557 YD− 0.261YD^2 (R^2 = 0.92, $P < 0.001$). In addition, fertilizability (Ft) was correlated to the ratio of yolk diameter and total egg diameter (TED), the relationship being Ft = − 2862.67 + 6786.67 TED–3891.62 TED^2 (R^2 = 0.77, $P < 0.001$).

Validation of Indices

Validation of the present indices was done using the data from the 1999 to 2000 spawning seasons. The results of these particular spawnings, predicted and observed parameters are given in Table 5. The mean predicted fertilizability for the five females differed from the observed value by 5.7%. In all instances except in one female (−1.8%) the predicted fertilizability was higher (6.7 ± 2.2%). The predicted fecundity, however, was more variable, particularly with respect to the estimation based on one female (Table 5).

DISCUSSION

In abalone culture, selection of broodstock is mainly based on gonad appearance. The mantle and foot are manipulated to expose the gonad, which is markedly swollen, blunt and rounded at the tip indicating gravidity (Grant 1989). Abalone are judged to be ready for induced spawning by the amount of swelling of the gonad. Without a careful handling procedure, broodstock selection based on this technique is bound to stress the animals. Therefore, a quick method of assessment with minimal disturbance is desirable. Present results demonstrate that female physical characteristics can be used for predicting the spawning performance.

Regression analysis is one of the most widely used statistical

TABLE 4.

Results of regression analysis of shell and egg characteristics and total weight to fertilizability and fecundity (1st order equation, $Y = a + bX$; 2nd order equation, $Y = a + b_1X + b_2X^2$ and 3rd order equation, $Y = a + b_1X + b_2X^2 = b_3X^3$).

Independent Variable (X)	Dependent Variable (Y)	a	b_1	b_2	b_3	n	R^2	P

YD = yolk diameter (μm); TED = total egg diameter; Other legend, see Table 2.

tools, because it provides a simple method for establishing a functional relationship between variables (Chatterjee & Price 1977). Linear relationship has been commonly used in performance studies on other species (Shepherd et al. 1992, Estay et al. 1999). In the present study, a polynomial regression model successfully estimated the reproductive performance of female blacklip abalone. As indicated here, most of the relationships are best fitted with nonlinear models.

Correlation analyses showed that some combinations of shell features correlated well with performance (Table 3). As indicated by correlation coefficients, we would expect bigger animals and ones with a flattened shell to be a good indication for performance estimation. The same trend was also observed in bigger and heavier animals. This conforms with other observations that larvae from blacklip abalone broodstock having bigger and wider sizes usually show a faster growth rate (SOM, pers. comm.).

Fecundity is one important performance criterion. The relationship of fecundity to size (length or weight) has important consequences for both fisheries management and aquaculture. Determinations of the size limit, which allows the harvest of immature animals, in abalone fisheries, will affect egg production. In aquaculture, however, fecundity plays a role in routine hatchery operations. Estimations of egg production could allow hatchery operations to be optimized.

In blacklip abalone populations, fecundity can be approximated by nonlinear relationships with length and has been described by a power function ($Y = aX^b$) by others (McShane 1990, Nash et al. 1994). Exponential increase of fecundity with increasing length has also been reported for other abalone species, *Haliotis roei* (Wells & Kessing 1989), *H. midae* (Newan 1967), *H. tuberculata* (Hayashi 1980), and *H. laevigata* (Wells & Mulvay 1995). In addition, McShane (1990) and Nash et al. (1994) suggested that fecundity is size dependent rather than age dependent. In a separate study, on the other hand, Prince et al.(1988) argued that fecundity of *H. rubra* was closely related to age rather than length. The present study indicates that fecundity varied widely, even among a small range of sizes (Table 1), and its relationship to length and weight was best described by a second-order polynomial function. As shown by the quadratic model (Fig. 2), fecundity increases with increasing size, but, decreased as animals grew beyond a certain size. This change may be brought about by a limited release of eggs by older and bigger animals, or simply because the number of eggs produced decreases as the animals grow beyond a certain size. It would be interesting to investigate whether or not there is a tendency for bigger animals to spawn early (or late) in the season and *vice versa*; a trend that may be of use in improving hatchery production.

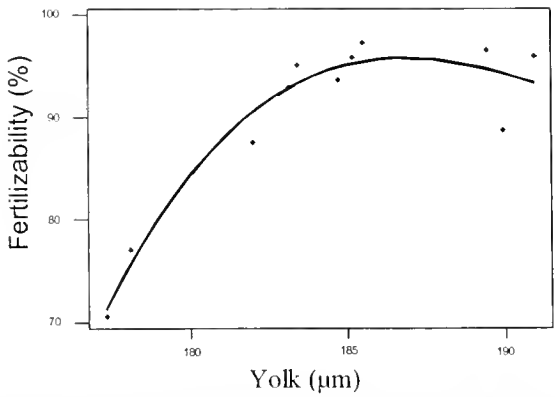

Figure 3. Quadratic model of mean yolk diameter (X) versus fertilizability (Y) (R^2 = 0.92, P < 0.001).

The egg yolk diameter and the ratio between yolk and total diameter seemed to be another method of predicting egg fertilizability (Figs. 3, 4). For such nonfeeding larvae, as those of abalone, future spawn success is determined by egg quality (size and biochemical content). It has been widely known that egg biochemical content is size-dependent. Consequently, it is obvious that egg diameter is an important key in determining performance (Brooks et al. 1997). Investigations on other invertebrates have shown that small differences in egg size and content might have important biological consequences (George 1999). This author found that larval seastars from small eggs tend to grow and develop more

NA = not available.

slowly than those from large eggs. According to the present findings, bigger egg size did not necessarily result in a better performance, however. A similar pattern was also noticed when the ratio of yolk diameter and total diameter was used as a fertilizability predictor. Yolk size of 182 to 188 μ and a ratio of yolk and total egg diameter between 0.83–0.87, respectively, seem to indicate the range where blacklip abalone performs best (Figs. 3, 4). It seems that a higher fertilization success is restricted to a certain range of egg sizes. A change in fertilizability beyond these limits may be attributable to age, overripe eggs or egg biochemical status.

In summary, female physical characteristics can be used to predict reproductive performance. The present results provide several easily useable indices for assessing the spawning performance of blacklip abalone. It would be useful in future to apply the present indices to a larger number of broodstock and also compare them to broodstock indices from other abalone species. From a nutrition point of view, it would be valuable to examine the relationship between egg size and biochemical content and its implications for the early life cycle of abalone.

ACKNOWLEDGMENTS

One of us, Magdalena Litaay, was funded by an AusAid postgraduate award, which is gratefully acknowledged. Broodstock used in this study were provided by Southern Ocean Mariculture Ltd., Port Fairy, Victoria, Australia. All the hatchery work was carried out at the facility at Port Fairy, and we are grateful to all staff for their cooperation.

EFFECTS OF COMBINED EXPOSURE TO ELEVATED AMMONIA AND LOW DISSOLVED OXYGEN LEVELS IN GREENLIP (*HALIOTIS LAEVIGATA* DONOVAN) AND BLACKLIP (*H. RUBRA* LEACH) ABALONE. I. GROWTH AND MORTALITY DATA FROM SIMULATED SYSTEMS FAILURE

ABSTRACT A growth trial was conducted on two Australian species of commercially cultured abalone to determine the effect of episodic exposure to suboptimal water quality on growth and mortality. This was primarily designed to simulate systems failure, resulting in partial or complete interruption in the normal water exchange and corresponding changes in dissolved oxygen and ammonia levels. Experimental abalone were nominally exposed, at intervals ranging from once in 6 wk to once a week, to 60% dissolved oxygen saturation and 150 μg L^{-1} un-ionized ammonia for 8 h. No significant effect on growth or mortality was found for either species, with observation of abalone behavior and food consumption indicating the exposures imposed a mild and transient stress. A more severe challenge exposure (nominally 30% dissolved oxygen and 600 μg L^{-1} un-ionzed ammonia for 8 h) at the end of the growth trial had a greater impact on food consumption and activity, but this disappeared within 24 h and did not cause any mortality after 2 days.

KEY WORDS: blacklip abalone, greenlip abalone, *Haliotis laevigata*, *Haliotis rubra*, dissolved oxygen, ammonia, pulse exposure, systems failure

INTRODUCTION

Although it is the desire of any aquaculturist to maintain a constant supply of air and water for the species under culture, forces outside human control will inevitably interrupt the supply of water during some part of the production cycle. Once the regular supply of air and water has been reduced or interrupted, a rapid decline in water quality can be expected as oxygen consumption continues and metabolites accumulate. In marine aquatic systems, this rapidly becomes problematic, because potentially toxic ammonia is the most common nitrogenous metabolite excreted by both vertebrate and invertebrate species (Colt & Armstrong 1981, Russo & Thurston 1991, Wajsbrot et al. 1991). In aqueous solution, ammonia exists as a combination of ionized and un-ionized forms, with the equilibrium between the two being governed by pH, temperature, and the ionic strength of the solution (Colt & Armstrong 1981, Meade 1985, Russo & Thurston 1991). Although un-ionized ammonia (UIA) has previously been accepted as the predominantly toxic form, there is some evidence that ionized ammonia may also exert a toxic effect (Thurston & Russo 1981, Meade 1985, Russo & Thurston 1991).

Gastropod mollusks, such as abalone, are biochemically suited to surviving periods of hypoxia or even anoxia, by using alternative biochemical pathways that are not dependent on oxygen for the generation of ATP (Brix et al 1979, Gäde & Ellington 1983, Storey & Storey 1990). This is presumably an adaptation to episodes of environmental hypoxia. It is not clear whether mollusks are similarly suited to episodes of elevated ammonia or low oxygen tensions in combination with elevated ammonia levels. Results from individual bioassays have shown that abalone are sensitive to chronic exposure to elevated ammonia or to low dissolved oxygen levels, with 5 and 50% reductions in growth rates reported at 41 and 158 μg L^{-1} UIA or 7.36 and 5.91 mg L^{-1} dissolved oxygen (DO) respectively (Harris et al. 1998, 1999a).

It is important for aquaculturists to have some knowledge of the sensitivity of the cultured species to changes in water quality that are likely to occur when the supply of water is interrupted for an extended period. Although there is an increasing body of general literature on abalone, there is a paucity of information on acute or chronic exposure to combinations of altered water quality variables. As well as the possibility of direct mortality, potential stress-related complications include secondary infections and growth reductions. Repeated episodes are likely either to augment such effects, or enable acclimation such that the abalone are better able to deal with more severe subsequent exposures.

The present trial investigated the effect on growth and mortality of episodic exposure to low dissolved oxygen levels combined with elevated concentrations of UIA in two species of abalone (blacklip, *Haliotis rubra* and greenlip, *H. laevigata*) cultured in Australia. The effect of exposure history on the response to a subsequent more severe challenge was also assessed.

METHODS AND MATERIALS

The trial was conducted at a research facility at Bicheno, Tasmania, Australia (E148°18′, S41°53′). The experimental tanks were circular fiberglass units (diameter = 70 cm, volume = 55 L). The 30 tanks used in the trial were enclosed within an area covered with shade cloth to prevent the development of algal biofilms. Each tank was individually supplied, on a flow-through basis, with sand-filtered oceanic seawater, drawn from subsurface intakes on an exposed coastline. The salinity was 34–35 g L^{-1} throughout the trial, and was not affected at any stage by freshwater runoff. Aeration was supplied through two 50-mm airstones per tank.

Experimental Abalone

The experimental abalone were obtained from commercial stock at two abalone farms in Tasmania, Australia. Blacklip abalone, 18–24 mo old (mean length = 42.9 ± 3.6 mm, mean weight = 13.00 ± 4.45 g, ± SD, N = 600), were obtained from Swansea,

*Corresponding author. P.O. Box 382 Beauty Point, Tasmania 7270, Australia. E-mail: shindrum@abiotech.bigpond.au.

Tasmania. Greenlip abalone, 24–30 mo old (mean length = 45.8 ± 3.9 mm, mean weight = 12.21 ± 3.01 g, ± SD, N = 600), were obtained from Bicheno, Tasmania. Both species had been held in 270-L holding tanks for 3–8 wk before being randomly allocated to individual tanks after being weighed (to 0.01 g) and measured for length (to 0.1 mm, using Vernier calipers). Polyethylene tags (Hallprint, Adelaide, Australia) had previously been applied, with any missing tags replaced using a cyanoacrylate adhesive gel. Abalone were stocked at 40 animals per tank with triplicate tanks for each species per treatment. The treatments were stocked at intervals of 6–7 days, with the abalone being carefully removed by spatula, without anesthesia, from the holding tanks.

The diet used before and during the trial was based on a commercial formulation (ABCHOW), with the addition of 10% algal meal. The tanks were routinely cleaned every 4–5 days by siphoning the bulk of the organic wastes, spinning the water gently, and then siphoning off the remaining wastes that collected in the center of the tank. The abalone were not exposed to air during cleaning. Fresh food was supplied every 2 days, with the weighed ration for each tank adjusted on an *ad libitum* basis.

Growth Trial

The growth trial ran for 47 days, with ambient water quality shown in Table 1. At the intervals indicated in Figure 1, the tanks were nominally exposed to 60% of the ambient dissolved oxygen concentration and 150 μg L^{-1} UIA. The actual conditions during these exposures are given in Table 1. The first exposure for Treatment 5 was 4 h; all subsequent exposures were 8 h (starting between 8:30 and 11 AM).

Based on lengths and weights for individual animals, the growth indices given in Figure 2 were calculated as follows:

Specific Growth Rate for Length (SGR-L) = {[ln(L2) − ln(L1)]*100}/T

Specific Growth Rate for Weight (SGR-W) = {[ln(W2) − ln(W1)] × 100}/T

Microns per Day = {(L2 − L1)/1000} × T

where L1 is length at T1 (mm), L2 is length at T2, W1 is weight at T1 (g), W2 is weight at T2, and T is time in days.

Pulse Exposures

On the day of exposure, water quality (pH, temperature, DO) were recorded, a sample was collected for subsequent ammonia analysis, and then the bulk of organic wastes (80–90%) was siphoned from the tanks. When the normal water level had been restored, conditions were altered by diverting influent water, infusing industrial grade N_2 into the tanks and adding 2.5 L of ammonia stock solution (0.33 g L^{-1} of technical grade ammonia chloride in sand-filtered seawater). Preliminary trials showed that this would achieve the desired UIA concentration. All tanks were adjusted to the same volume at the start of the trial.

Submersible aquarium pumps were placed in each tank immediately before altering the water quality to ensure that the conditions were uniform throughout the water column during the pulse exposure. Initially, large volumes of N_2 were infused to reduce the oxygen level rapidly, with 60% saturation being achieved within 3 min. This concentration was subsequently maintained using small amounts of N_2 and air, infused through separate 50-mm airstones.

The return to ambient conditions was achieved by restoring influent water flow and removing the N_2. The pumps were left running in the tank for 1 h postexposure to expedite the return to ambient conditions. Time-course sampling at the start of the trial showed that DO returned to ambient levels within 1 h, and ammonia within 6 h (data not shown). The pumps were placed in control tanks, and tanks not being exposed on a given week, as for the pulsed tanks, to reduce the possibility of any confounding influence on growth.

TABLE 1.

Water quality during ambient, pulse, and challenge periods (mean ± SE). All values are based on means from replicate tanks (N = 15 for ambient, N = 12 for pulse and challenge).

Water quality variable	Sample				
		Pulse		Challenge	
	Ambient	T = 15 min	T = 8 h	T = 15 min	T = 8 h

Greenlips	0.92 ± 0.23	157.31 ± 8.68	73.68 ± 6.73	625.77 ± 144.10	384.47 ± 115.23
Blacklips	1.91 ± 0.27	163.57 ± 8.98	91.73 ± 8.05	547.87 ± 95.86	372.43 ± 107.98

Because of lack of difference from ambient conditions, data at T = 0 h and T = 24 h from the pulse exposures are included in the ambient data. Ambient DO, pH, and temperature data are based on readings taken every 2–3 days; ambient ammonia data are based on weekly samples from treatments not being exposed to pulse or challenge conditions. DO values from pulse and challenge periods are based on readings taken ≈30–40 min apart during the exposure period. pH, temperature, and ammonia data were based on single readings taken as indicated, from replicate tanks on each treatment.

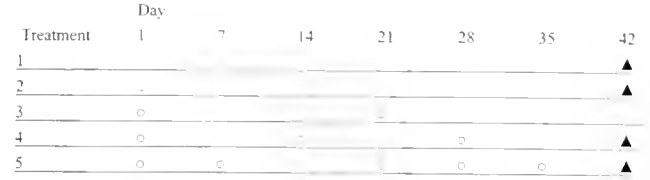

Figure 1. Pulse exposure regime for growth trial. ○ = pulse exposure. ▲ = challenge exposure. Animals were weighed and measured 2–3 days before the first exposure on day 1, and again on day 47. All animals were individually tagged. Treatment 1 is the control.

Water Quality

DO, pH, ammonia, and temperature for both pulse and challenge exposures were recorded before any alteration to conditions in the tank (T = 0 h). pH and ammonia were then measured after 15–20 min (T = 15 min), at 8 h (before restoring ambient conditions) and the morning following exposure (T = 24 h). Once DO had stabilized, it was checked on average every 30–40 min and flow of N_2 adjusted as required. DO, temperature, and pH were recorded for all tanks every 2–3 days throughout the trial. Samples for ammonia analysis were taken from two tanks on each treatment not being pulsed each week to provide ambient ammonia levels. DO was measured using hand- held meters (WTW Oxi96, TPS WP82-Y or Oxiguard Handy Gamma), which were calibrated daily and checked against saturated seawater and occasional Winkler titrations. The three meters gave similar readings when checked against each other. pH was recorded on a hand-held TPS meter and probe (WP 81), calibrated daily in fresh buffers (phosphate at pH 7.00, borate at pH 9.28, after Bruno & Svoronos (1989). Temperature was recorded using the thermistor on the DO meter, which was checked against a calibrated mercury thermometer.

All samples for ammonia analysis were collected in acid-washed glassware rinsed with deionised water. Samples were filtered through Whatman GF/C filters and frozen in polypropylene bottles (acid washed, rinsed in deionised water) for subsequent analysis. Total ammonia was measured within 4–5 wk of the samples being collected, by the method of Grasshoff (1989) but using the salicylate reagent of Bower and Holm-Hansen (1980). UIA was calculated from pH and temperature using the equation in Bower and Bidwell (1978). Where necessary, samples were diluted with the sand-filtered seawater such that TA was <0.5 mg L^{-1}. Nitrite was analyzed by the diazotization method of Grasshoff (1989). Influent flow rates were recorded every 5–10 days (mean ≈ 1500 mLmin^{-1}).

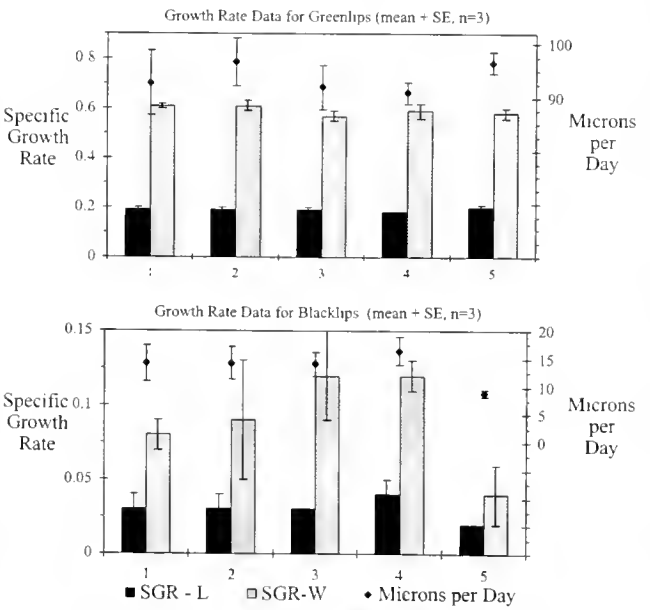

Figure 2. Growth rate data from pulse exposures of two species of abalone (mean ± SE, *n* = 3). Treatments are given in Figure 1. SGR-L = specific growth rate for length, *n* SGR-W = specific growth rate for weight.

Challenge Exposure

On day 45 of the growth trial, two tanks for each species on treatments 1, 2, 4, and 5 were exposed for 8 h to more severe challenge conditions (Table 1), as described above, but using a stock solution of 1.33 g L^{-1} of ammonia chloride.

Statistical Analysis

The raw data were tested for homogeneity of variance by examination of residual plots generated by JMP 3.2 (SAS Institute). Normality was assessed by observation of the distribution plotted by JMP 3.2. No transformations were required to meet the assumptions of analysis of variance (ANOVA), as given in Underwood (1981). One-way ANOVA, using the replicate means for each treatment, was used to look for significant treatment effects, and Tukey's HSD was used to compare means.

RESULTS

Behavioral Observations

Under ambient conditions, species-specific behavioral differences were observed. Blacklips clustered in one or two spots in the tank, but greenlip abalone tended to gather in smaller groups dispersed more evenly over the available surfaces. Although generally inactive, small numbers of blacklip abalone (1–3) were observed to be active at any one time during the day; whereas, greenlips were rarely observed to be active during the day. For both species, inactive animals had all tentacles withdrawn and shells clamped tightly onto the substrate. During the pulse exposures, no change in behavior was observed until the end of the exposure period, when signs of stress were evident (shells starting to lift off the substrate, tentacles becoming actively extended).

These behavioral effects were more pronounced during the final challenge exposure. In both species, the animals tended to separate from the clusters within 40–60 min of commencing the exposure, but once separated, did not continue moving. Rather, in both species, the front of the shell was lifted off the substrate, and epipodial tentacles were extended. However, abalone in this position were not readily removed from the substrate, and if disturbed, clamped the shell back onto the substrate and withdrew the tentacles.

Although food consumption was not directly determined by collecting uneaten food, ration was adjusted *ad libitum* for each tank, and no difference in weight of food fed between treatments was observed. However, in both species, consumption tended to decline slightly the night immediately after exposure to the pulse condition, and the abalone were also observed to be less active than normal. Consumption and foraging activity returned to normal the following night (24-h postexposure). Following the challenge exposure, this reduction in consumption and activity was

even more marked, but again returned to normal the following night.

Mortality

Over-all mortality was 0.8% for greenlips and 2% for blacklips during the growth trial. No mortality was observed as a direct result of the pulse or challenge exposures. There was no clinical evidence (such as lack of vigor, lesions, or mortality) of any secondary infection becoming established as a result of the pulse exposure regime. Two tanks of blacklips did show signs of bacterial infection at different points during the growth trial, with some mortality, although no causative agent could be identified. The other replicate tank on this treatment showed no similar signs, and these were considered unrelated events. These mortalities were excluded from the mortality calculations. Apart from these events, both species seemed generally healthy throughout the growth trial.

Water Quality

Table 1 shows the ambient water quality for days when DO and ammonia were not manipulated and the alterations achieved during pulses of ammonia and low DO. Table 1 also shows the water quality achieved during the final challenge exposure. Nitrite was always undetectable. The initial and final data collected for each pulse (at T = 0 h and T = 24 h) were always consistent with ambient conditions and, thus, were included in the ambient water quality.

Total ammonia was elevated throughout both the pulse and challenge exposure periods (Table 1). pH and UIA declined over the 8-h period, and DO was kept relatively constant by adjusting the gas flow. Temperature increased, to an extent dependent on ambient air temperature, by 1–5°C during the exposure periods. During the highest temperature increases, mucus production was evident, and the water became noticeably cloudy.

Growth Data

The growth data are shown in Figure 2. For greenlip abalone, growth rates (≈100 μm d^{-1}) were close to commercial growth rates. The blacklip abalone growth rates (≈15 μm d^{-1}) were approximately 10% of commercial growth rates. In terms of both length and weight, no significant difference was observed in growth of either species for any of the treatments ($P < 0.05$). For blacklip abalone, treatment 5 reduced growth, especially in terms of weight, although the difference was not significant.

DISCUSSION

The primary aim of this trial was to simulate a major systems failure, with an extended period of no influent water and little, if any, supplementary aeration, and the desired alterations in water quality were achieved within 5 min. This rapid change was designed to exacerbate the severity of the exposures further, because any similar changes during a real life event would take much longer to achieve. Although dissolved oxygen and ammonia were the primary water quality variables being manipulated, the lack of influent water flow also resulted in temperature increasing and pH declining over 8 h, which added to the reality of the simulation. Temperature changes reflected the ambient air temperature, which was beyond experimental control; whereas, the decline in pH was presumably attributable to respiration and metabolic excretions. Table 1 shows that substantially elevated TA levels were achieved over the baseline condition. Although TA levels did not change greatly during the exposure period, the decline in pH reduced the concentration of UIA.

It was considered possible that the water currents generated by the submersible pumps may have modified the response of the abalone to the stress induced by the pulses of poor quality water, perhaps by improving water movement past the gills. This is certainly consistent with known water-flow dynamics around and through abalone shells (Voltzow 1983), although animal behavior, in terms of both gross body positioning (Voltzow 1983) and underlying physiological modifications (see later), are also likely to be modifying factors. We are uncertain if this has been a significant factor in this trial, but note that at the end of the growth trial for Treatment 3, a pulse exposure was conducted without the submersible pumps, and no behavioral differences were observed from previous exposures (data not shown).

Based on observations of mortality and animal behavior, the pulse exposures and exposure regime used in this trial did not result in more than a transient stress. Coupled with the lack of significant effects on growth, this indicates that the two species used in this trial are well able to withstand periodic and relatively severe declines in water quality. Although a brief reduction in foraging activity was observed immediately following the pulse exposure, activity returned to normal the following night. The abalone seemed healthy throughout the growth trial, with the exception of an isolated event, and mortality was similar to previous trials in this system (e.g., Maguire et al. 1996). Conditions in the final challenge exposure seemed to be more stressful than the pulse exposures, based on observations of animal behavior, but were still not sufficient to produce mortality after 3 days. Consumption and activity patterns returned to normal within 24 h, as for the pulse exposures. The transient nature of the stress observed from the pulse and challenge exposures may have been at least partly attributable to optimal quality of the ambient conditions (Table 1).

Harris et al. (1998, 1999a) reported that greenlip abalone were more sensitive than other invertebrate species and fish when chronically exposed either to elevated UIA or nitrite or decreased DO. For DO and UIA, growth declined through the experimental range in these chronic studies (25–188 μg L^{-1} UIA and 8.9–4.2 mg L^{-1} DO (117–55% saturation)). However, these levels of UIA and DO were achieved in the pulse exposure from the current trial without producing a significant growth depression. Hindrum (unpublished data) also found that growth of blacklip and greenlip abalone was significantly reduced as compared to controls when chronically exposed to similar combinations of DO and UIA as achieved in the pulse exposures.

The chronic exposures outlined above were based on continuous exposure to altered water quality for several weeks. The pulse and challenge exposures in the current trial were for 8 h, during the normally inactive daytime period. It is likely that gill activity is reduced during this quiescent period. Certainly, for mollusks in general, this is the case, with activity levels, heart rate, gill perfusion rates, gill ventilation rates and resultant oxygen uptake intimately related. This has been shown in sedentary species like *Mytilus edulis* (Bayne 1971) and in different gastropod species exhibiting various survival/feeding strategies (Newell & Roy 1973, Morton 1990). Indeed, for abalone, temperature and external oxygen levels have been clearly linked to such factors as heart rate, blood pressure, and resultant oxygen uptake (Nimura & Yamakawa 1989, Russell & Evans 1989). In the quiescent period, tissue exposure to such toxicants as ammonia may be reduced as a

result of lower transfer across the gills and lower tissue perfusion rates. Indeed, low DO and the expected reduction in heart rate as seen for other haliotids (Nakanishi 1978, Russell & Evans 1989) may well have functioned in this way as a protective mechanism in our experiment. It is possible that a similar mechanism may also work in penaeids, as Allan and Maguire (1991) report that tiger prawns (*Penaeus monodon*) tolerated conditions for several hours that in chronic exposures resulted in significant growth reductions.

It is possible that a greater impact on growth may have been observed if the pulse exposures had been conducted during the nocturnal foraging period, or over a longer period (e.g., 12–24 h.). Potentially, the altered water quality would then have a bigger effect on the metabolic processes of the abalone, because they are active. However, the observed behavioral changes indicate that the altered water quality was still detected by the inactive abalone. The fact that exposing the abalone weekly to the pulse condition did not reduce growth or induce any clinical signs of stress, such as disease or morbidity, indicates that there was no additive effect. This is further confirmed by the lack of mortality and apparent recovery after the challenge exposure at the end of the growth trial.

The pH after 8 h of either challenge or pulse exposure was in the range 7.91–7.62. Harris et al. (1999b) found that chronic exposure to pH 7.76 significantly reduced growth in both species of abalone as compared to controls at pH 8.27. Although temperatures in individual tanks reached 22–23 degrees during periods of high ambient air temperature, the temperatures recorded after the 8 h of either pulse or challenge exposures were still within the tolerance limits defined by Gilroy and Edwards (1998) for these species. The mucus production observed in the current exposures on warmer days has been reported in abalone (Gilroy & Edwards 1998) and other bivalve mollusks (Bartsch et al. 2000) as a response to thermal stress.

Studies of haliotids in the wild show that these animals tend to be found in large groups, commonly stacked around boulders and in crevices at various depths (Shepherd 1973, Douros 1987, Shepherd & Partington 1995). *H. rubra*, in particular, occupies cave-like crevices during the quiescent daytime period in sufficient density that competition for space is a factor in their distribution (Shepherd 1973). In warmer weather and periods of low wave or tidal activity, low DO levels and elevated ammonia concentrations would be expected in these caves as a result of metabolic activity. This would be exacerbated when decaying organic matter accumulates (Wells et al. 1998). Not surprisingly, gastropod mollusks are physiologically and biochemically well suited to cope with episodes of hypoxia (Brix et al. 1979, Gäde & Ellington 1983, Storey & Storey 1990). The tolerance shown in this trial is, therefore, not unexpected.

CONCLUSION

Greenlip and blacklip abalone are resilient to periodic short-term exposure to low dissolved oxygen levels in conjunction with elevated ammonia levels. Transient effects on behavior and foraging activity were observed. Based on lack of mortality and on behavioral observations, exposure history had little effect on the response to a more severe challenge exposure. Evidence from the literature suggests that the low DO levels during the pulse and challenge exposures reduced tissue exposure to ammonia by reducing uptake across the gills.

ACKNOWLEDGMENTS

Funding for this trial was provided by the Abalone Aquaculture Sub-Program of the Fisheries Research and Development Corporation and the Cooperative Research Center for Aquaculture. Marine Shellfish Hatcheries hosted the research, and Crown Scientific provided backup oxygen meters.

ONTOGENETIC TRENDS OF MINERALOGY AND ELEMENTS IN THE SHELL OF ABALONE, *HALIOTIS DISCUS HANNAI* INO

GEN HE AND KANGSEN MAI*

Aquaculture Research Laboratory, College of Fisheries, Ocean University of Qingdao, Qingdao, 266003, People's Republic of China

ABSTRACT Japanese abalone, *Haliotis discus hannai*, with shell lengths 8, 14, 25, and 55 mm were used for mineralogy and element composition studies. Besides calcite and aragonite, dolomite ($CaMg(CO_3)_2$) was detected for the first time in abalone shells. No calcite was detected in the 8-mm shells. The percentage of calcite increased steadily from 1.6% to 13.6% in shells from 14 to 55 mm, while that of aragonite decreased from 95.3% to 83.9%. Dolomite varied from 2.5% to 9.0%. The level of Mg, Mn, Fe, Na, and Al in 8 to 55 mm shells increased, whereas those of Zn and Cu declined. Possible reasons for these trends are discussed.

KEY WORDS: ontogenetic trend, mineralogy, elements, abalone, *Haliotis discus hannai*

INTRODUCTION

The mineral composition of molluscan larval shells comprises exclusively of aragonite, regardless of postlarval or adult forms (Watabe 1988). In *Haliotis discus hannai*, the larval shells consist of aragonite spherulites (Iwata 1980), whereas the prismatic layer of adult shell is composed of calcite and aragonite (Dauphin et al. 1989, Shepherd et al. 1995). The changing pattern of shell mineralogy from larvae to adult remains unexplored.

Many factors that can influence the mineralogy and chemistry of molluscan shells have been investigated, including water temperature and salinity (Wilbur 1972, Taylor & Reid 1990, Cohen & Branch 1992, Mann 1992), taxonomic differences (Turekian & Armstrong 1960, Dauphin et al. 1989), ontogeny (Fuller 1985, Carriker et al. 1982, Carriker et al. 1982), and physiological conditions for shell formation (Simkiss 1976, Almeida et al. 1996). However, almost all of these studies investigated bivalves. Gastropods have been largely neglected. To our knowledge, there are no data on the ontogenetic trends of abalone shell mineralogy and chemistry.

In this study, the shells of different sizes of abalone, *Haliotis discus hannai*, were analyzed to study the ontogenetic trend of shell mineralogy and element composition.

MATERIALS AND METHODS

Abalone Shells

Live *H. discus hannai* individuals were purchased from Rongcheng Abalone Farm, China, in October 1998. These were cultured under the same environmental and nutritional conditions in the hatchery. Shells 8 ± 1 mm, 14 ± 1 mm, 25 ± 1 mm, 55 ± 1 mm (mean shell length ± s.d.) were used for this study. Upon sacrificing the abalone, their soft tissue was immediately removed.

X-ray Powder Diffraction

The mineralogical composition of the whole shell was investigated by X-ray powder diffraction. Ten to 20 shells were ground into a powder mixture for every replicate of each shell length. Three replicates of each shell length were used. A Philips counter diffractometer was employed, with a proportional counter and monochromatized copper target set at 40 kV and 80 mA. The ratio of polymorphs was calculated from the relative intensities of the principal reflection characteristic of each mineral through a calibration curve derived from mixtures of natural aragonite, calcite and dolomite (Neri et al. 1979).

Element Analysis

The abalone shells were ground into fine powder and carefully digested in double distilled nitric acid. Minor and trace elements in the digestion were analyzed by inductively coupled plasma atomic emission spectroscopy (ICP-AES) on a JOBIN (Model JY 70PLUS).

Statistical Analysis

All percentage data were square-root arcsine transformed prior to analysis. Tests of normality and homogeneity of variances confirmed that the data sets met the requirements for one-way ANOVA (Zar 1984). When overall differences were significant at the 5% level, Tukey's test was used to compare the mean values between individual treatments. Correlation analysis was employed to evaluate the relationship between abalone size and mineralogical or element composition.

RESULTS

Shell Mineralogy

The percentages of different crystal polymorphs detected for different shell lengths are given in Table 1 and Fig. 1. Dolomite was detected for the first time in abalone shells. Dolomite and aragonite were found in all samples. However, although expected, calcite was not detected in 8-mm shells. The percentage of calcite increased steadily from 1.6% to 13.6% in 14–55 mm shells, whereas that of aragonite decreased from 95.3% to 83.9%. Correlation analysis showed that the percentages of both calcite and aragonite were significantly correlated with abalone sizes (calcite: $r = 0.985$, $P < 0.0001$; aragonite: $r = -0.830$, $P < 0.001$). The proportion of dolomite increased from 4.7 to 9.0% in 8–25 mm shells, but dropped to 2.5% in 55-mm shells.

Element Composition

The element composition of different sized shells is listed in Table 2. Ontogenetic changes of selected elements differed. The levels of Mg, Mn, Fe, Na, Al in shells increased from 8 to 55-mm shells, whereas those of Zn and Cu dropped. The positive correlation between abalone size and the level of Fe ($r = 0.947$, $P < 0.0001$), Mg ($r = 0.769$, $P = 0.003$), Al ($r = 0.787$, $P = 0.002$),

TABLE 1.

The mean percentage of different crystal polymorphs in abalone, *Haliotis discus hannai* Ino. of different shell length (n = 3, mean ± SD).

Shell length (mm)	Calcite (%)	Aragonite (%)	Dolomite (%)
8	n.d. (0.0)^a	95.3 (0.9)^b	4.7 (0.9)^a
14	1.6 (0.1)^a	93.3 (0.4)^c	5.1 (0.5)^a
25	6.6 (0.6)^c	84.5 (0.2)^a	9.0 (0.5)^b
55	13.6 (1.1)^b	83.9 (1.2)^a	2.5 (0.11)^a
ANOVA			
F	212.09	113.91	17.23
P	0.000	0.000	0.009

n.d.: not detectable

Means in the same row sharing the same superscript letter were not significantly different as determined by Tukey's test ($p > 0.05$).

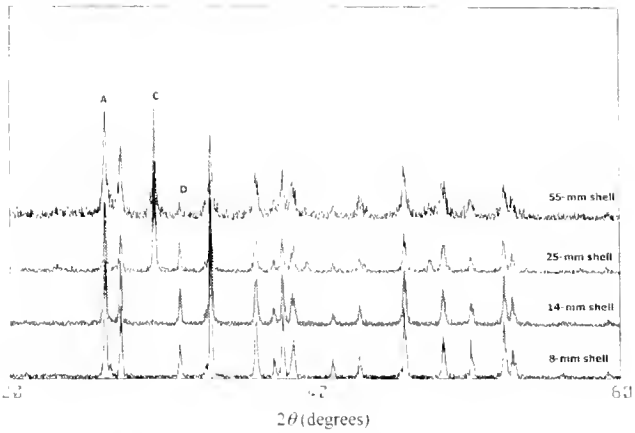

Figure 1. X-ray diffraction profiles of different *Haliotis discus hannai* shell sizes. Main reflections specific to aragonite (peak labeled 'A'), calcite (peak labeled 'C'), and dolomite (peak labeled 'D') are indicated.

or Na (r = 0.612, P = 0.034) was significant, as were the negative correlation between abalone size and Zn (r = −0.721, P = 0.008) and Cu concentrations (r = −0.646, P = 0.023). No significant correlation was established between abalone size and the level of Mn (r = 0.480, P = 0.114).

DISCUSSION

It has been reported that the shell mineralogy of adult and larval shells is quite different (Watabe 1988), although to date this had never been investigated in abalone. This is an important avenue of research, however, as the ontogenetic change of shell structure can determine the hardness of the shell, and thus affect the survival of a mollusk since its shell is usually its main source of defense.

In our experiments, clear ontogenetic trends of mineralogy and element composition were observed. The definite intrinsic mechanisms that determine the mineral composition of shells during ontogenetic development remain unknown, although several factors are known to be involved in the process. In *in vitro* tests, matrix proteins secreted by mantle epithelial cells determine the biomineral polymorphs of shells. Macromolecules extracted from the aragonite layers of some mollusk species induced aragonite formation *in vitro*, and macromolecules from calcite layers induced mainly calcite formation under the same conditions (Belcher et al. 1996, Falini et al. 1996). It has been reported that the composition of matrix proteins of abalone shell varied in different developmental stages (Cariolou & Morse 1988). We obtained similar results in our laboratory (unpublished data). Therefore, we suggest that the matrix proteins can play a vital role in controlling the composition of crystal polymorphs in shells. Further work is needed to characterize proteins in different shell layers during ontogenetic development and relate their composition to the crystal formation. On the other hand, some environmental factors, such as water temperature and salinity can also influence shell mineralogy (Taylor & Reid 1990, Cohen & Branch 1992). However, given the constant environmental conditions (e.g. water temperature, salinity and nutritional conditions) in our hatchery, the influences of these factors on our results can be largely excluded.

Unexpectedly, besides calcite and aragonite, dolomite was detected in the current study. The mechanism of its formation remains unknown. It is reported that the arrangement of atoms in aragonitic and calcitic lattice structures allows for the substitution of some divalents for calcium ions (Rosenberg 1990, Lingard et al. 1992). Under certain circumstances, this substitution can even result in separate crystal polymorphs. Several isomorphs, such as vaterite (Wilbur & Watabe 1963), strontianite ($SrCO_3$) (Odum 1951), dahllite (Watabe 1956) and barite (Fritz et al. 1990) have been reported. Pytkowicz (1965) points out that under conditions in which the Mg concentration is five times that of Ca, which is common in sea water and some bivalve extrapallial fluids (Crenshaw 1972, Wada & Fujinuki 1976), collisions producing Mg-Ca-CO_3 aggregates are more frequent than those resulting in $CaCO_3$.

TABLE 2.

Mean concentration (ppm) of certain elements in abalone, *Haliotis discus hannai* Ino. of different shell length (n = 3, mean ± SD).

	Shell length (mm)				ANOVA	
Element	8	14	25	55	F	P
Zn	27.2 (0.0)^b	53.1 (6.0)^c	6.9 (0.2)^a	0.2 (0.2)^a	123.89	0.000
Mn	4.7 (0.0)^a	1.7 (0.1)^a	16.4 (1.4)^b	10.5 (3.0)^b	44.12	0.002
Fe	28.9 (2.0)^a	29.6 (3.5)^a	133.8 (28.4)^b	211.9 (1.3)^c	76.08	0.006
Mg	140.1 (0.7)^a	119.2 (6.8)^a	386.8 (22.4)^b	373.7 (0.5)^b	305.28	0.000
Cu	6.2 (0.2)	9.1 (4.0)	2.7 (0.3)	2.5 (0.2)	3.63	0.122
Al	1498.8 (10.6)	1373.3 (30.3)	1344.4 (44.5)	1785.2 (36.1)	4.93	0.079
Na	6883.6 (11.7)^a	9527.2 (96.1)^b	10439.1 (24.6)^b	10064.6 (74.5)^b	20.21	0.007

Means in the same line sharing the same superscript letter were not significantly different as determined by Tukey's test ($p > 0.05$).

There is still no report regarding the concentration of these ions in abalone extrapallial fluid (EPF).

This study reports that the levels of Mg, Mn, Fe, Na, and Al in shells increased with shell size (age), whereas those of Zn and Cu dropped. This is similar to what is reported by Carriker et al. (1982) concerning the oyster *Crassostrea virginica* (Gmelin). These changes can be attributed to many factors. For example, magnesium and manganese are enriched in calcite rather than aragonite (Dauphin et al. 1989). Mn can accumulate during the process of shell thickening (Yoshioka & Terai 1996). Hawkes et al. (1996) reported that the concentrations of elements in the shell were very different in the outer prismatic shell layer and the inner nacre layer. Therefore, the concentration changes of elements can be regarded as the effects of changes of shell mineralogy during ontogenetic development.

ABSTRACT Growth rates of juvenile *Haliotis fulgens* (green abalone) were evaluated with four different diets over 106 days. Three diets were based on the algae palm kelp *Eisenia arborea*, giant kelp *Macrocystis pyrifera*, and *Gelidium robustum*, and one on seagrass *Phyllospadix torreyi*. One artificial diet was used as a control. The best growth rates and specific growth rates were found in abalone fed *M. pyrifera*, which were significantly different from growth achieved on the other natural diets. The pattern of growth in juveniles fed an artificial diet was similar to juveniles fed *M. pyrifera*. The highest mortality (11%) was in juveniles fed the red algae *G. robustum*.

KEY WORDS: *Haliotis fulgens*, green abalone, growth, algae, diets

INTRODUCTION

In recent years, dietary research in abalone has focused on the production of formulated feeds in countries with a history of abalone culture (Uki & Watanabe 1992, Wee et al. 1992, Viana et al. 1993, Viana et al. 1994, Britz 1996a, Britz 1996b, Fleming et al. 1996, Knauer et al. 1996, Britz et al. 1997, Clarke & Creese 1998, López et al. 1998, Monje & Viana 1998) because of potential use of these feeds in commercial production. Information on natural diets is important in understanding the biology of abalone species. Abalone food preferences have been studied from both analysis of gut contents and feeding experiments in species such as *Haliotis cracherodii* Leach, *H. discus hannai* Ino, *H. fulgens* Philippi, *H. tuberculata* (L.), and *H. rufescens* Swainson (Sakai 1962, Leighton & Boolootian 1963, Culley & Peck 1981, Uki 1981, Uki et al. 1986, Leighton 1966, Mercer et al. 1993, Corazani & Illanes 1998, Leighton & Peterson 1998, Simpson & Cook 1998). Shepherd and Steinberg (1992) reviewed the literature on the feeding biology of abalone. In Mexico, research into natural diets has been limited to the brown alga *Macrocystis pyrifera* (L.) C. Ag. as a control in feeding trials (Viana et al. 1993, Viana et al. 1996). It has been assumed that abalone feed on the kelp alga *M. pyrifera*. Regional hatcheries use this species as a main source of natural food. *M. pyrifera* does not occur at the southern limit of the distribution of abalone species along the Baja California Peninsula. However, there are many subtidal algae along the coast that may be used as potential food. In Baja California Sur, the most common food items in gut content of adults of green abalone *Haliotis fulgens* were the seagrass *Phyllospadix torreyi* S. Watson and the macroalgae *Sargasum* sp., *Eisenia arborea* Aresh., *Cryptopleura crispa* Kylin, and *Rhodymenia* sp. (Serviere-Zaragoza et al. 1998). It is important to develop feeding experiments oriented to test growth rates and feed conversion efficiencies on single species diets to evaluate local algal species as diets for abalone. Day and Fleming (1992) mentioned that although an alga may not support sustained growth when fed alone, it may be of great value when part of a mixed diet by providing essential nutrients to the diet. This study was designed to assess the growth of juvenile green abalone fed with common species in the benthic environments inhabited by abalone along the western coast of Baja California.

MATERIALS AND METHODS

Diets

Macrocystis pyrifera (MP) was selected as the primary alga species (the control) because it is the dominant algal species of southern California (Dawson et al. 1960) and it is believed by fishermen that Mexican abalone species feed extensively on this alga. The brown alga *Eisenia arborea* (EA), red alga *Gelidium robustum* (GR), and the sea grass *Phyllospadix torreyi* (PT) are thought to be important species in abalone communities as potential food along Baja California (Guzmán del Próo et al. 1972, Guzmán del Próo et al. 1991, Serviere-Zaragoza et al. 1998). Natural diets were harvested, dried, and stored at the beginning of the experiment, because chemical composition varies during the year. The growth rate of abalone fed with algal diets is low and variable over time. Therefore, we decided to include an artificial diet as a control (AD). AD was manufactured by the nutrition group of Instituto de Investigaciones Oceanológicas, B.C. The dietary formulation is in Table 1. Proximate analyses (crude protein, ether extractables, crude fiber, and ash) were performed using the methods of the Association of Official Agricultural Chemists (1995).

Experimental Procedure

Animals used in this experiment were reared in a commercial hatchery in Eréndira, Baja California, and transferred to the CIBNOR laboratory in La Paz, B.C.S. at age 8 mo. Feeding experiments commenced six months later. During this period, animals were fed the brown alga *Eisenia arborea*. Six hundred animals (17.3 (±2.2) mm shell length and 0.44 (±0.2) g body weight) were used to test the growth response of abalone fed four diets for 106 days. Experimental animals were held in 16-L fiber glass containers (50 × 30 × 35 cm, experimental units) with a concave bottom. Three replicates per treatment were made with 40 abalone per experimental unit (EU). Animals were marked with plastic tags attached to the shell. The EUs were supplied with temperature controlled (20 ± 1°C), fresh, filtered (10 μm) water with a flow rate of 73 mL/min. The water was aerated vigorously. Salinity, oxygen, pH, nitrate, nitrite, ammonium content, and phosphate were monitored every week. Dead animals were removed and replaced to maintain densities. Shell length was measured with a vernier caliper, and body weight was measured with an electronic balance (to 0.001 g) at the beginning, and at 30, 60, and 106 days.

TABLE 1.

Percent composition of the artificial diets tested in this study, given as percentage of dry matter.

Ingredients	g/100 g
Fish meal	30.0
Silage (dry basis)	2.0
Soy bean meal	10.0
Corn meal (whole)	12.0
Vegetable meal	15.0
Corn starch	19.37
Gelatin	6.0
Vitamin mixture	1.7
Mineral mixture	3.3
Choline chloride	0.11
Methionine	0.23
BTH	0.086
Sodium Benzoate	0.23

Diets were given *ad libitum*. Natural diets were fed every 42 hours in the afternoon and the artificial diet each night. The remaining food was carefully collected for drying and weighing; every other morning for natural diets and each morning for the artificial diet. This was undertaken throughout the feeding experiment. Algae growing on the inside walls of the EU were removed twice a week with a soft brush. For diets, the amount of dry matter lost in seawater was estimated during the experiment by using EUs without abalone under the same conditions as those of the growth experiments.

Growth rates were calculated by the equation:

$$GR_{SL} = (SL_f - SL_i)/T \text{ and } GR_{BW} = (BW_f - BW_i)/T$$

where SL_f = mean final shell length, SL_i = mean initial shell length, BW_f = mean final weight, BW_i = mean initial weight, and T = time in days.

Specific growth rate (SGR % day^{-1}) was calculated for shell length and body weight by the equation (Britz 1996b):

$$SGR_{SL} = \{(\ln SL_f - \ln SL_i)/T\} \times 100 \text{ and}$$

$$SGR_{BW} = \{(\ln BW_f - \ln BW_i)/T\} \times 100$$

where SGR_{SL} is percent shell length gain per day, SL_f = mean final shell length, SL_i = mean initial shell length, and T is time in days between measurements. SGR_{BW} is percent body weight gained per day, BW_f = mean final weight, and BW_i = mean initial weight.

Consumption was calculated in terms of dry weight with the equation (Uki & Watanabe 1992):

$$FC = (GS/100) - R$$

where G is the weight of food offered per animal per day (in grams), S is the percentage of food recovered, obtaining a factor for each diet (from the controls without abalone), and R is the remaining food (in grams) after the abalone had fed.

Food conversion efficiency ratio was calculated as (Uki & Watanabe 1992):

$$FCE = \text{wet weight gain (g)/dry weight of food consumed (g)} \times 100$$

This measure of food utilization is related to conversion efficiency, but is in fact the ratio of animal live or wet weight gain to the amount of dry diet consumed (Monje & Viana 1998).

Statistical Analyses

Data for experimental replicates were pooled because no significant differences were found between them by one-way analysis of variance (ANOVA) at a significance level of $P = 0.05$. Data from each different treatment were analyzed by ANOVA test and Tukey test to determine differences of means (Sokal & Rohlf 1995). Statistical analysis was done with software STATISTICA 6.0 for PC.

RESULTS

The highest protein content was found in *Gelidium robustum* (GR) followed by *Phyllospadix torreyi* (PT), *Macrocystis pyrifera* (MP), and *Eisenia arborea* (EA). The lipids were between 1.06% for *G. robustum* and 1.30% for *M. pyrifera* (Table 2). The daily average temperature was 20 ± 1°C. Water quality analyses showed the following averages (±*s*) for pH 8.03 (±0.06); oxygen 6.52 (±0.74) mg/L, salinity 40 (±1.29) ppm, nitrites 0.0052 (±0.0004) µmol/L, nitrates 0.1253 (±0.0029) µmol/L, ammonium 0.0226 (±0.00001) mg/L, and phosphate 0.00552 (±0.000017) µmol/L throughout the experiment.

Growth of Abalone

A significant difference in means was shown between shell length and body weight of juvenile green abalone fed with the natural diets ($P < 0.05$). At 30 days of the experiment, the mean length, 19.15 mm ± 0.23 (SE), and weight, 0.59 g ± 0.02 (SE), of juveniles fed MP were statistically different from the means of juveniles fed EA, 18.28 mm ± 0.21 (SE) and 0.02 g ± 0.18 (SE), and GR, 18.24 mm ± 0.19 (SE) and 0.50 g ± 0.02 (SE). After 60 days, the differences increased and were significant. Both mean length and weight of juveniles fed MP were statistically different from the other diets; EA, GR, and PT. Differences between juveniles fed these latter three diets were not detected.

Mean shell length and body weight increased over time on all diets (Fig. 1). The best growth in length and weight for green abalone was obtained with MP, 22.29 mm ± 0.33 (SE) and 1.0 g ± 0.06 (SE). The percent of survival was between 89% and 95% in natural diets. For AD, it was 97% (Table 3). The pattern of growth in juveniles fed the artificial diet, 22.01 mm ± 0.22 (SE) and 0.91 g ± 0.03 (SE), was similar to juveniles fed MP (Fig. 1).

TABLE 2.

Proximate analysis of the species and artificial diet used in experimental diets. EA, *Eisenia arborea;* MP, *Macrocystis pyrifera;* GR, *Gelidium robustum;* PT, *Phyllospadix torreyi;* and AD, artificial diet.

	Component				
Diet	Crude Protein	Ash	Crude Fiber	Ether Extract	N-free Extract
EA	7.60	27.13	6.44	1.15	57.68
MP	12.0	41.33	7.0	1.30	38.37
GR	17.61	21.26	10.19	1.06	49.88
PT	15.94	31.88	13.45	1.28	37.44
AD	35.85	10.70	5.85	7.09	40.51

Values are given as percent of dry matter.

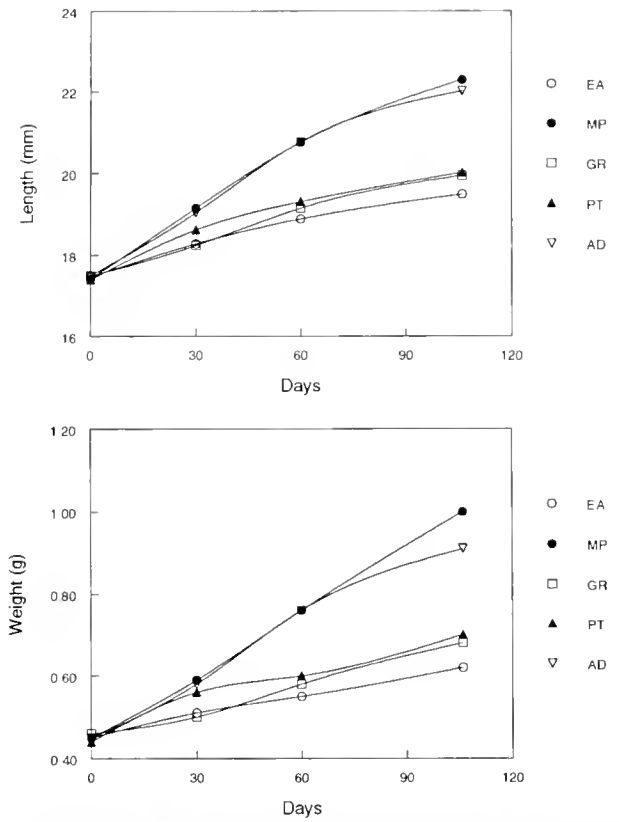

Figure 1. Mean growth of abalone fed with different diets. EA, *Eisenia arborea;* MP, *Macrocystis pyrifera;* GR, *Gelidium robustum;* PT, *Phyllospadix torreyi;* and AD, artificial diet.

Growth Rates

Significant differences occurred, between natural diets, in the daily growth rates of the shell length (SL) and body weight (BW) ($P < 0.05$). During the experimental period, 106 days, both mean SL and BW growth rates of animals fed MP were higher than mean growth rates of the juveniles fed the other natural diets ($P < 0.05$) (Table 3). The growth rates of the juveniles analyzed varied within the same diet during the experiment. In EA and PT a gradual decrease was observed during the experiment. For MP and GR, in the second month a gradual increase was measured, and at the end of the experiment the values had decreased. Juveniles fed EA showed the lowest shell length growth rates, 15 μm ± 1 (SE), during the third experimental month and the highest was in juveniles fed MP, 53 μm ± 2 (SE), during the second month. Body weight growth rates were between 0.92 mg ± 0.13 (SE) for GR during the first month and 6.70 mg ± 1.29 (SE) for MP during the third month.

The daily growth rates of juveniles fed artificial diet were similar to growth rates of juveniles fed MP (Table 3). The values ranged between 31 μm ± 2 (SE) in the third month to 57 μm ± 2 (SE) in the second month. Daily body weight rates were between 3.63 mg ± 0.18 (SE) in the first month and 6.13 mg ± 0.23 (SE) in the second month.

SGR

The ANOVA showed that there was no significant difference in mean SGR for any of the replicate diets. Using the Tukey test on the SGR (Tukey test $P < 0.05$) for green abalone, the existence of a significant difference in mean was shown between the SGR shell length and body weight of the abalone fed with MP and the other diets (EA, GR, PT). The same analysis revealed there was no significant difference in the mean SGR for EA, GR, and PT, except for SGR body weight of juveniles fed PT, which was higher than EA and GR (Fig. 2). SGRs obtained from juveniles fed the artificial diet were similar to juveniles fed MP.

The feed consumption rate of abalone ranged from 0.0033 g/day for EA to 0.0108 g/day for MP. Consumption did not differ significantly between EA and GR, and PT and MP ($P > 0.05$). Abalone consumed significantly greater amounts of PT and MP (Table 4). FCE ratios for the natural diets vary between 30% for PT and 63% for MP (Table 4). Differences between FCE ratios were not detected ($P < 0.05$).

DISCUSSION

Mean shell length and body weight increased over time on all diets. The best growth in length and weight for green abalone was obtained with *Macrocystis pyrifera.* Feeding abalone on *Eisenia arborea, Gelidium robustum,* and *Phyllospadix torreyi* diets resulted in lower growth and FCE, 46% to 81% of the values obtained with *M. pyrifera.* These results indicate that the dietary value of the common species along the coast of Baja California Sur, *Eisenia arborea, Gelidium robustum,* and *Phyllospadix torreyi,* was inferior to that of the dominant algal species of southern California *M. pyrifera.* This result may be related to the trends described by Guzmán del Próo et al. (1976) about the size and weight means for *Haliotis* spp., which decrease from north to south along the Baja California Peninsula. In southern California, the

best growth rates for juveniles and young adults have been observed when the alariacean brown alga, *Egregia menziesii*, served as food. The giant kelp, *Macrocystis pyrifera*, is of relatively minor value as a food of green abalone (Leighton & Peterson 1998). *E. menziesii* does not occur in the natural habitats of the different abalone species in southern Baja California (Guzmán del Próo et al. 1991). Local studies oriented to evaluate common algae along southern Baja California as a diet of abalone are of interest in the knowledge of abalone biology and for abalone hatcheries developed along this area of the coast. Fishermen have been forced to develop abalone hatcheries to produce juveniles and to increase natural stock. Hatcheries are going to use microalgae and macroalgae as the diet for juveniles until an artificial diet is successfully developed.

The nutritional value of food rations depends on many factors, including nutrient composition, bioavailability, palatability, and digestibility. Food palatability is an important factor in determining feeding rates (Leighton & Boolootian 1963, Leighton 1966, Poore 1972, Fleming 1995). In this study, the difference in growth between juveniles fed MP and EA or GR might be caused mainly by differences in palatability because of the lower amount consumed using both EA and GR. Differences between growth of juveniles fed MP and PT might be related to the digestibility of the protein sources because of the lower FCE of the seagrass. Poor abalone growth rates observed for seaweed diets could be attributed to a deficiency of essential nutrients or a low protein to energy ratio, because marine algae, in general, are rich in storage carbohydrates but low in protein. Thus the abalone fed macroalgal diets may satisfy their energetic requirements primarily from carbohydrate, but sufficient protein may not be available for tissue deposition (Britz 1996b). Beside variables associated with the food quality, digestion of the food is an important issue in nutrition. Our group hereby describes the enzymes responsible for digestion of this protein found in the organism's digestive system. In the adult green abalone trypsin and chymotrypsin activity was found in both intestine and rectum, but not in hepatopancreas and crop-stomach content. In juvenile green abalone digestive extracts revealed hepatopancreas and viscera hydrolyzed trypsin, chymotrypsin, and acid phosphatase specific substrates. (Serviere-Zaragoza et al. 1997, Picos-Garcia et al. 2000).

The growth rate of juvenile green abalone was slow and heterogeneous. The average growth rates of the juveniles analyzed varies from 19 μm day^{-1} and 1.52 mg day^{-1} for *Eisenia arborea* to 46 μm day^{-1} and 5.49 mg day^{-1} for *M. pyrifera*. Viana et al. (1993, 1996) reported averages of 12 μm day^{-1} and 16 μm day^{-1} for juveniles fed fresh kelp, *M. pyrifera*, and 18 μm day^{-1} for juveniles fed an artificial diet based on kelp meal for the same abalone species. *Gelidium robustum*, *Eisenia arborea*, and *Phyllospadix* spp. are of low acceptability for green abalone in Southern California and support minimal growth (Leighton pers. comm.). Simpson and Cook (1998) found shell length growth rates of *H. midae* ranged between 15 and 53 μm day^{-1} on single-species diets of *Ecklonia*, *Laminaria*, *Porphyra*, *Ulva*, *Aeodes*, and *Gracilaria*.

Using EA and PT, a gradual decrease was observed during the experiment. For MP and GR in the second month, a gradual increase was observed, and at the end of the experiment the values had decreased. This is similar to the trend reported by Viana et al. (1993); the daily growth rates decreased throughout time. Feeding trials on *H. rubra* using single species of dried algae revealed that abalone cease to grow after a period ranging from 50 to 200 days (Day & Fleming 1992). In the wild, abalone species consume more than one species. In *H. fulgens* the average number of plant species per gut was between two and four (Serviere-Zaragoza et al. 1998). This suggests they obtain the required nutrients for growth from combinations of species.

An artificial diet provides better growth rates than a natural one (macroalgae) in abalone cultures (Nie et al. 1986, Hahn 1989, Uki & Watanabe 1992, Viana et al. 1993, Viana et al. 1996). Nevertheless, in this study the growth of juveniles fed the artificial diet used as a control was similar to growth of juveniles fed MP. The lower growth of juveniles fed AD may be related to the leaching of some components during the transport or storage of the artificial diet. All environmental variables were constant during the experiment with abalone strongly attached and active throughout. Additionally, growth rates in juveniles fed MP were similar to that reported in the literature for the same species (Viana et al. 1993, Viana et al.1996).

ACKNOWLEDGMENTS

This work was supported by CONACyT (Grant No. 225130-5-4107PN), SIMAC (Grant No. 99-0107002) and Institutional project ABM8. Germán Ponce has a CONACyT fellowship (Reg. # 119827). We thank José Luis Ramírez and Manuel Mazón for technical support, AQUAM and Dra. Teresa Viana for the supply of juveniles and artificial diet. We thank Dr. D.L. Leighton for this valuable suggestion, and Dr. Ellis Glazier, CIBNOR, for editing the English-language text.

IDENTIFICATION OF EXPRESSED HSP'S IN BLACKLIP ABALONE (*HALIOTIS RUBRA* LEACH) DURING HEAT AND SALINITY STRESSES

BRIAN DREW, DEAN MILLER, TES TOOP AND PETER HANNA*

School of Biological and Chemical Sciences, Deakin University, Geelong, VIC 3217, Australia

ABSTRACT Both prokaryotes and eukaryotes express a set of highly conserved proteins in response to external and internal stress. The stressors include tissue trauma, anoxia, heavy metal toxicity, infection, changed salinity, and the most characterized, heat shock. The result is an expression of stress proteins or heat shock proteins (HSP's) which lead to protection of protein integrity, and also to tolerance under continued heat stress conditions. The Australian blacklip abalone (*Haliotis rubra*) is found principally in southern coastal waters and also in estuarine/bay environments. Estuarine/bay environments have greater fluctuations in environmental conditions, especially those of salinity and water temperature, than are found along oceanic coasts. Abalone from estuarine/bay and oceanic coastal environments were subjected to either increased temperature (2°C/day for a total of 10°C) or hyposalinity (80% seawater). Estuarine/bay abalone were less affected than the oceanic animals by temperature increase and also demonstrated the ability to volume regulate 3 h after the initial salinity shock. SDS-PAGE and Western blotting techniques, together with dot blots of total protein, using HSP70 specific antibodies, were used to detect HSP70s in the foot muscle of the animals and indicated an expression of HSP70 in response to heat shock in abalone, but not following hyposalinity shock. RT-PCR yielded a partial cDNA clone of HSP70 from the foot muscle.

KEY WORDS: abalone, *Haliotis rubra*, heat shock proteins, HSP70, stress, cDNA

INTRODUCTION

Extreme environmental conditions cause all organisms previously studied, from mammals to bacteria, to evoke a heat shock response (HSR) (Gehring & Wehner 1995). The HSR is a rapid reaction to environmental or internal stresses that can be elicited by factors such as tissue trauma, mutagens, anoxia, heavy metals, salinity and exposure to abnormally high temperatures (Laursen et al. 1997). The HSR is more generally known as the stress response, because previous studies have shown that a wide range of stressful conditions induce its initiation. One exception to date has been established, *Hydra oligactis*, a freshwater Cnidarian that lives in thermally stable environments (Bosch et al. 1988).

Following stress, the HSR leads to significant alterations in expression of a small number of specific genes in the organism, designated as heat shock genes. These genes become actively transcribed under stressed conditions, which in turn leads to production of certain proteins, aptly named heat shock proteins (HSPs). The name is derived from the original stressor which led to the discovery of these proteins (Gehring & Wehner 1995). Upregulation in the transcription of one of these HSPs, HSP70, during stress is thought to be due to an elevation in the cellular levels of denatured proteins that activate a transcription factor termed the heat shock factor (HSF), which in turn binds to GC rich DNA in the promoter regions upstream to the HSP70 gene (Sanders 1993). Upon binding of HSF the upregulation of HSP70 expression is possibly 100 times basal levels (Wilkins & Lis 1997). The significance of the HSR is only partially understood, but there is sufficient evidence to indicate that production of HSPs leads to protection or tolerance of the stress to which the organism is exposed (Wood et al. 1998).

HSP70s are among the most highly conserved family of proteins known. There is approximately 50% homology in the amino acid (AA) sequence of every species characterised (Parsell & Linquist 1994). This high homology suggests there has been little phylogenic divergence in the protein, highlighting the importance of HSPs to survival. Most of the highly conserved regions in HSPs are found in the amino-terminus (N-term) of the protein, where an ATP binding domain is located. The carboxy-terminus (C-term) is the more divergent as it contains the substrate binding domains that recognize the vast array of proteins.

There are two distinct types of proteins in the 70kDa class, the inducible HSP70 proteins and non-inducible (constitutive) heat shock cognates, HSC70s (Wood et al. 1998). HSC70s are important in the normal function of a cell under non-stressed conditions and therefore are present at detectable low levels under such conditions. HSC70 proteins are important in the translocation of proteins within cells and especially in the transport of proteins into the mitochondrion (Stuart et al. 1994). HSC70s also prevent folding of polypeptide chains by cradling them when incorrectly folded or not completely assembled. Such a mechanism prevents the appearance of nonsense proteins and the aggregation of unfolded AA chains, which leads to cellular damage.

Earlier observations on HSPs were interspecies comparisons in expression, or differences between HSP expression in control and stressed animals of the same species. These demonstrated variations in the protein expression in both cases. For example, the lamprey *Lampetra appendix* has a HSP induction temperature (26°C), which is approximately 4°C higher than that of *Petromyzon marinus*, another lamprey species (Wood et al. 1998). Such differences are believed to be a consequence of evolutionary histories that ultimately led to genetic differences in the heat shock response. In another study, HSP expression was observed in two Californian mussel species, *Mytilus trossulus* and *Mytilus galloprovincialis* (Hofman & Somero 1996). Different latitudes separate these species, *M. trossulus* being the more northern of the two. *M. trossulus*, was the more thermally sensitive, as measured by HSP70 standing-stocks and ubiquitin conjugates present in the gill tissues of animals maintained at 13°C for 8 wk. In addition, induction temperatures for new HSP70 synthesis were lower in *M. trossulus* than in M. *galloprovincialis* (23°C versus 25°C), suggesting protein damage at lower temperatures and greater temperature sensitivity in the species from the cooler climate. More recently, Chen and Chen (1999) have shown that juvenile abalone acclimated to higher temperatures survived heat shock at higher

*Corresponding author. E-mail address: pjh@deakin.edu.au

temperatures. Interestingly, these abalone heat shock responses were negatively correlated with salinity.

Salinity stress is another factor encountered by coastal marine organisms. *Eurytemora affinis*, a crustacean found in estuaries of North America and Europe, expresses a range of proteins when exposed to a salinity gradient, with particular groups of proteins being expressed at different salinities (Gonzalez & Bradley 1994).

Molecular evidence for tolerance to heat has been characterised in a molluscan cell line from *Biomphalaria glabrata*, a fresh water snail (Laursen et al. 1997). Western blotting showed increased expression of HSP70 resulting from a 10°C increase. Northern blots and RT-PCR led to the cloning of an induced HSP70 cDNA in this snail, which was sequenced and compared to that of other organisms. The highest sequence homology was to that of HSP70s of other aquatic animals, including HSP70a and HSP70b in *Aplysia californica*.

Abalone (genus *Haliotis*) is a marine mollusc which inhabits coastal and bay waters of southern Australia. During summer, bay abalone have been observed to dramatically lose weight and deteriorate in condition. Factors causing such deterioration could include the hotter seawaters (e.g. bay 10°C greater than ocean) and fluctuating salinity during periods of high rainfall. Therefore, we started the current study examining the HSR in commercially important blacklip abalone, *Haliotis rubra* (Leach) exposed to elevated temperatures. In addition, we compared the ability of bay and oceanic populations to volume regulate after a hyposaline challenge.

MATERIALS AND METHODS

Animal Collection and Maintenance

Haliotis rubra (Leach) were collected during Spring under permit number 97/R/049A from a northern Port Phillip Bay site near Point Cook and from a site in ocean water near Barwon Heads in Victoria, Australia. The animals were transported to aerated holding tanks with a fresh filtered flow-through seawater system where ambient water temperature ranged from 12–16°C. They were provided an excess diet of mixed red macroalgae. The animals were held for 2–4 wk before experimentation.

Environmental Manipulation: Salinity Stress

Two replicate hyposalinity tests took place in two 36-L tanks in which 80% sea water was produced from sea water taken from the holding tanks and distilled water. Water temperatures of the two replicate tanks were 16 ± 0.2°C for test 1 and 13.5 ± 0.2°C for test 2, being the ambient temperatures at the times of experimentation. Plastic plates of 300 mm × 300 mm were weighed wet, numbered, and placed vertically in the tanks. Six abalone were taken from each population, weighed, measured by shell length, and then placed on plates in the tanks (one population per tank). No water flow was permitted during the salinity trials and a carbon fiber filter and aerator were placed in each tank to provide sufficient oxygen and remove any organic matter the abalone might produce. The animals were weighed at 0.5 hour on the plates to reduce disturbance, and then weighed (on the same plate each time) at 1 h intervals for 6 h. Weights were also measured at 24 h, 48 h and 72 h. Abalone were returned to their respective holding tanks after the 72 h test period had finished. No animal was used more than once.

Additional abalone were treated in the same manner for 1.5 h before taking tissues for molecular studies.

Environmental Manipulation: Heat Stress

Responses to heat stress were examined in a 90-L glass tank in which 15 abalone were taken at random from the bay and ocean populations. The critical thermal maximum (CTM) was determined using the point at which an abalone can no longer remain attached to the substrate, this being considered the temperature at which no long-term survival is considered likely. Each abalone was weighed, measured by shell length, and tagged with plastic discs, and then placed onto suspended vertical plates (600 mm × 300 mm) in the well-aerated trial tanks. No food was provided for the abalone during the tests. Ambient water temperature was 15 ± 0.2°C for test 1 and 12.5 ± 0.2°C for test 2. The tank was fitted with a 1000 W thermoregulator and the temperature was raised by 2 ± 0.2°C per h until it reached 20°C, after which it was then raised 1 ± 0.2°C per h until none of the animals could keep contact with the vertical plates.

Continual visual monitoring of the trials was undertaken to record any behavioral responses of the abalone during the trials and to record the time and temperature that each abalone detached. Immediately after an abalone had detached, it was weighed and then placed into a well-aerated recovery tank 2 ± 0.5°C lower than the test tank.

Two replicate trials were undertaken for each of the two populations. Different animals were randomly selected for each of the tests. Differences between groups were tested using a 50% CTM calculated by linear regression.

Only bay abalone were used for molecular studies. Before tissue collection, the water temperature was increased by 2°C daily until a temperature of 25°C was reached, representing a total rise of about 9°C. Animals were subsequently removed from the containers and immediately killed by severing of cerebral ganglia. Tissues were quickly removed and snap frozen in liquid nitrogen prior to storage at −80°C.

DNA Extraction

Approximately 0.5 g of frozen tissue from each foot muscle was minced (in a sterile petri dish using scalpel blades) until the tissue formed a coarse paste. Cells were then lysed by shaking the tissue in a 1.5 ml microfuge tube with 1ml of DNAzol (Life Technologies, genomic DNA isolation reagent), and the tube was then centrifuged (13000 × *g*, 10 min, 4°C) (MSE Microcentaur, microfuge). The supernatant was removed and the DNA was prepared by standard chloroform/isoamyl/alcohol precipitation. Extraction was confirmed using separation in agarose gels.

Polymerase Chain Reaction (PCR)

PCR was carried out on genomic DNA in order to gain sequence information from the genes encoding HSP70 in *H. rubra*. PCR on cDNA was used to characterize expressed sequences (mRNA) of HSP70 genes within stressed animals. All reactions were performed using an automated thermocycler (FTS-320 Thermal Sequencer; Corbett Research) and all reactions were layered with one drop of mineral oil prior to cycling.

Primers for PCR were designed from regions of high amino acid (AA) homology seen between aligned sequences of organisms previously cloned. Figure 1 is a general overall positioning of the primers (shown in italics and arrows) on the HSP70 mRNA transcript, together with estimated sizes of PCR products.

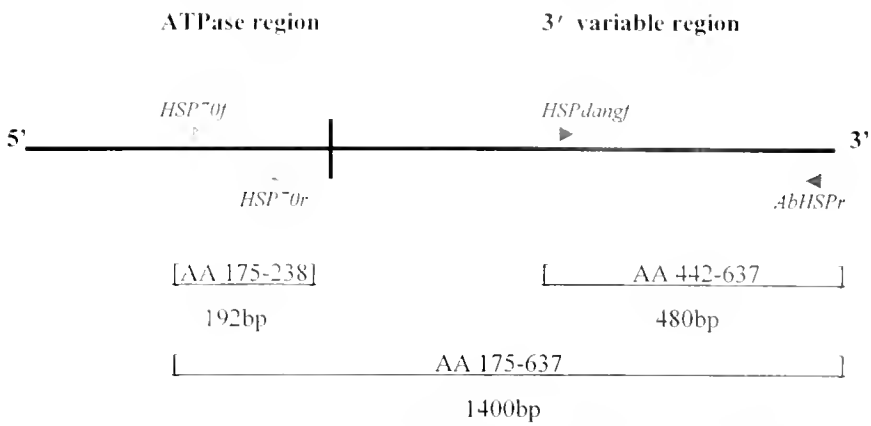

Figure 1. PCR primer binding sites on HSP70 cDNA and expected PCR product sizes.

Genomic DNA (HSP70 192bp): 50 µl reactions containing 200 ng *H. rubra* genomic DNA, 5 µl 10x reaction buffer (Life Technologies), 2–4 mM $MgCl_2$ (Life Technologies), 5 mM of dNTP's (Boehringer), 8 mM of both forward (HSP70f: 5′-GNATHATHAAYGAASCANC-3′) and reverse (HSP70r: 5′-GNATHATHAAYGAASCANC-3′) primers, 2.5 units of *Taq* Polymerase (Life Technologies) and ddH_2O were cycled through 36 cycles (1: 95°C for 5 min; 2–35: 95°C for 120 s, 52°C for 90 s, 72°C for 90 s; 36: 72°C for 5 min).

Genomic DNA (HSP70 1400bp): 50 µl reactions containing 200 ng *H. rubra* genomic DNA, 5 µl 10x reaction buffer (Life Technologies), 2-4 mM $MgCl_2$ (Life Technologies), 5 mM of dNTP's (Boehringer), 8 mM of both forward (HSP70f) and reverse (AbHSPr: 5′-YARTCNACYTCYTCNAC-3′) primers, 2.5 units of *Taq* Polymerase (Life Technologies) and ddH_2O were cycled through 31 cycles (1: 95°C for 5 min; 2–30: 95°C for 120 s, 52°C for 90 s, 72°C for 120 s; 31: 72°C for 5 min).

cDNA (HSP70 192bp): 25 µl reactions containing 1 µl cDNA, 2.5 µl 10x reaction buffer (Sigma), 2-4 mM $MgCl_2$ (Life Technologies), 5 mM of each dNTP's (Boehringer), 8 mM of both forward (HSP70f) and reverse (HSP70r) primers, 1.25 units of RedTaq Polymerase (Sigma) were cycled for 30 cycles (1: 95°C for 5 min; 2–29: 95°C for 90s, 52°C for 90s, 72°C for 60s; 30: 72°C for 5 min).

cDNA (HSP70 480bp): 25 µl reactions containing 1 µl cDNA, 2.5 µl 10x reaction buffer (Sigma), 2-4 mM $MgCl_2$ (Life Technologies), 5 mM of each dNTP's (Boehringer), 8 mM of both forward (HSPdangF: 5′-GAYATHGAYGCNGAYGG-3′) and reverse (AbHSPr) primers, 1.25 units of RedTaq Polymerase (Sigma) and ddH_2O were cycled for 30 cycles (1: 95°C for 5 min; 2–29: 95°C for 90 s, 50°C for 90 s, 72°C for 90 s; 30: 72°C for 5 min).

cDNA (HSP70 1400bp): 25 µl reactions containing 1 µl cDNA, 2.5 µl 10x reaction buffer (Sigma), 2-4 mM $MgCl_2$ (Life Technologies), 5 mM of each dNTP's (Boehringer), 8 mM of both forward (HSP70f) and reverse (AbHSPr) primers, 1.25 units of RedTaq Polymerase (Sigma) and ddH_2O were cycled for 30 cycles (1: 95°C for 5 min; 2–29: 95°C for 90 s, 50°C for 90 s, 72°C for 120 s; 30: 72°C for 5 min).

Purification of PCR Products and Cloning

Fragments amplified by PCR were separated on agarose gels, and, if PCR products were single products, ligations into plasmids were carried out directly from the PCR reaction mixture. Other PCR products were excised from agarose gels under UV light using sterile scalpel blades, and DNA extracted using QIAEX II gel extraction kits (QIAGEN) and QIAquick gel extraction kits (QIAGEN) following the manufacturer's instructions. Alternatively, gel pieces containing desired products, were cut from agarose under UV light and incubated in 50 µl ddH_2O at 60°C overnight, then centrifuged at 13000 × *g* for 15 min to obtain supernatants which were used in reamplification of product via PCR or used directly in ligation reactions.

Ligations of PCR products were carried out within 24 hours of PCR reactions. PCR products were ligated into pCR2.1 plasmid vectors using the Original TA cloning kit (Invitrogen) according to the manufacture's instructions. Plasmids were then transformed into INVαF′ competent *E. coli* cells (Invitrogen) and transformed cells screened by standard blue/white screening procedures. White colonies were chosen as insert-containing clones and screened via PCR directly from colonies using the universal plasmid M13 (forward) and T7 (reverse) primers. Positive clones were selected and a QIAprep spin mini-prep kit (QIAGEN) used to prepare mini-preps of plasmids for subsequent sequencing on an Applied Biosystems Automated Sequencer at Westmead Hospital, Sydney, using the dye terminator method.

RNA Extraction from Frozen Tissue and Production of cDNA

RNA was extracted from foot muscle tissue using a modification of the acid/phenol method (Chomczynski & Sacchi 1987). Frozen tissue (300 mg) was minced finely using sealpel blades and then homogenized with 3ml of TRIzol extraction reagent (Life Technologies), until a cloudy solution was obtained. Samples were centrifuged (13000 × *g* for 15 min at 4°C) in order to remove lipoproteins and fats, and the supernatant removed. RNA was then isolated using the standard chloroform/isopropanol technique, and final pellets washed with sterile 75% EtOH prior to air-drying pellets and storage at −20°C.

First strand cDNA was made from freshly extracted RNA using a Superscript II kit (Life Technologies), according to the manufacturer's instructions. cDNA was synthesised from total RNA and RNase H used to remove the remaining RNA. The cDNA was then stored at −20°C.

Western Blotting

Frozen foot muscle samples (300 mg of tissue) were minced quickly into a coarse paste and the cells lysed by boiling for three

min in 2 ml of lysis buffer (32 mM Tris-HCl pH6.8, 2% SDS, 1 μM PMSF, 2 μg/mL each of pepstatin, chymostatin and leupeptin), followed by homogenization on ice with a teflon pestle (Cole-Parmer, U.S.A.) until all the tissue was suspended. The samples were boiled for a further 5 minutes, followed by centrifugation (13000× *g* for 10 min at RT) and the supernatant collected for protein quantification using a BCA Protein Assay Reagent kit (Pierce), following manufacturer's instructions. Sample concentrations were then equalised by dilution and immediately separated by standard 10% SDS-PAGE, or stored at −20°C until used. Replicate gels were used for electro-transfer of proteins onto nitrocellulose (NC) membranes or Coomassie blue staining.

Dot-blots of Total Protein

NC membranes and two pieces of Whatman chromatography paper were pre-soaked in 1× Western transfer buffer (200 ml MeOH, 5.24 g Tris, 17.6 g Glycine) for 15 minutes. The papers were placed under the NC membrane in a Bio-Dot apparatus (Bio-Rad) and the apparatus assembled. Proteins were prepared in a logarithmic series dilution (10-fold dilutions in lysis buffer) from a 100 μg stock solution (see Western blotting), to 0.01 μg, and boiled for three minutes prior to being loaded and blotted under vacuum. NC membranes were blocked and visualized following probing with specific antibodies as described below.

Immunostaining

NC membranes from Western transfers and dot-blots were blocked with 5% Blotto (5 g skim milk in 100 ml TBS-T), overnight with constant rocking. Membranes were then incubated with a primary (1°) goat anti-human HSP70 polyclonal antibody (Ab) (Santa-Cruz) in a 1:100 dilution with 5% Blotto for 2 h with constant rocking. This Ab was raised against the AA region 572–591 of the C-term of human induced HSP70 and was non-cross reactive with HSC70. NC membranes were washed three times with TBS-T (2.42 g Tris, 5.85 g NaCl, 1 ml Tween-20 made up to 2l with dH_2O), each for 15 minutes before being incubated with a secondary (2°) anti-goat horseradish peroxidase (HRP) conjugated Ab (Life Technologies) in a 1:2000 dilution with 5% Blotto for two h. Membranes were again washed three times each for 15 minutes with TBS-T. Bands were visualized with HRP developing solution (60 mg 1-chloro-4-napthol, 20 ml MeOH, 100 ml TBS, 60 μl 30% H_2O_2) until bands appeared. Results were recorded under white light using an Eagle Eye II still video system (Stratagene). A preabsorption control was performed to confirm that the bands were specific. In brief, 1°C Ab was preabsorbed overnight at 4°C with an excess of the antigen (Santa Cruz).

RESULTS

Responses to Reduced Salinity (Hyposalinity)

All animals were allowed to acclimate in tanks for three days prior to experiments. The shell lengths (mm ± SD) of abalone used in the replicate tests were 115.67 ± 3.2 (test 1) and 111.0 ± 11.47 (test 2) for the ocean abalone, and 108.17 ± 8.4 (test 1) and 111.4 ± 6.02 (test 2) for the bay abalone. Exposure to hyposalinity stress caused swelling of tissue, particularly of the soft tissues behind the head.

Only the data for test 1 are shown in Figure 2, but similar response curves were observed in both tests. Immediately after transfer into the lower salinity medium there was a distinct increase of weight in both abalone groups (ie. approximately 10% at 0.5 h). Following this initial increase the bay abalone decreased their weight over the next 5 h to about that of pre-treatment (ie. 98.8% in test 1; 100.4% in test 2). In contrast, the ocean abalone of both groups did not decrease to the same extent as bay abalone (106.7% in test 1; 102.8% in test 2). The differences between the two groups was significant at 5 h in test 1 ($p = 0.012$) but not in test 2 ($p = 0.083$). Overall, these studies on *H. rubra* populations suggest that the bay abalone are more able to volume regulate.

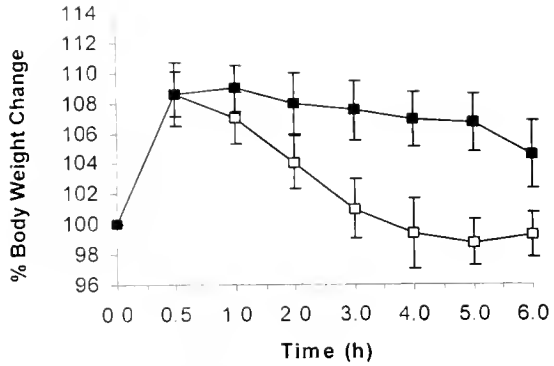

Figure 2. Percent body weight changes of *H. rubra* in response to a hypotonic salinity stress. Abalones from oceanic (■) and estuarine/bay (□) populations were subjected to 80% seawater. Bar lines represent SE of means.

Responses to Elevated Heat Shock

The behavior of the animals subjected to rising temperatures changed at approximately 19°C, when lamellapodia were erected and there was an observed lack of mobility in both ocean and bay abalone. Mucous production was evident in both abalone groups at temperatures above 20–21°C. At about 23°C the abalone raised their shell from their foot by the extension of the adductor muscle and rotated from side to side around its own axis. Above 23.5°C for ocean abalone, and above 24.5°C for bay abalone, retraction of foot from the vertical plates started, and continued until the abalone lost their footing completely. One obvious sign of stress in the more stressed animals was a swelling of the soft tissue around the back of the head, causing it to protrude.

Figure 3 shows the results of test 1 to establish the critical thermal maximum (CTM) for bay and ocean abalone. Replicate tests were performed but there was no significant difference at the $p < 0.05$ level between the groups. Starting from an acclimation temperature of 15 ± 0.2°C, the first ocean abalone in test 1 started to lose hold at 26°C, and bay abalone at 26.7°C, while the last to fall were 28.9°C, and 29°C, respectively. In test 2, starting with an acclimation temperature of 12.5 ± 0.2°C, the first ocean abalone started to drop off the plate at 25.3°C, and bay abalone at 25°C, whilst the last to fall were at 28°C, and 29°C, respectively. The temperature at which 50% remain attached (50% CTM) was calculated at 27.4°C for ocean abalone ($r = 0.92$), and 27.9°C ($r = 0.93$) for bay abalone in test 1, and 26.8°C for ocean abalone ($r = 0.92$), and 27.0°C for bay abalone ($r = 0.95$) in test 2, using linear regression on all points below 100%. The shell lengths (mm ± SD) for the ocean abalone were 116.27 ± 9.41 in test 1 and 115.73 ± 8.80 in test 2, whereas those for the bay abalone were 110.6 ± 7.1 in test 1 and 108.67 ± 4.79 in test 2.

A further test using bay abalone, was performed to obtain tissues from heat-shocked abalone and controls. In this test the water

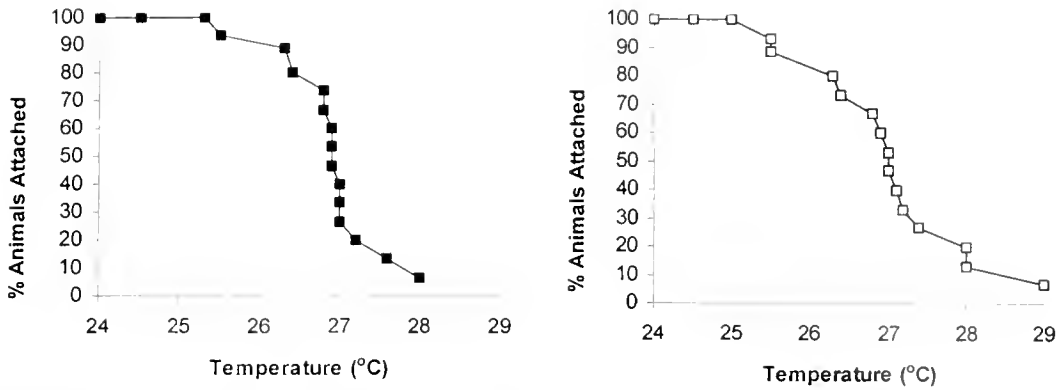

Figure 3. Responses of *H. rubra* to heat stress. Scattergrams showing percent of animals remaining attached as temperature increases for oceanic abalone (■) and estuarine/bay abalone (□).

temperature over the 7-day period for controls was 15.6 ± 2.36° C. The final temperature at which heat stress tissues were sampled was 25.4°C (i.e. an increase of 9.4° C).

Western Blotting

The polyclonal antibody (Ab) raised in goat against human heat inducible HSP70 bound to abalone proteins approximately 70 kDa (Fig. 4). A more intense band was observed in muscle proteins from heat-shocked animals. It is possible that the reactions observed in the salinity stressed or control animals were due to undegraded 70 kDa molecules which had been induced as a result of prior stress, such as transport to the laboratory. In additional Western blots, preabsorption of the Ab with HSP70 protein produced no band, indicating that the HSP70 Ab was specific for abalone HSP70.

Dot-blots of Total Protein

The results of dot-blots on total proteins isolated from heat shocked and control foot muscle of abalone are shown in Fig. 5. There was an increased expression of HSP70 in all 4 heat shocked animals compared with the 4 controls. Heat shocked animals 3 and 4, both of which showed the least stress to heat (ie. attached to substrate and showing no swelling of tissues), also produced the greatest amounts of HSP70, with the detection limit occurring at 1 μg of total protein. This increase in HSP70 was a 10 to 100-fold order of magnitude compared with controls (detection limit 10–100 μg of protein).

Total protein dot-blots were not performed on salinity stress animals, as HSP70 expression in the foot muscle of *H. rubra* did not appear to be upregulated by the stress (Fig. 4).

Cloning of Induced Heat Shock Gene Regions from Abalone Genomic DNA

DNA extraction and purification from *H. rubra* tissues was carried out and confirmed by the presence of a strong DNA band at approximately 23 kb in agarose gels (data not shown). There was almost no shared DNA.

PCR of a 192 bp HSP70 fragment, using HSP70f and HSP70r primers, was not successful. Upon cloning and sequencing of the fragments in three separate attempts, it was apparent 177 bp fragments had been cloned and was not from the HSP70 ATPase region using BLAST searches in Genebank.

PCR of a 1400 bp HSP70 fragment from genomic DNA, using primers HSP70f and AbHSPr, was successful (Fig. 6A). The 1400 bp fragments were cloned and white colonies were obtained with plasmids having the correct size inserts (Fig. 6B). Nested PCR using primers (HSP70f and HSP70r) were used on the plasmid

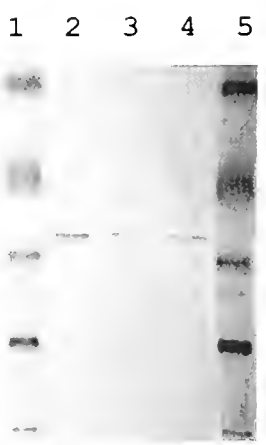

Figure 4. Western blot using a HSP70 specific antibody on total proteins extracted from abalone foot muscles. Western blot showing 70kDa products following membranes being probed with goat anti-human HSP70 polyclonal 1° antibody, then visualised via a HRP conjugated anti-goat 2° antibody. Lanes: 1 and 5, protein MWM of 118, 85, 61, 50 and 38 kDa (Life Technologies); 2, heat shocked abalone proteins; 3, salinity shocked abalone proteins 4, control non-stressed abalone proteins.

Figure 5. Dot-blots of total protein from heat shocked and control *H. rubra*. Membrane showing proteins extracted from foot muscle of heat shocked and control abalone bound and probed with specific goat anti-human HSP70 polyclonal 1° antibody visualised via a HRP conjugated anti-goat 2° antibody. Lanes: 1–4 heat shocked animals; 5–8, control animals. Protein concentrations (top to bottom row): 100 μg, 10 μg, 1 μg, 0.1 μg, 0.01 μg.

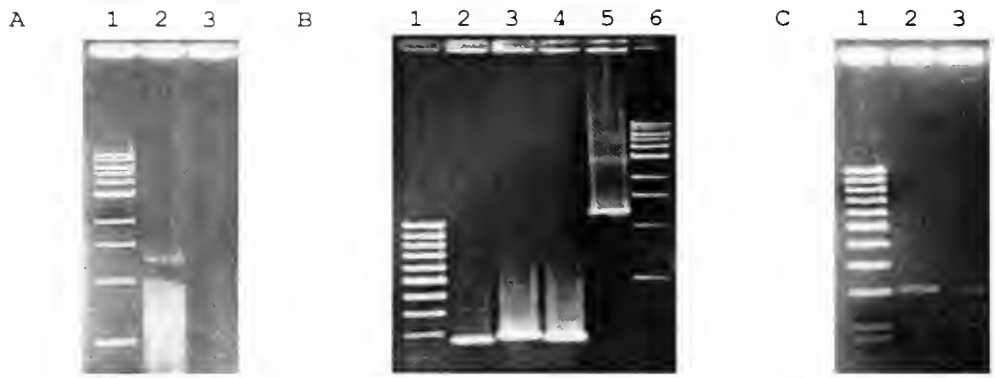

Figure 6. Analysis of PCR products obtained in the cloning of a 1400 bp HSP70 fragment from *H. rubra* DNA using 1.5% agarose gel electrophoresis. A. PCR products amplified using primers AbHSPr and HSP70f. Lanes: 1, 1 kb marker (New England BioLab); 2, 1400 bp fragment plus non-specific bands, 3, negative control (no cDNA). B. PCR screening of bacterial colonies for a 1400 bp HSP70 insert using M13 and T7 vector primers. Lanes: 1, 100 bp MWM (Life Technologies), starting with a 200 bp marker (bottom); 2, negative (no insert, 167 bp of vector); 3 and 4, false positives (small inserts); 5, positive (1400 bp insert plus 167 bp of vector), 6, 1 kb MWM (New England BioLabs). C. Nested PCR on the vector containing the 1400 bp insert using HSP70f and HSP70r primers. Lanes: 1, 100 bp marker (MB1), 2, positive (192 bp fragment); 3, negative plasmid control.

containing the 1400 bp insert, and this gave a 192 bp product (Fig. 6C). These primer sets were subsequently used to identify induced abalone HSP70 sequences in cDNA.

Cloning of Expressed Heat Shock Sequences from cDNA

High quality total RNA (182 ng/μl and a purity of 1.7) was extracted from tissues of abalone that had been heat shocked. This RNA showed characteristic 26s and 18s ribosomal RNA (rRNA) bands amidst other RNA's. The conversion of mRNA into cDNA was confirmed by successfully performing PCR on the cDNA using actin specific primers to produce a 474 bp fragment with >84% homology to three invertebrates (data not shown).

PCR of a HSP70 192 bp fragment from heat shocked abalone foot muscle cDNA gave a product running at the appropriate size (Figure 7A). This fragment was purified and cloned to produce white colonies containing plasmids with the inserts (Fig. 7B). Sequencing of a plasmid insert, along with similarity searches in GeneBank using BLAST, revealed that the clones were part of an abalone HSP70 sequence (Fig. 8). The sequence of 192 bp aligned with the same nucleotide sequence of other organisms with most homology to *B. glabrata* and *Drosophila* at 76% and 73%, respectively (Fig. 8A). A deduced amino acid sequence (AA), when aligned with known AA sequences, showed highest homologies to two other molluscs, *B. glabrata* and *A. californica*, exhibiting homologies of 87% and 84%, respectively (Fig. 8B).

The 192 bp sequence was also compared with known constitutive heat shock proteins (HSC's) and relatively lower homologies were observed in this region of *H. rubra* HSP70 (Fig. 8C). As well, these HSC70 sequences all had the GTC triplet (see Fig. 8A), encoding valine, absent. These data give a strong indication that the sequence obtained is in fact that from an induced HSP70.

PCR of a 1400 bp and 480 bp fragments from abalone heat shock cDNA were successful. However, several attempts to re-amplify and clone these fragments were unsuccessful.

DISCUSSION

The blacklip abalone (*H. rubra*) is primarily found in southern Australian waters and is an economically important species to Australia, worth millions of dollars a year through exports alone. The condition of the animals in wild-catch and cultured stocks, including meat weight, can affect their economic value. Stress is especially seen in summer and during periods of high rainfall which affect water temperature and salinity. These conditions apply particularly to those species in estuarine/bay environments. The heat shock response (HSR) is imperative to the survival of organisms and protects against protein aggregation and cellular damage, notably when an organism is under stressful conditions. These stressful conditions lead to the upregulation of HSPs, including HSP70.

Our research indicates that the bay abalone are more physiologically adapted to respond to hypo-osmotic stress than the ocean abalone. Most marine molluscs, including presumably abalone, are osmoconformers, which means that the extracellular fluid is almost iso-osmotic with the environment. Usually, such animals

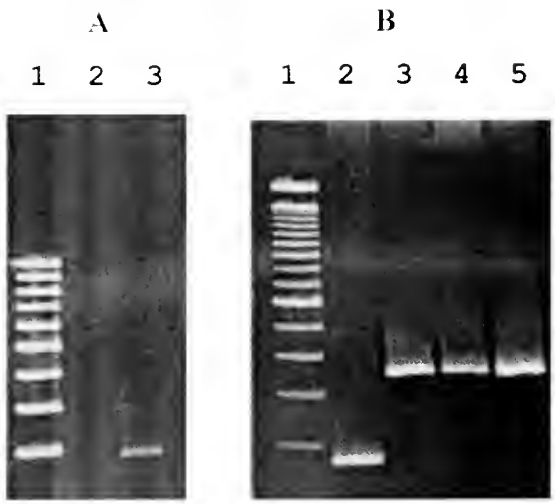

Figure 7. Analysis of PCR products obtained in the cloning of a 192 bp HSP70 fragment amplified from *H. rubra* cDNA using 2.0% agarose gel electrophoresis. A. PCR using HSP70f and HSP70r primers. Lanes: 1, 100 bp ladder (MB1), starting with a 200 bp marker (bottom); 2, DNA negative control; 3, 192 bp product, which was subsequently isolated for TA cloning. B. PCR screening of white colonies for a 192 bp insert using primers M13 and T7. Lanes: 1, 100 bp ladder (MB1); 2, negative (167 bp of vector pCR2.1 with no insert); 3, 4 and 5, positive (359 bp including a 192 bp insert).

Figure 8. Sequence alignments of HSP70 ATPase region from a 192 bp PCR fragment of *H. rubra* heat shock cDNA compared with other invertebrates. A. Nucleotide sequence shows homologies of 76% and 73% with others HSP70s. Letters in bold print represent primer sequences. B. Deduced amino acid sequence shows homologies of 87% and 84%, respectively (AA residues 175–238 of HSP70s). C. HSP70 nucleotide sequence shows homologies of 69%, 69% and 68% with HSC70s. Region in italics and underlined indicates a region of low homology. Three nucleotides in bold (encoding valine) are absent in HSC70s.

protect cells from volume perturbation, due to altered salinity, by modulating the concentration of free amino acids and other organic solutes in the intracellular compartment (Burton 1983). In these marine invertebrates exposed to low salinity, a rapid increase in fluid volume is compensated in a matter of hours (good volume regulators) or days (weak volume regulators) (Oglesby 1981, Davenport 1985). The success with which an osmoconforming species tolerates environmental dilution can vary between populations of the same species, depending on the variability of the salinity normally encountered in the environment. For example, in a study on the bivalve, *Geukensia demissa,* animals from an estuarine environment tolerated reduced salinities better than conspecifics from a higher salinity site (Garthwaite 1989). In the current study, we observed that the Port Phillip Bay population, which is exposed to a greater salinity range than oceanic populations, compensated for volume gain in reduced salinity faster and more effectively than the oceanic abalone (Fig. 1). Such a difference may be genetically determined because the bay abalone have a greater than 12% genetic difference compared to the oceanic populations (Huang et al. 2000). Studies on other molluscs have indicated that genetic variation at the *LAP* locus is correlated with populations which are distributed along a salinity cline (see for example, Garthwaite 1989, Gardner & Palmer 1998). However, we were not able to correlate environmental salinity with changes in the expression of HSP 70.

In our heat stress experiments, the upper lethal temperature for *H. rubra* was not determined, but the 50% CTM and the final temperature at which all animals had dropped off the plates were not significantly different. Similar 50% CTM's have been observed for *H. midae* at 27.9°C (Hecht 1994), and *H. rubra* at 26.9 C

and *H. laevigata* at 27.5°C (Gilroy & Edwards 1998). Hecht (1994) infers that differences in 50% CTM are considered to be of a greater zoogeographic significance than fixed physiological differences since they reflect adaptation to local environmental conditions. We had expected differences in 50% CTM as the bay populations can experience summer seawater temperatures of 30°C for short periods (unpublished), and there appears to be approximately a 12% genetic divergence between bay and oceanic populations (Huang et al. 2000).

In the current study, attempts to characterise the HSR in *H. rubra* during stress by expression of HSP70 proteins, proved to be successful. Proteins were identified from the foot muscle of abalone through Western blotting and upregulation of HSP70 was observed in heat-stressed animals via dot-blots of total protein. All sample groups in the experiments showed HSP70 expression with heat-shocked animals displaying obvious upregulation over salinity-stressed and control animals. Control and salinity-stressed animals did display some expression of the HSP70 protein. Given that antibodies were specific for an induced HSP70, it may be assumed that control animals in these experiments were under some form of minimal stress and were expressing induced HSP70, which may be basal level expression. All animals would also be expressing HSC70s, the non-induced form of the HSP70 family, but these proteins could not be monitored because of specific recognition of the antibody for the induced member. This assumed basal expression of HSP70 might not necessarily be basal expression at all, but a response to one of many stresses the control animals experienced during their transport and maintenance, similar to that observed in a study of the HSR response in *Mytilus californianus* (Roberts et al. 1997). Therefore, it would be favorable to execute the experiments after one or two months of moving the animals to the new environment because, after initial expression, HSP70s are not degraded for approximately two weeks, assuming no further stress is encountered (Sanders 1993).

Upregulation of HSP70 during heat shock, as seen by the 100-fold increase in expression of HSP70 proteins in *H. rubra*, has been previously well-documented in a variety of organisms, including other marine animals. A reported maximum 1000-fold increase of HSP70 has been observed after a heat shock in *D. melanogaster* (Parsell & Lindquist 1994), but levels resembling those of *H. rubra* have been monitored in oyster haemocytes (Tirard et al. 1995), cells originating from the fresh water snail *B. glabrata* (Laursen et al. 1997), the mussel *M. californianus* (Roberts et al. 1997), and the lamprey species *Petromyzon marinus* and *Lampetra appendix* (Wood et al. 1998). Genetic differences in the HSR between closely related species was reported in *Collisella* limpets, *C. scabra* and *C. pelta* (Sanders et al. 1991). This study monitored HSP expression under heat stress in both species, and found HSP70 expression was induced at lower temperatures, and at increased levels, in *C. scabra*, compared with *C. pelta*.

An upregulation of HSP70 was not observed in salinity-stressed *H. rubra*. This lack of increased expression of HSP70 does not imply that the HSR was not engaged in *H. rubra*, as it could be due to the expression of proteins other than HSP70. This has been observed in *Eurytemora affinis* (Gonzalez & Bradley 1994). In this study, osmotic shock did not increase the expression in HSP70. However, new proteins in the ranges of 24–29 kDa, 45–50 kDa, 55–65 kDa and 75–85 kDa were expressed in response to changing salinities. Because the antibody used in our *H. rubra* study was against HSP70 specifically, it would not detect other types of expressed proteins. In contrast, HSP70 was induced by hyperosmotic salinity stress in *Salmo salar* (Atlantic salmon), together with another stress protein, Osp54 (Smith et al. 1999). The increase in expression of proteins was accompanied by an overall decrease in other cellular proteins during salinity stress, which suggests that stress proteins were preferentially expressed. These findings present the first substantial evidence that HSP70, specifically, is expressed under salinity stress and it is hypothesised to function in restoring osmotic homeostasis and renaturing proteins that have been destabilized during osmotic stress.

The molecular cloning of HSP70 fragments using PCR of genomic DNA and cDNA was initiated to characterise and identify genes of *H. rubra* that may be induced in response to stress. In particular, sequencing of the 3′ variable end of an expressed mRNA would be useful in production of oligonucleotide probes for studying regulation of HSP70 in northern blots and for cDNA library screening.

The cDNA sequence of the 192 bp region of HSP70 ATPase region had high homology to HSP70s of other species. This sequence was unlikely to be constitutive HSC70 because there was less homology (<69%). In addition, a triplet at position 218 was absent from all the HSC70s. The HSC70s contained a region of low homology (encoding AA positions 188–191 in HSP70). It has been reported that position 190 in the HSP70 AA chain is a region not involved in tertiary structure formation in the overall functional HSP70 protein, and is therefore prone to mutation (McKay et al. 1994). The overall evidence indicates that the sequence obtained from *H. rubra* was in fact that from the heat-induced HSP70.

The two larger fragments PCR amplified from cDNA (viz 1400 bp and 480 bp) show that we now have tools to further investigate the nature of the HSR in abalone. Sequence data, particularly of the 3′ end of an induced HSP70, would provide probes for future use in expression patterns of HSP70 mRNA and HSP70 proteins during stress. Such techniques have been employed previously using HSP70, where a nucleic acid HSP70-binding-protein was detected (Raynes & Guerriero, 1998).

Overall, the current study has shown that abalone respond to heat stress with expression of HSP70. The identification of additional molecules induced by heat stress, and the identification of a constitutive HSC70, are still to be carried out. In addition, the physiological factors responsible for the difference in volume regulation ability between bay and oceanic abalone remain to be elucidated.

LOCATION OF EGG-LAYING HORMONE IN REPRODUCTIVE STRUCTURES AND NEURONS OF *HALIOTIS RUBRA* (LEACH) USING ANTIBODIES RAISED AGAINST RECOMBINANT FUSION PROTEINS

SCOTT CUMMINS,[1] AMPORN THONGKUKIATKUL,[2] AND PETER J. HANNA[1,*]
[1]*School of Biological & Chemical Sciences, Deakin University, Geelong, VIC 3217, Australia;*
[2]*Department of Biology, Burapha University, Bangsaen, Chonburi, Thailand*

ABSTRACT Recombinant abalone egg-laying hormone was produced using a bacterial expression vector. This required directional cloning of a 108-bp abalone egg-laying hormone (aELH) gene sequence, using PCR of genomic DNA with primers incorporating restriction enzyme sites, into a pGEX-2T vector. Following transformation of the recombinant vector into *Escherichia coli*, a GST:aELH fusion protein was produced in large quantities and then purified. This fusion peptide was used to immunize mice for the production of polyclonal and monoclonal antibodies, which were subsequently tested for specificity using ELISA's and Western blots. Antisera and two IgM monoclonal antibodies were shown to react with aELH. These antibodies were used in immunocytochemistry studies of neural and gonad tissues of sexually mature female abalone. The aELH was found to be located in neurosecretory cells of cerebral and pleuro-pedal ganglia, statocysts, and trabeculae in female gonads.

KEY WORDS: egg-laying hormone, aELH, fusion protein, monoclonal antibodies, immunocytochemistry

INTRODUCTION

Immunocytochemistry has previously been used to characterize central neurons which react to antibodies raised against neuropeptides, including the α-caudodorsal cell peptide (α-CDCP) and caudodorsal cell hormone (CDCH) in *Lymnaea stagnalis*, and corresponding egg-laying hormone (ELH) in *Aplysia californica* (Van Minnen et al. 1989, Nambu & Scheller 1986). These antibodies allowed the identification of the neurosecretory cells controlling egg laying. In *Lymnaea*, the neurosecretory cells are located within the caudo dorsal cells (CDC) of the cerebral ganglia. The CDCs are arranged in two clusters in the left and right cerebral ganglia. In *Aplysia*, bag cells of the abdominal ganglion appear immunoreactive for ELH. The bag cells consist of two clusters of 250 to 400 cells located in the abdominal ganglion, near the origin of the pleurovisceral connectives.

Further investigations have indicated that the egg-laying preprohormone is relatively conserved across a wide range of molluscan classes (Nambu & Scheller 1986), resulting in the identification of additional peptides associated with neurons, which possibly control egg-laying and egg-laying behavior. Van Minnen et al (1992) have found that a number of gastropod molluscs, including *Helix aspersa*, *Biomphalaria glabrata* and *Limax maximus*, contain immunoreactive proteins using antibodies raised against α-CDCP, a short peptide within the CDCH preprohormone. Using these antibodies, as well as antibodies against CDCH in cross-reaction studies, it has also been shown that neurons in the bivalves *Mytilus*, *Mya* and *Placopecten* also contain a similar vitellogenic factor (Croll et al. 1993). These selective immunological markers, therefore, suggest that related peptides may be involved in the egg laying of a wide range of gastropod and bivalve molluscs.

In addition, peptides immunoreactive to antisera specifically directed against CDCH, α-CDCH and β-CDCH (another short peptide in the CDCH preprohormone), have been detected in the central nervous system of the rhyonobdellid leech, *Theromyzon tessulatum* (Salzet et al. 1997). As well, it has been shown that polyclonal antisera directed against the same three peptides results in positive immunoreaction in *Sarcophaga bullata* (Diptera), *Leptinotarsa decemlineata* (Coleoptera), *Locusta migratoria* and *Periplaneta americana* (Orthoptera) (Theunis et al. 1990).

Abalones are classified as primitive gastropods and have a nervous system containing cerebral ganglia rather than a defined brain. Nerve cords and connectives lead from the cerebral ganglia, two of which join to a single pleuro-pedal ganglion. This ganglion is composed of fused pleural and pedal ganglia, both of which are elongated and flattened (Crofts 1929). A common feature of all these ganglia is the possession of an outer cortex of ganglion neurons and glial cells surrounding a central neuropil. The small neuronal cells and glial cells lie below the surface layer but do not extend into the neuropil.

Neurosecretion in the cerebral ganglia was investigated in *H. discus hannai*, in order to determine the role of hormones in the regulation of reproduction (Hahn 1994). The study showed that four types of cells exist in the cerebral ganglia, and these were defined as cell types A, B, C and D, of which only cell types A and B appear to be neurosecretory. Cell type A shows a correlation with vitellogenesis and gametogenesis in the ovary (Hahn 1994). More recently, similar neurosecretory cells of cerebral ganglia have been identified in *H. asinina* (Upatham et al. 1998). In other experiments, Yahata (1973) induced spawning of abalone by injection of homogenized pleuro-pedal and visceral ganglia of mature females, indicating the existence of an egg-laying hormone. However, injections of homogenized cerebral ganglia produced no notable change in the ovaries. Despite these cytological and physiological studies indicating the existence of sets of neurosecretory cells in the ganglia, there is no definitive evidence that peptides produced in these cells are regulating reproduction and growth.

The nucleotide sequence of an abalone ELH (aELH) has been recently obtained for *H. rubra* (Wang & Hanna 1998), and other abalone sequences (Hanna et al. 2000), all of which show high homology. Fig. 1 shows the egg-laying precursor peptide arrangements of *L. stagnalis* and *A. californica*, together with the location of the sequence encoding the aELH of *H. rubra*. The nucleotide homology of the aELH is 94% compared with the CDCH of *L. stagnalis* and 56% compared with the ELH of *A. californica*.

Despite this, very little is known about the regulation of egg-laying hormones during reproductive cycles in the genus *Haliotis*, and the sites at which aELH is expressed. Therefore, research was

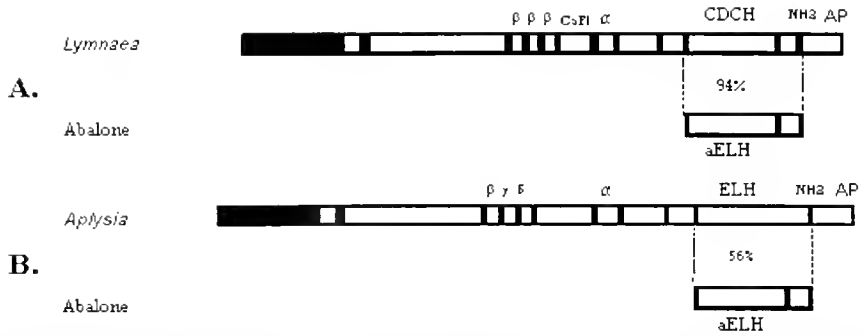

Figure 1. Comparison of *Lymnaea* CDCH (A, Vreugdenhil et al. 1988) and *Aplysia* (B, Scheller et al. 1982) egg-laying preprohormone sequences with the known abalone sequence. NH2 represents a potential amidation signal. Percentage nucleotide homology between corresponding regions are indicated. Positions of potential peptides are indicated by β_{1-3}-CDCP/β-BCP, γ-BCP, α-CDCP/αBCP, δ-BCP, calfluxin (CaFl) and an acidic peptide (AP). Known or potential cleavage sites are shown with black bars, and the larger black regions (left) represents signal sequences at the 5′ region.

carried out to develop antibodies for subsequent use in immunological techniques to locate cells producing egg-laying hormone within abalone neural and reproductive organs.

MATERIALS AND METHODS

Recombinant Protein Expression and Purification

Recombinant aELH was expressed in large quantities and purified by the use of a pGEX-2T (Amersham) expression vector in which the 108-bp egg-laying hormone sequence of *H rubra* had been inserted (Wang & Hanna 1998). This recombinant plasmid was transformed into *E. coli* competent cells and colonies selected on LB medium containing ampicillin. A 10-mL bottle of prewarmed 2× LB/Amp medium was loop inoculated with cells from one colony, and incubated at 37°C with shaking overnight. This culture was transferred into 1 L of the same medium and grown at 37°C with shaking until A_{600} reached 0.5-0.2. Bacterial fusion proteins were induced by adding 0.5 mL of 100mM IPTG with incubation for another three to five hours. The culture was centrifuged at 8,000 rpm for 5 min at 4°C (Beckman, JA-20) in 40-mL conical flasks. The supernatants were discarded and the tubes placed on ice. The pellets were resuspended in ice-cold PBS and the cells sonicated for five 30-second intervals on ice, ensuring that no frothing occurred. Immediately following this, 10% Triton X-100 was added to make final concentrations of 1% and the solutions were then incubated for 30 minutes with gentle mixing on ice to aid in solubilization of fusion protein. The suspensions were centrifuged at 10,000 rpm for 10 min at 4°C and supernatants transferred to 50-mL centrifuge tubes. Glutathione sepharose 4B beads were mixed with each 100 mL of sonicate and the contents left to stand for one hour. The glutathione sepharose 4B beads with fusion protein were sedimented by centrifugation and the supernatant collected for later reference. Ice-cold PBS was added and beads washed three times by repeated centrifugations. The fusion protein was then eluted with glutathione elution buffer, and analysis of fusion protein was performed by SDS-PAGE and Coomassie blue staining.

Production of Antibodies

Antigens used in primary immunizations were prepared by mixing 50 μg of the fusion protein with an equal volume of Freund's complete adjuvant (Sigma). BALB/c mice were then immunized intraperitoneally. Subsequent immunizations were performed each wk, for 3 wks, using the same dose of fusion protein but mixed with Freund's incomplete adjuvant (Sigma).

Polyclonal antisera were obtained by tail-bleeding mice and stored for use when ELISA end-point titres of >10,000 were obtained. For immunocytochemical studies, antisera were diluted 1/500 to 1/5000. Monoclonal antibodies were prepared four days after the last injection of immune mice, using standard techniques (Goding 1987). The mice were killed by cervical dislocation and the spleens removed aseptically. Spleen cells were fused with Sp2/0-Ag-14 myeloma cells using PEG 4000. The supernatants of the hybridomas surviving the selective medium consisting of RPMI 1640, bovine fetal calf serum and HAT, were tested for the presence of specific antibodies by means of ELISA. Antibodies secreted from positive clones were isotyped and the cells re-cloned twice to ensure monoclonality.

Quantification and Specificity of Antibodies in ELISA

ELISAs were undertaken to determine the titre of anti-aELH sera obtained from mice and for screening hybridomas and specificity of reaction with antigen. Antigen concentrations, which were calibrated to 20 μg/ml, consisted of expressed GST-aELH fusion protein or expressed GST.

The wells of a microtitre plate (Bio-Services) were coated with 50 μL of antigen solution, which was allowed to adsorb to the plate at 4°C overnight. Unoccupied binding sites on the plates were blocked with 1% BSA in coating buffer for one hour at 37°C. The plates were then washed three times in washing buffer and incubated with 50 μL of polyclonal antiserum diluted to 1:50, 1:100, 1:500, 1:1000, 1:5000 and 1:10000, in incubation buffer at 37°C for one hour. Supernatants of hybridomas were substituted for the antisera in additional tests. For the detection of bound antibody, plates were washed three times in washing buffer and incubated for one hour at 37°C with 50 μL per well of a secondary alkaline phosphatase labeled antibody (Sigma) diluted 1000-fold in incubation buffer. Plates were then washed three times in washing buffer and reacted with a 50 μg/mL solution of the enzyme substrate. After 100 min of color development, the plates were read on an automated ELISA plate reader (Titertek Multiskan MCC/340) at 405 nm.

Dissection of Abalone Tissues

Live female *H. rubra* (Leach) with mature gonads were collected under a research permit (97/R/049A), during the months

September to November. If not used immediately they were transferred to an abalone aquaculture facility where they were kept for no more than 5 days under a 12-h light/12-h dark cycle. Animals were removed from the shell prior to dissection.

To remove the left and right cerebral ganglia (cg), a blunt probe was used to separate the tissues from each side of the head. The cg with two nerves protruding was then detached. Next, the pleuropedal ganglia (ppg) and statocysts were exposed by removing all organs in the head cavity with a scalpel and then removed from within the muscle tissue. A piece of female gonad was also removed from the conical end of the organ.

Fixation and Sectioning of Tissues

After dissecting out the ganglia and pieces of gonad, they were fixed in freshly prepared 4% paraformaldehyde at 4°C for 24 h. They were then transferred to phosphate buffer, and stored at 4°C before further processing.

Prior to cryosectioning, tissues were transferred to 30% sucrose in phosphate buffer and stored overnight at 4°C. The preparations were then frozen in TissueTek (Bayer Diagnostics) in the cryostat at −20°C and subsequently sectioned at 6 μm. Alternate sections were placed on separate slides so that different antibodies or control procedures could be compared. Slides were then stored at −80°C, until required.

Western Blots

Standard SDS-PAGE of expressed GST and GST-aELH were carried out prior to Western transfer of the proteins onto 0.45 μm nitrocellulose membranes. The membranes were then reacted with antisera or mAbs to determine the sizes of antigenic proteins.

Fresh tissues of cg, ppg and gonad were used to prepare total protein extracts using TriPure isolation reagent (Roche), according to the manufacturer's instructions. These extracts were separated on SDS-PAGE. Proteins were transferred, as before, and probed with antisera or mAbs.

Immunocytoehemistry

A DAKO LSAB2 (streptavidin-biotin labeled) kit was utilized to identify the location of aELH in sections. Initially, sections were heated in buffered citrate (pH 6.0) to enable antigen retrieval. To prevent endogenous peroxidase activity, the slides were treated with 3% hydrogen peroxide, after which, primary antibody (diluted polyclonal or monoclonal in ascites fluid) was added and the slides incubated for 1 h at RT. After washing with PBS, biotinylated anti-mouse immunoglobulins were added and the slides incubated for 30 min at RT. After a brief washing, two drops of streptavidin peroxidase were added and another incubation carried out at RT for 20 min. During this step, a fresh solution of 3-amino-9-ethylcarbazole (AEC) chromogen was prepared. The chromogen was added after another washing and a further incubation at RT for 3 to 5 min performed, before being examined for color development. When appropriate, color development was stopped by washing the slides in distilled water, a counterstain in Mayer's haematoxylin performed, and the slides washed again and before mounting in Faramount aqueous mounting solution (DAKO). Digital images were then taken using a Zeiss Axioskop MC 80.

Immunofluorescence was performed on stored frozen sections. The sections were allowed to thaw at RT for 30 min before blocking, first in 1% glycine for 30 min, then in 4% BSA for 30 min. They were rinsed three times in PBS, and then incubated for 1 h at room temperature in primary antibody (i.e. polyclonal or monoclonal). After three rinses in PBS, they were incubated in FITC-labeled goat anti-mouse secondary antibody (Silenus) in the dark at RT for 1 h, and then rinsed three more times in PBS, before mounting in FITC mounting solution. Sections were viewed under blue light with a Zeiss Axioskop MC 80 microscope and images recorded.

Negative control procedures included the omission of primary antibodies and preadsorbing the anti-aELH antibody with recombinant aELH.

RESULTS

Monoclonal Antibodies

Table 1 shows the properties of five monoclonal antibodies (mAbs) that were produced with medium to strong reactions in ELISA and immunofluorescence testing. MAbs with weak reactions were discarded. Three mAbs (i.e. F61P3E3, F62P1A1 and F62P6D4) reacted with the GST component of expressed GST-aELH fusion protein as well as expressed GST. The other two mAbs (i.e. F61P1A5 and F62P4C1) reacted with the aELH component of expressed GST-aELH fusion protein. It was unusual that most of the mAbs were IgM as a period of four days from the last immunization of peptide to the production of mAbs would have allowed for class-switching of cells from IgM to IgG's.

Specificities of mAbs were also confirmed using Western blots of expressed GST and GST-aELH fusion proteins (data not shown).

Western Blots of aELH in Abalone Tissues

The results of Western blots of cg, ppg and mature female gonad proteins are shown in Fig. 2. There were no bands at approximately 4 kDa, the estimated size of aELH (36 amino acid residues deduced from a 108 nucleotide sequence), in any of the four experimental lanes. This absence may be attributed to the small size of the aELH (i.e. 4 kDa) and relatively small amounts present, compared with the total protein present. However, the cg showed 6 bands of sizes ranging from 24 to >77 kDa, the ppg 3 bands of which two were between 34 and 48 kDa and the other >77 kDa, and the gonad showed two bands between 34 and 40 kDa. The presence of these multi-bands indicates the different processing of preprohormones in the tissues and/or the presence of multigene products.

TABLE 1.

Monoclonal antibodies produced and their properties

Monoclonal Antibody	Isotype	Specificity in ELISA	Reactivity using Immunofluorescence
F61P3E3	IgM	GST	+++
F62P1A1	IgM	GST	++
F62P6D4	IgG_1	GST	+++
F61P1A5	IgM	aELH	++
F62P4C1	IgM	aELH	++

+++, strong reaction; ++, medium reaction; +, weak reaction (mAb discarded)

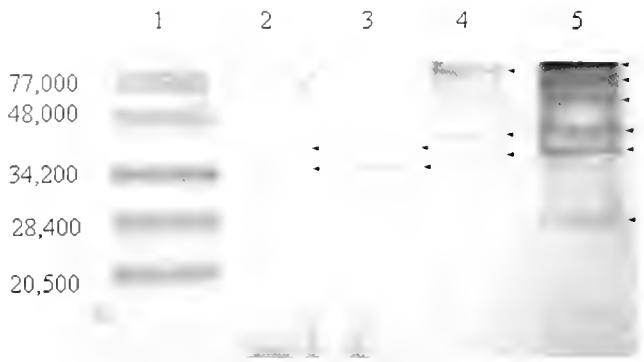

Figure 2. Western blots of proteins from *H. rubra* tissues using anti-aELH antibodies. Lanes: 1, pre-stained molecular weight markers (Bio-Rad); 2 & 3 mature female gonad; 4, pleuro-pedal ganglia; 5, cerebral ganglia.

Immunocytochemistry

A brick-red precipitate of the immunological test, together with a blue haemotoxylin counter stain, gave clear indications of antigen location. We had initially used 3,3′ diamino-benzidine tetrahydrochloride (DAB) in the final reaction, to give a brown precipitate, but found that there were endogenous brown pigments in control tissues (data not shown). This made it difficult to determine the location of the immune reaction, so this method was substituted by the AEC substrate to give a clearer result.

Consequently, immunopositive reactions were observed in eg, ppg, and mature female gonads (Fig. 3). However, there were marked differences in each of the structures. The cells reacting in the eg were equivalent to the NS1 neurosecretory cells observed by Upatham et al. (1998). In the ppg, peripheral neurosecretory cells have also been identified by the same group (unpublished), and our current work showed these cells immunoreactive. Immunoreactive material was also observed around the statocysts. In the gonads, a small number of cells spread throughout the trabeculae showed strong immunoreactions.

The results obtained using immunofluorescence location of aELH were the same as for immunoenzyme staining (Fig. 3).

DISCUSSION

Production of immunocytochemical probes has relied extensively on the use of native protein to provide specific polyclonal and monoclonal antibodies. However, there has been a transgression toward the use of synthetic or recombinantly expressed proteins, to facilitate antibody probe production. The advantage of these proteins is three-fold: large amounts of protein can be produced; only partial sequence data needs to be obtained; and laborious protein purification techniques can be avoided. In this study, the aELH sequence data obtained (Wang & Hanna 1998) was used for the *in vitro* expression and subsequent immunization of experimental animals. Antibodies were then produced that with immunoreactivity toward the recombinant protein in ELISA. However, further analyses were required to determine immunoreactivity to native protein *in vivo*, and this was ratified by immunocytochemical studies. This was not unexpected as previous studies have shown that antibodies raised against native ELH protein of *Aplysia* is immunoreactive against a synthetic ELH peptide.

In addition to ELISA, further specificity of the monoclonal and polyclonal antibody immunoreactivity to aELH was achieved by Western blots. These confirmed that the antibody probes were reactive to a protein extracts from the central nervous system and the gonad. The antibodies against aELH recognized proteins of various sizes within gonad, cerebral and pleuro-pedal ganglia extracts. This indicates that there are a number of polypeptides of different sizes, each containing the aELH peptide component. These bands probably represent differential cell processing of the polypeptides, typical of that found in *A. californica* (Fisher et al. 1988). They showed by Western blot analysis that antibodies recognized small final-product peptides, intermediates in the processing pathway which contain the sequence used as the immunogen, and also the large prohormone. However, the multi-band data may also be the result of the presence of a multigene aELH family, the genes of which are expressed in different tissues. We have preliminary data (unpublished) indicating that abalone have several genes encoding aELH. Our data is consistent with the findings of Nambu and Scheller (1986), in their studies of *Alysia* genomes. They used Southern blotting, gene cloning and immunocytochemical techniques to identify and characterize ELH related genes. Overall, there is a need for a substantial investigation into the number of aELH related genes in the abalone genome, the cellular expression of these genes, and the processing of preprohormones in each tissue to give immunoreactive proteins of various sizes.

In vivo expression of the female *H. rubra* aELH was shown in our studies of sections of abalone tissues, using monoclonal and polyclonal antibodies. The aELH appeared to be localized to the NS1 cells within the cerebral, and were also found in pleuro-pedal ganglia, statocysts, and to the trabeculae of the gonad. Our data supports the previous research by Hahn (1994) and Upatham et al. (1998), in which they showed that differential staining could identify neurosecretory cell types in the cerebral ganglia. In addition, the cerebral ganglia of other molluscan species are known to be a major site of ELH-like expression (Croll et al. 1993, Van Minnen et al. 1992).

Immunoreactivity within the pleuro-pedal ganglia was not only localized to the cells of the periphery, but also the statocyst margins and interior. The statocyst is a chambered sense organ containing granules to sense the direction of gravity.

Despite extensive research being conducted on neuropeptide immunoreactivity within the central nervous system, little research has focused on the reproductive tissue. Our study, however, shows aELH located in the trabeculae of the mature pre-spawned female gonad. It was only located within certain cells, which may function to store aELH with the maturing gonad. It is postulated that a stimulus may act to release the hormone that acts directly on the smooth muscle of the gonad to release ova. Evidence from *Drosophila* shows that when a male mates and releases sperm, he also deposits an egg-laying hormone that induces egg-laying in the female (Park & Wolfner 1995). This hormone is related to the ones found in gastropods and other invertebrates.

The large amount of aELH expressed within the reproductively pre-spawned mature female may be a function of the gastropod requirement to release high concentrations of hormone into the hemolymph. It is known in molluscs that hormone release areas are high in number (Joosse 1979).

The antibodies we have produced can now be extended to further studies. They could be used to determine site-specific expression of aELH during the reproductive cycle *of H. rubra*, and other abalone species. Preliminary tests have indicated that they do react with the aELH in *H. asinina*. It would be interesting to determine if bioassays of gonads could quantify the presence aELH sufficiently to indicate spawning readiness. We are already doing bioassays with the aELH to induce spawning.

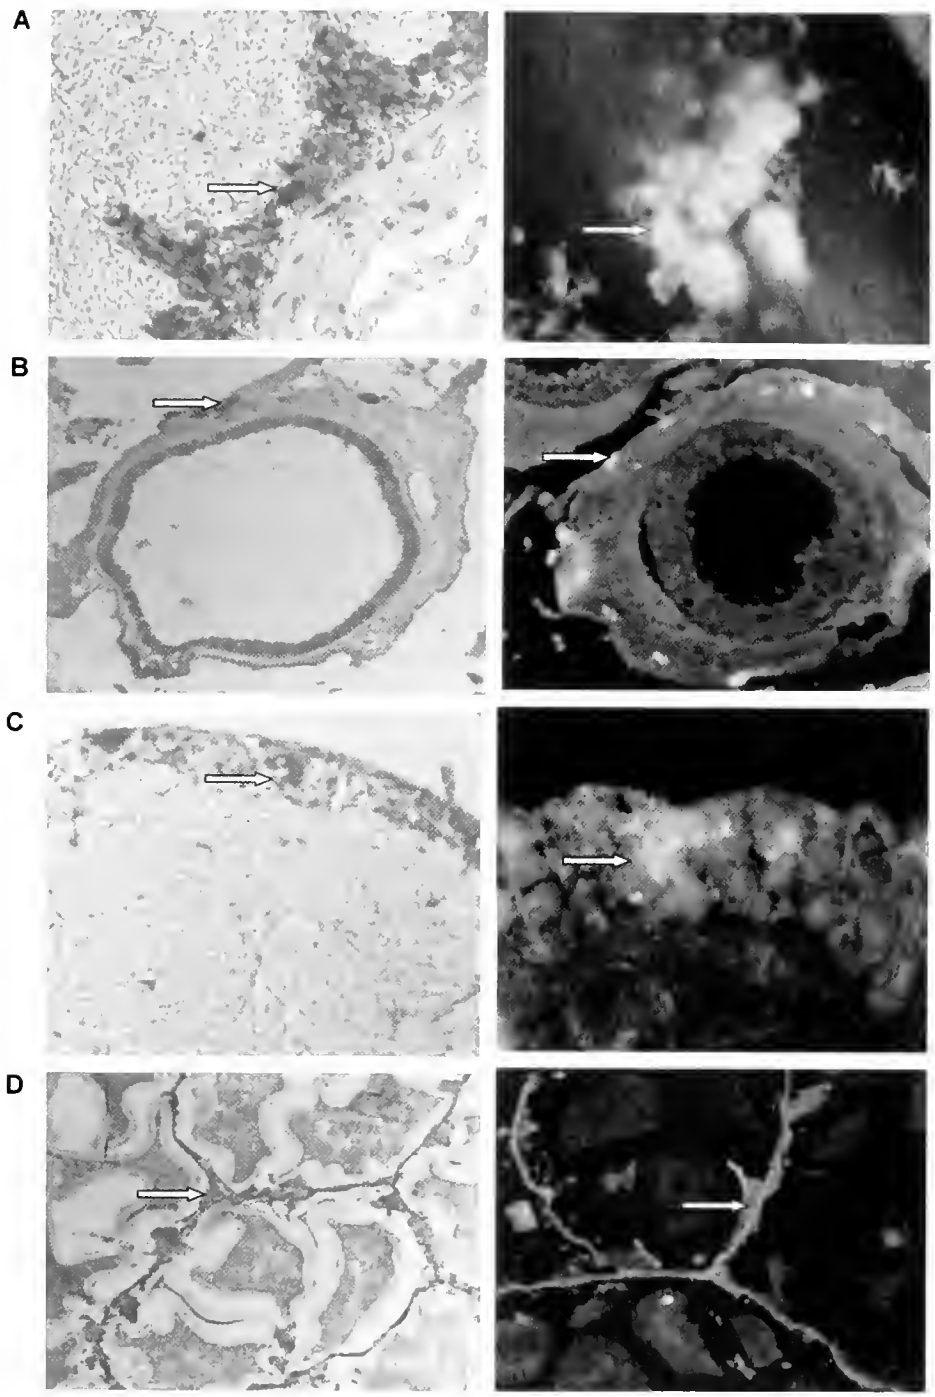

Figure 3. Localization of aELH in tissues of *H. rubra* using immunocytochemistry staining. Left: Tissues incubated with murine anti-aELH prior to detection using a DAKO LSAB2 kit to produce brick-red precipitate. Right: Tissues incubated with murine anti-aELH prior to detection using secondary incubation with FITC-conjugated goat anti-murine Ig to produce a green immunofluorescence under UV. A, immunoreactivity of aELH in cerebral ganglia; B, immunoreactivity of aELH in cells of a pleuro-pedal ganglia; C, immunopositive material around statocysts; D, immunopositive cells in the trabeculae of mature female gonads.

ABSTRACT The hemocytes of abalone (*Haliotis asinina*) were studied by light and electron microscopy in order to describe their main morphological features and to relate these to their role in immune defense. The cells are comprised of two differentiated types: agranulocyte or hyalinocyte and granulocyte. The hyalinocyte is characterized by the presence of several filopodia, a large nucleus with dense chromatin, a moderate amount of cytoplasm, microfilaments, oval and round-shaped mitochondria with rather dense matrix, a considerable amount of rough endoplasmic reticulum, few cytoplasmic granules, coated pits and vesicles, phagocytic vacuoles, and numerous large and small vacuoles. Like the hyalinocyte, the granulocyte possesses similar cytoplasmic organelles but in fewer number, and a peripheral organelle-free zone containing numerous dense granules of various types. The shape of the granules varies from round to oval to elongated forms. Several dense granules exhibit a crystalloid substructure that show close relationship to the plasma membrane. The average size of granulocytes is 9.68 ± 1.12 μm and hyalinocytes is 8.65 ± 0.77 μm.

KEY WORDS: *Haliotis asinina*, hemocytes

INTRODUCTION

Approximately 75 species of abalone have been reported in the world. Thailand harbors three species, namely, *Haliotis asinina*, *H. ovina*, and *H. varia* (Nateewatana and Hylleberge 1986, Tookvinart et al. 1986, Nateewatana and Bussarawit 1988). Among the three species, *H. asinina* is the biggest and has the most economic potential because of its large proportion of flesh and its good taste (Singhakriwan & Doi 1993). Due to the economic potential of this abalone species, a thorough understanding of the biology of *H. asinina* including its immune response is needed. In molluscs, hemocytes are involved in a variety of physiological and pathological functions including nutrient transport and digestion, wound and shell repair, internal defense, and exogenous and endogenous material excretion (Cheng 1981, Bayne 1983, Fisher 1986). In the literature, most of the morphological studies of molluscan hemocytes reported are of bivalve molluscs; only a few exist on abalone. There has been no study on the hemocytes of *H. asinina*. In this report, we studied the morphology of *H. asinina* hemocytes by using light and electron microscopy.

MATERIALS AND METHODS

Hemolymph was withdrawn from the cephalic arterial sinus of individual abalone and pooled. Pooled hemolymph was immediately poured into cold 2% glutaraldehyde in 0.1 M sodium cacodylate buffer pH 7.4, at 4°C, overnight. The hemocytes were centrifuged at 800 × g for 10 min at 25°C. The hemocyte pellets were post-fixed in 1% osmium tetroxide in 0.1 M sodium cacodylate

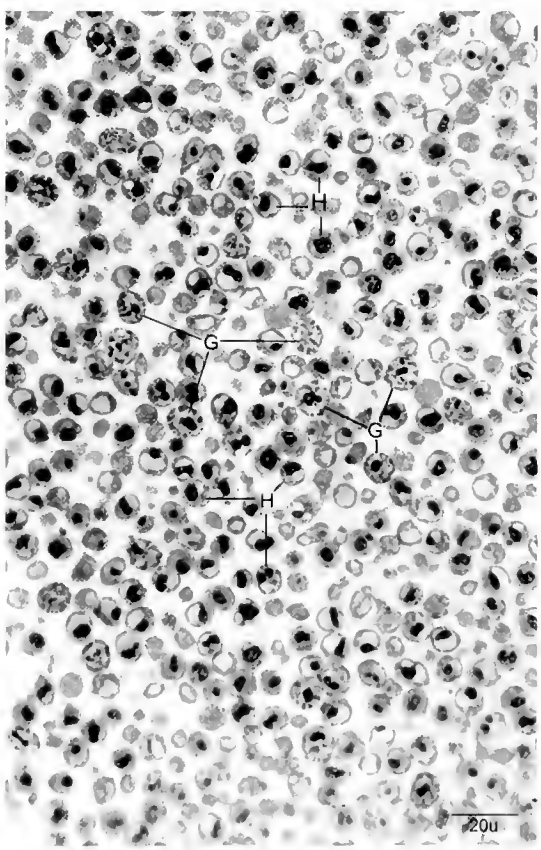

Figure 1. Semi-thin section of hemocytes of *H. asinina*, methylene blue stain. At this magnification, granulocytes (G) and hyalinocytes (H) are clearly differentiated.

*Corresponding author. E-mail address: sessh@mahidol.ac.th

buffer, at 4 C, for an additional 2 h. They were then washed with sodium cacodylate buffer, dehydrated in a graded series of alcohol, cleared in propylene oxide and embedded in Aradite 502 resin. Blocks were sectioned at one-micron thickness by an ultramicrotome and stained with methylene blue for light microscopic observation. Ultrathin sections were cut and stained with uranyl acetate and lead citrate and viewed by Hitachi TEM H-300 at 75 kV.

RESULTS

Light Microscopy

Micrographs of the semithin sections of the *H. asinina* hemocytes are shown in Figures 1 and 2. Two populations of hemocytes, granulocytes and agranulocytes or hyalinocytes, were observed based on the presence and the absence of cytoplasmic granules. The proportions of granulocytes and hyalinocytes are 11.43% and 88.57% in this present study, respectively.

Granulocytes are characterized by the presence of numerous cytoplasmic granules. The granules tend to be arranged at the periphery of the cell, thus leaving the clear zone around the nucleus. Most of the cells are spherical or slightly oval, the largest measured 13.15 μm (9.68 ± 1.12 μm in diameter on average) with some filopodia extending from the plasma membrane. The nucleus is round to oval shaped and centric with a rather small nucleus/cytoplasmic ratio. The maximum nuclear size is 4.70 μm with an average of 3.70 ± 0.59 μm. Some nuclei are bilobed, elongated and indented.

The agranulocytes or hyalinocytes are spherical or oval. They are characterized by large nuclei and contain one or two prominent clear cytoplasmic zones. The cells are only slightly smaller than the granulocytes. The largest cell measured 11.22 μm in diameter and the average size is 8.65 ± 0.77 μm. Similar to the granulocytes, the nuclear profiles were round or oval, with some bilobed and indented. Nuclei were both eccentrically and centrically placed. The maximum nuclear size of the hyalinocyte is 5.98 μm with an average of 4.70 ± 0.60 μm. The nucleus/cytoplasmic ratio was relatively larger than that of the granulocyte. Filopodia were clearly visible extending from the cell.

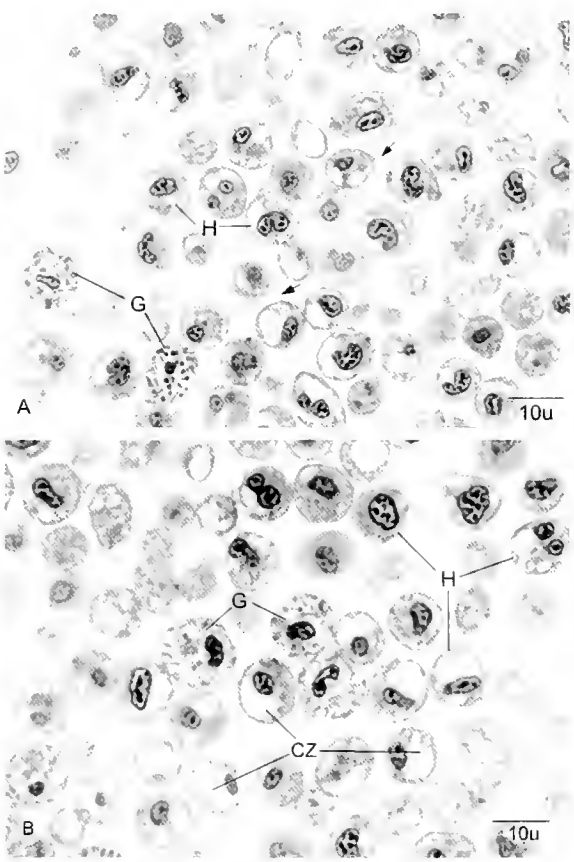

Figure 2. A–B. At higher magnification, more details are seen. Note the peripheral distribution of the granules and perinuclear clear area in the granulocytes, while large cytoplasmic clear zones (CZ) are seen in the hyalinocytes. Different shape, size and location of the nucleus in both granulocytes and hyalinocytes can be observed. Note also the filopodia (arrow) in both cell types.

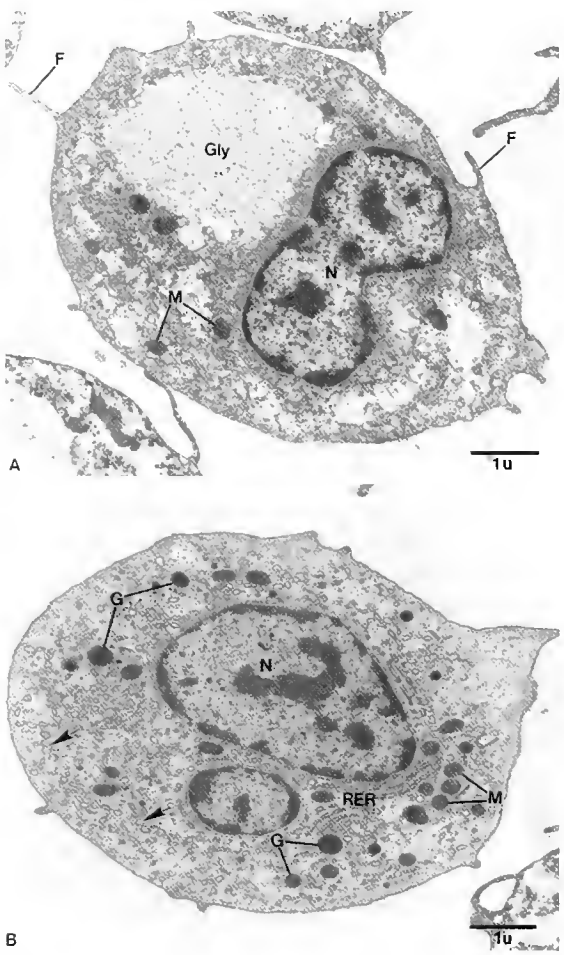

Figure 3. Electron micrographs of a hyalinocyte. A. Hyalinocyte showing bilobed nucleus (N) with moderate amount of heterochromatin. A lake of glycogen (Gly) is prominent. Few mitochondria (M) are seen. F, filopodia. B. In contrast to figure A, this hyalinocyte does not contain as prominent a glycogen area. There are few small round electron dense granules (G), rough endoplasmic reticulum (RER) and mitochondria (M). Note the presence of small vesicular bodies (arrow).

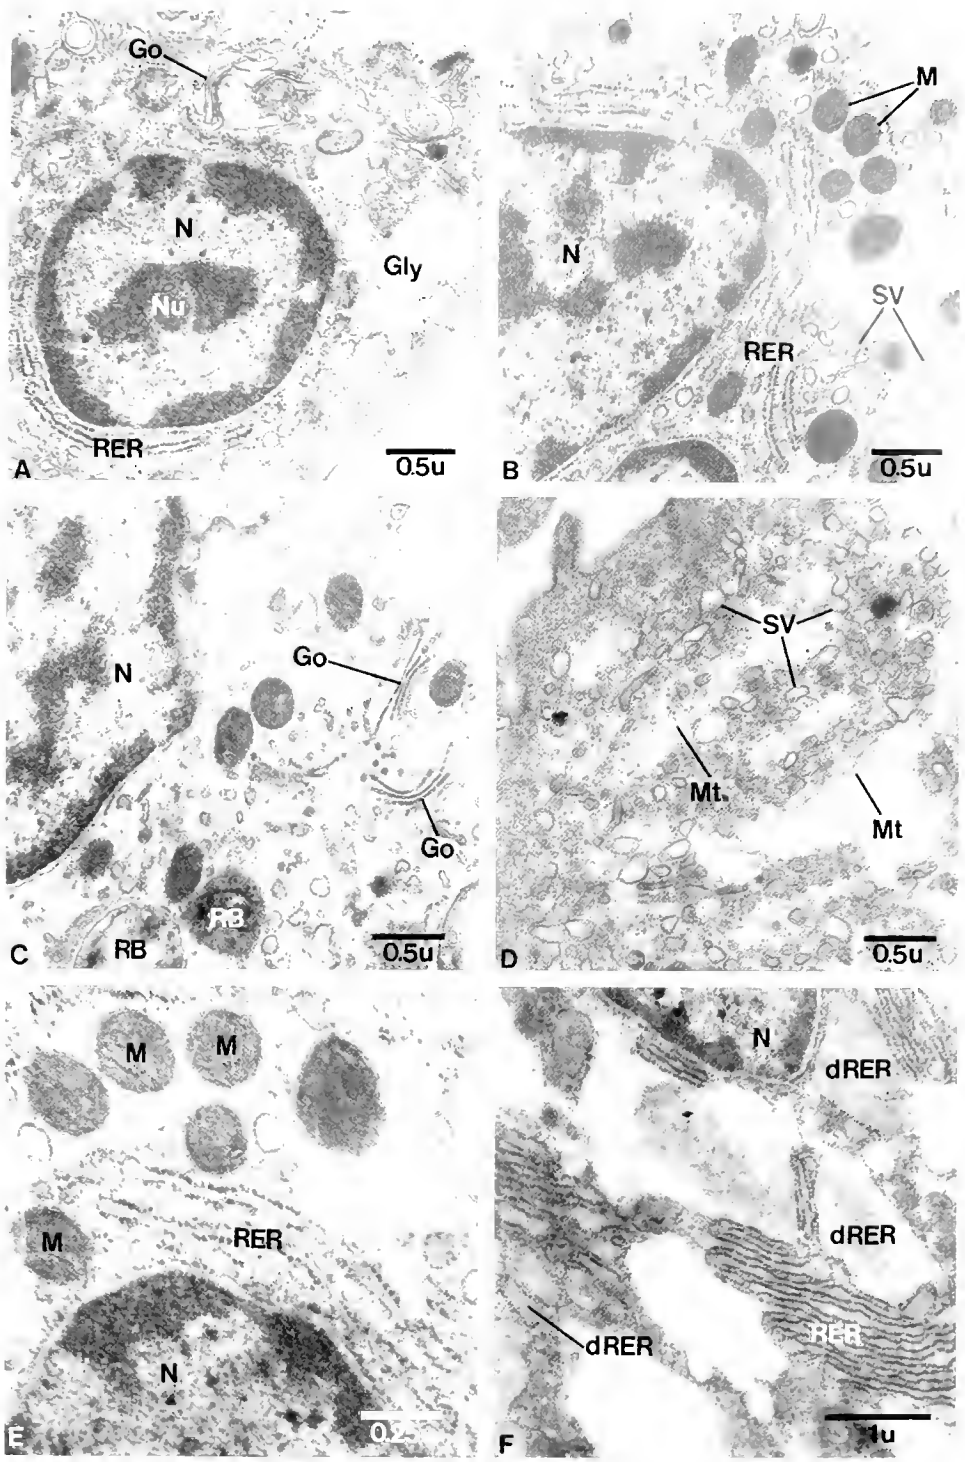

Figure 4. A series of electron micrographs showing details of some hyalinocyte organelles. A. Hyalinocyte with spherical nucleus (N) containing a moderate amount of chromatin and a prominent nucleolus (Nu). Note the presence of a glycogen area (Gly), Golgi apparatus (Go), and rough endoplasmic reticulum (RER). PM, plasma membrane. B. Hyalinocyte showing profiles of oval shape mitochondria (M) with rather dense matrix. Several small vesicles (SV) are also seen. M, mitochondria. N, nucleus. RER, rough endoplasmic reticulum. C. Well developed Golgi apparatus (Go) and residual bodies (RB) are seen here in this electron micrograph. Go, Golgi apparatus. N, nucleus. RB, residual body. D. Microtubules (Mt) and small vesicles (SV) are seen in the cytoplasm of the hyalinocyte. Mt, microtubule. SV, small vesicle. E. Mitochondria (M) with rather dense matrix are shown here with rough endoplasmic reticulum (RER). N, Nucleus. F. Hyalinocyte showing stack of rough endoplasmic reticulum (RER) and a few dilated endoplasmic reticulum (dRER) with light density amorphous material within cisternae. N, nucleus, RER, rough endoplasmic reticulum.

Electron Microscopy

The hyalinocyte is characterized by the presence of several filopodia, a large nucleus with dense chromatin and a moderate amount of cytoplasm Fig. 3. The mitochondria are round or oval in shape with rather dense matrix. A considerable amount of rough endoplasmic reticulum, Golgi apparatus, few cytoplasmic granules mostly of round shape, coated pits and vesicles, phagocytotic vacuoles, numerous large and small vacuoles including microfilaments were observed Fig. 4. When viewed by electron microscopy, the clear cytoplasmic zones observed by light microscopy corresponded to the areas composed mostly of unstained glycogen with some visible glycogen particles within. In some cells the pools of glycogen are quite large and seem to push the nuclei to the periphery.

Like hyalinocytes, the granulocyte possesses similar cytoplasmic organelles but in fewer numbers and a peripheral organelle free zone containing cytoplasmic granules of various shapes and sizes and various densities Fig. 5. The shapes of the granules vary from round, to oval to polyhedral elongated forms. The maximum size of the granule is 0.78 μm and the average size is 0.34 ± 0.11 μm. However, most of them are polyhedral elongated and only a few are spherical or oval. The close relationship of the granules and plasma membrane is noted. Some of the granules protruded from the plasma membrane Fig 6, while others coalesced or fused with the cell membrane. The nucleus is relatively small in size, round and located either eccentrically or centrically.

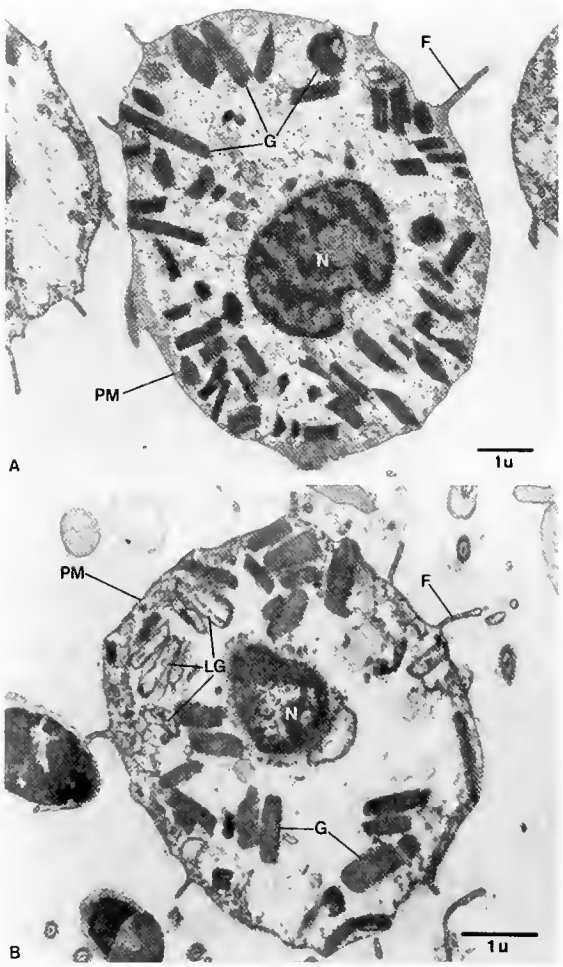

Figure 5. Electron micrographs of a granulocyte. A. Granulocyte showing different shapes and sizes of its granules. Note the peripheral distribution of the granules (G), several of them in close relationship with the plasma membrane (PM). As in hyalinocytes, the oval shaped nucleus contains moderate amount of heterochromatin. This cell is almost devoid of recognizable organelles. F, filopodia, N, nucleus. B. Variation of intragranular densities are illustrated in this micrograph from marked to light electron dense. The light granules (LG) contain intragranular inclusion bodies. F, filopodia, N, nucleus, PM, plasma membrane.

DISCUSSION

In this preliminary study on the hemocytes of the *H. asinina*, were composed of two differentiated cell types, the granular and the agranular or hyalinocytes. Cheng (1981) suggested that hemocytes should be designated as granulocytes and hyalinocytes. By using different techniques such as phase contrast microscopy, several fixatives and stains including electron microscopy, Foley and Cheng (1972), Foley and Cheng (1974), Cheng and Foley (1975), identified another cell type in the hemolymph of the bivalve mollusc, the fibrocyte. Fibrocytes were also described in the black abalone, *Haliotis cracherodii* (Shields et al. 1997).

In this study, we have shown that hyalinocytes contained very prominent areas or aggregates of glycogen. Cheng and Cali (1974) however reported that the granulocytes not the hyalinocytes contained a large aggregate of glycogen in the cytoplasm. This is in contrast to our findings in which we found glycogen primarily in the hyalinocytes Fig. 3B.

Of interest, is the observation of the close relationship of the granules of the granulocyte to the plasma membrane. Several granules protruded from the membrane and some fused with the membrane. This represents the process of releasing the content of the granules or most likely the lysosomes into the serum. The migration of the lysosome to the cell membrane and the extrusion from the granulocytes in *Mercenaria mercenaria* as evidenced by scanning and transmission electron microscopy were reported by Mohandas et al. (1985) and Mohandas and Cheng (1985). Fewer organelles observed in granulocytes indicate that when a cell becomes fully differentiated, reduction in the number of organelles accompanies this process.

This present study shows for the first time, the presence of two main types of hemocytes in *H. asinina*: hyalinocytes and granulocytes. We believe that the granules are the lysosomes based on the marked morphological resemblance to the lysosomal granules observed in the eosinophil. The particular function of each population in the defence mechanism in this species of abalone will be further studied.

ABSTRACT Trabeculae are the connective tissue sheets that extend perpendicularly from the outer capsules of both the testis and ovary to make contact at their innermost ends with the inner capsules separating the gonad from the hepatopancreas. Thus they divide the gonad into small compartments, and each trabecula forms the axis for individual spermatogenic or oogenic units, from which maturing germ cells are generated. When studied by light and electron microscopes, each trabecula is composed of central capillaries surrounded by muscle cells, collagen fibers, fibroblasts, and granulated cells that contain large rugby-shaped electron dense granules about 270 × 550 nm in size. The granulated cells branch extensively, and their processes become closely associated with bundles of nerve fibers that contain two types of granules, i.e., electron-dense and electron-lucent spherical-shaped granules with a diameter of about 165 nm and 150 nm, respectively. Thus, bundles of nerves and branches of granulated cells provide profuse innervation of the capsules and trabeculae. The granulated cells may be endocrine cells of the gonad which produce certain gonadotrophic factors yet to be identified.

KEY WORDS: *Haliotis asinina*, gonad, capsules, trabeculae, connective tissue cells, endocrine cells

INTRODUCTION

Studies on endocrinology of reproduction in molluscs present a number of interesting challenges because of a great variability of existing patterns. Most detailed studies of the modes of reproduction and corresponding endocrine controls have been carried out in *Aplysia* spp. (subclass Opisthobranchiata) and *Lymnaea* spp. (subclass Pulmonata) (Joose 1979, Joose 1988). In Prosobranchiata, including *Haliotis* spp., little is known about the reproductive hormones and their cellular origins. In molluscs studied so far, neurosecretory cells that are the putative sources of reproductive hormones, such as egg-laying hormone, are mostly localized in cerebral, pleuropedal and visceral ganglia (Bern & Hagadorn 1965, Dorsett 1986, Hahn 1994). The gonad represents another site where hormones controlling reproduction may be produced, as seen in the cases of Leydig cells and Copora luteal cells that lie in the connective tissue scaffold of vertebrates' gonad.

Our previous observations indicated a close association between cells in the connective tissue scaffold of the gonad of *H. asinina* and gamete cells during their development in various phases of the reproductive cycle (Sobhon et al. 1999). There are several types of cells present in the connective tissue of the gonad, including highly granulated cells with structural characteristics resembling those of endocrine cells (Apisawetakan et al. 1997, Sobhon et al. 1999). These observations together with the report by Chanpoo et al. (2000) strongly imply that reproductive hormones, such as egg-laying hormone, may also be produced intramurally within the connective tissue of the gonad by certain granulated cells. Moreover, there could be other cell types that are involved in the development of germ cells in the gonad that could evolve from the connective tissue compartment. Therefore, in the present study we have characterized various types of cells in the connective tissue scaffold of the gonad and attempted to define their possible functions.

MATERIALS AND METHODS

Collection of H. Asinina Specimens

Adult *H. asinina*, reared in the land-based culture system, were provided by the Coastal Aquaculture Development Center, Prachaubkirikhun province, Thailand. They were cultured in concrete tanks that were well flushed with a mechanically circulated water and air delivery system to maintain a stable environment. Seawater was pumped directly from the nearby bay and passed through subsand filter before use (Singhagraiwan & Doi 1993). The animals were fed a diet of macroalgae (usually *Gracilaria* spp. and *Laminaria* spp.), supplemented with artificial food.

Specimen Preparation

Gonads were cut into small pieces, fixed in Bouin's fluid, and prepared for light microscopic examination by the paraffin method. For sem-ithin sections and TEM studies, specimens were fixed in a solution of 3% glutaraldehyde in 0.1 M sodium cacodylate buffer pH 7.8 at 4°C overnight, postfixed in 1% osmium tetroxide in 0.1 M sodium cacodylate buffer at 4°C for 2 h, then dehydrated in graded series of ethanol, cleared in propylene oxide, infiltrated and embedded in Araldite 502 resin, which was finally polymerized at 30°C, 45°C and 60°C for 24, 48 and 48 h, respectively. The specimens were then semi-thin-sectioned at one-micron thickness in a Porter Blum MT-2 ultramicrotome, stained with Methylene Blue or PAS, and observed in an Olympus Vanox light microscope. Ultrathin sections were cut and stained with lead citrate-uranyl acetate and viewed under a Hitachi TEM H-300 at 75 kV.

RESULTS

Connective Tissue Scaffold of the Gonad

The connective tissue frameworks that support the gonad in *H. asinina* consist of the outer capsules surrounding the ovary and testis, and the inner capsules that separate the hepatopancreas from the surrounding gonadal tissues. Flat connective tissue sheets, called

trabeculae, extend perpendicularly from the outer gonadal capsules through the interior of the gonads to touch the inner capsules. As a result, the gonads are partitioned into small incomplete compartments (Fig. 1A and B). Each trabecula acts as the axis on which early and growing germ cells are closely attached (Fig. 1C and D), thus giving rise to a discrete gametogenic unit representing, perhaps, a clone of germ cells which may arise from a single group of gonial cells. In each trabecula, muscle cells (Fig. 2A and D) lying alongside the central capillaries and fibroblasts together with collagen fibrils form the trabecular core. Granulated cells, which may be endocrine cells, are distributed in rows along both sides of each trabecula, separated from the gonadal compartment by thick basal laminae (Fig. 4A–C).

The Gonadal Capsules

The connective tissue of the trabeculae blends imperceptibly with those of the outer and inner capsules. The outer gonadal capsule is 40–50 μm thick and consists of 10 layers of cells (Fig. 2A and B). It is covered externally by a single layer of cuboidal or columnar epithelium, which consists of 2 types of cells. Type 1 are the principal cells which are tightly adhered to each other (Fig. 3A

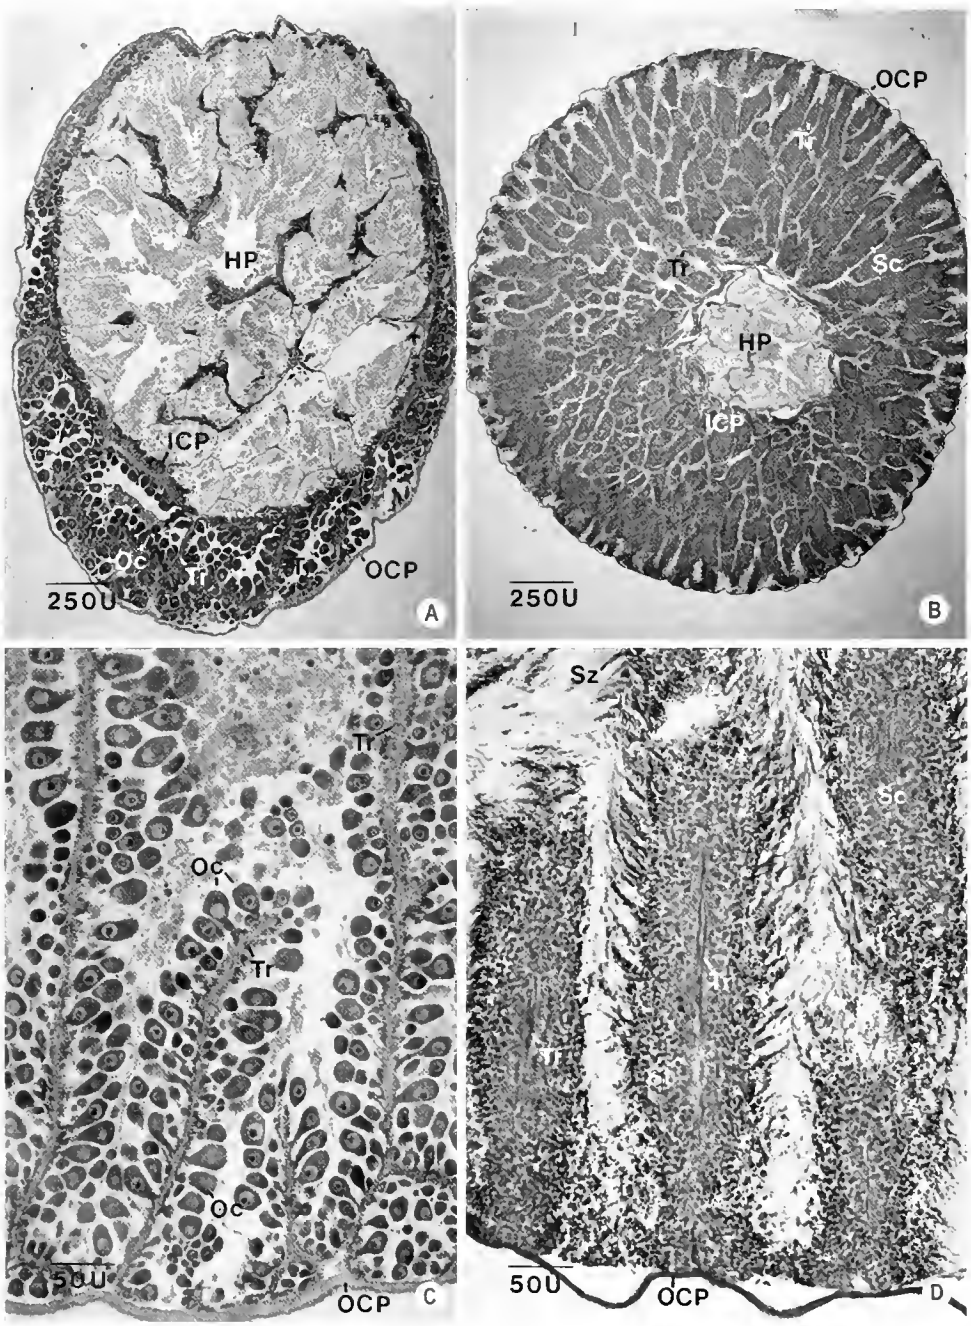

Figure 1. (A, B) Paraffin sections of an ovary (A) and testis (B) around the hepatopancreas (HP). Both organs are surrounded by outer and inner capsules (OCP, ICP), and trabeculae (Tr) form partitions between gonadal compartments. (C, D) Paraffin sections, showing oogenetic units of growing oocytes (Oc), and spermatogenic units of spermatocytes (Se), spermatids (St) and spermatozoa (Sz) around each trabecula (Tr).

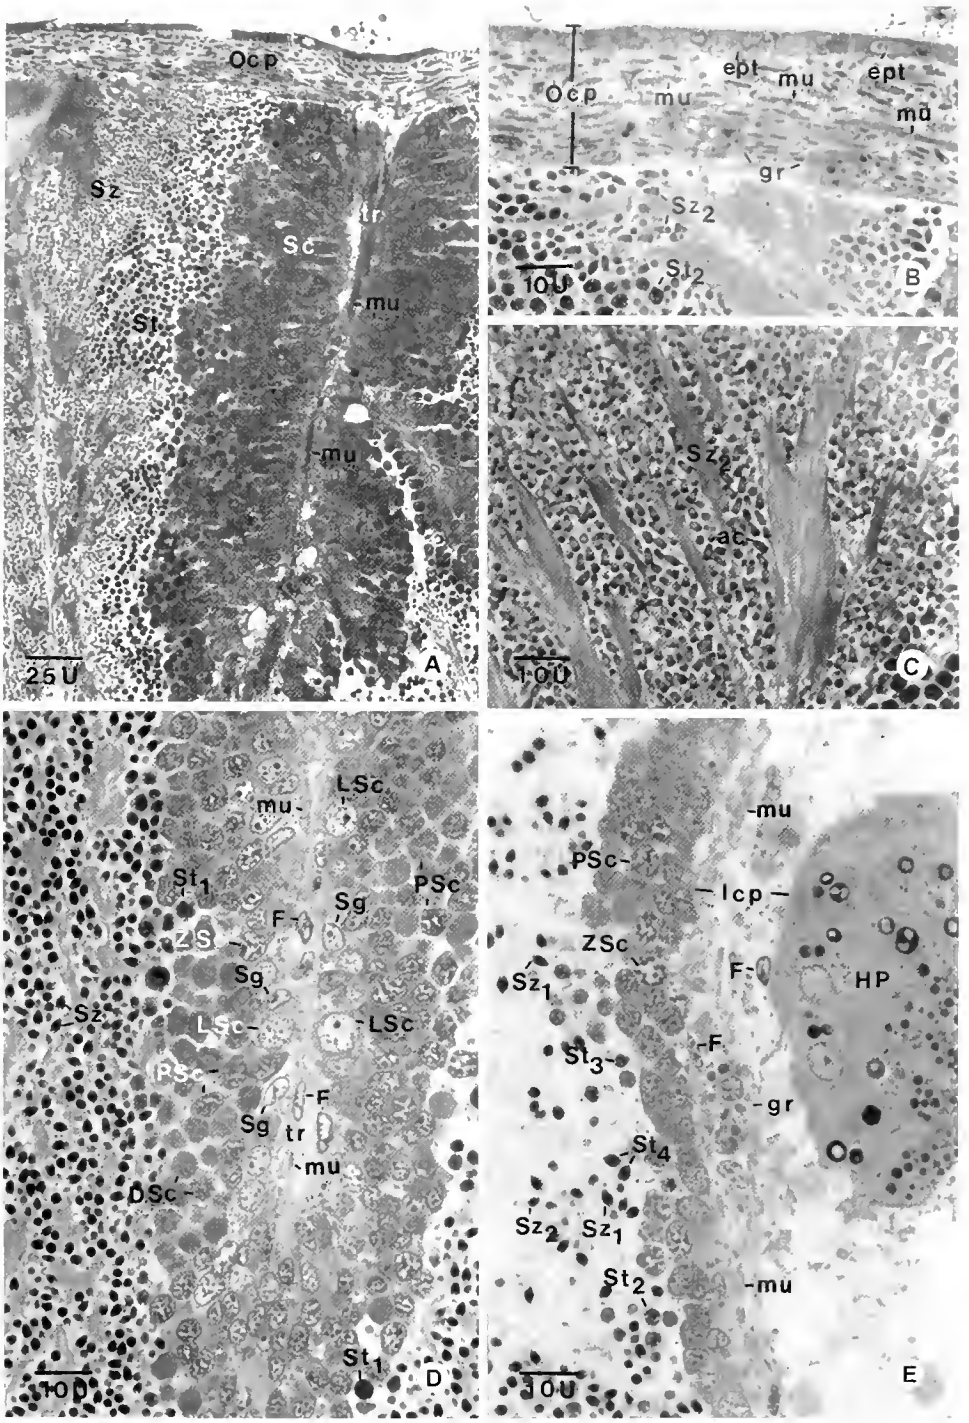

Figure 2. (A–C) Semithin sections of the testis stained with PAS, showing the outer capsule (OCP), and a spermatogenic unit around each trabecula (tr) (in A, B) and the accumulation of mature spermatozoa in the gonadal lumen (in C). In B, note that the outer capsule consists of cuboidal epithelium (ept) with alternate layers of muscle cells (mu) and collagen bundles. Granulated cells and their processes (gr) are present in large numbers. (D, E) Semithin sections of the testis stained with methylene blue, showing cellular components of trabeculae (in D) and the inner capsules (in E-ICP), and various stages of spermatogonia, spermatocytes, spermatids and spermatozoa surrounding the trabecula (Sg, LSc, PSc, ZSc, SSc, St, Sz) (granulated cells = gr; fibroblast = F; muscle cells = mu).

and B). The nuclei of these cells are elongated and have a thin rim of heterochromatin along the inner facet of the nuclear envelopes, and prominent nucleoli. There are large connecting blocks of heterochromatin scattered throughout the inner part of the nuclei. The cytoplasm is filled up with rough endoplasmic reticulum, and the apical cytoplasm contains a few dense irregular bodies that appear like lysosomes. The outer surface of the cells bears numerous microvilli. Type 2 are the goblet-like cells, whose apical cytoplasm is filled with moderately dense spherical granules, each about 600–650 nm in diameter (Fig. 3A and C). The nuclei of these cells are

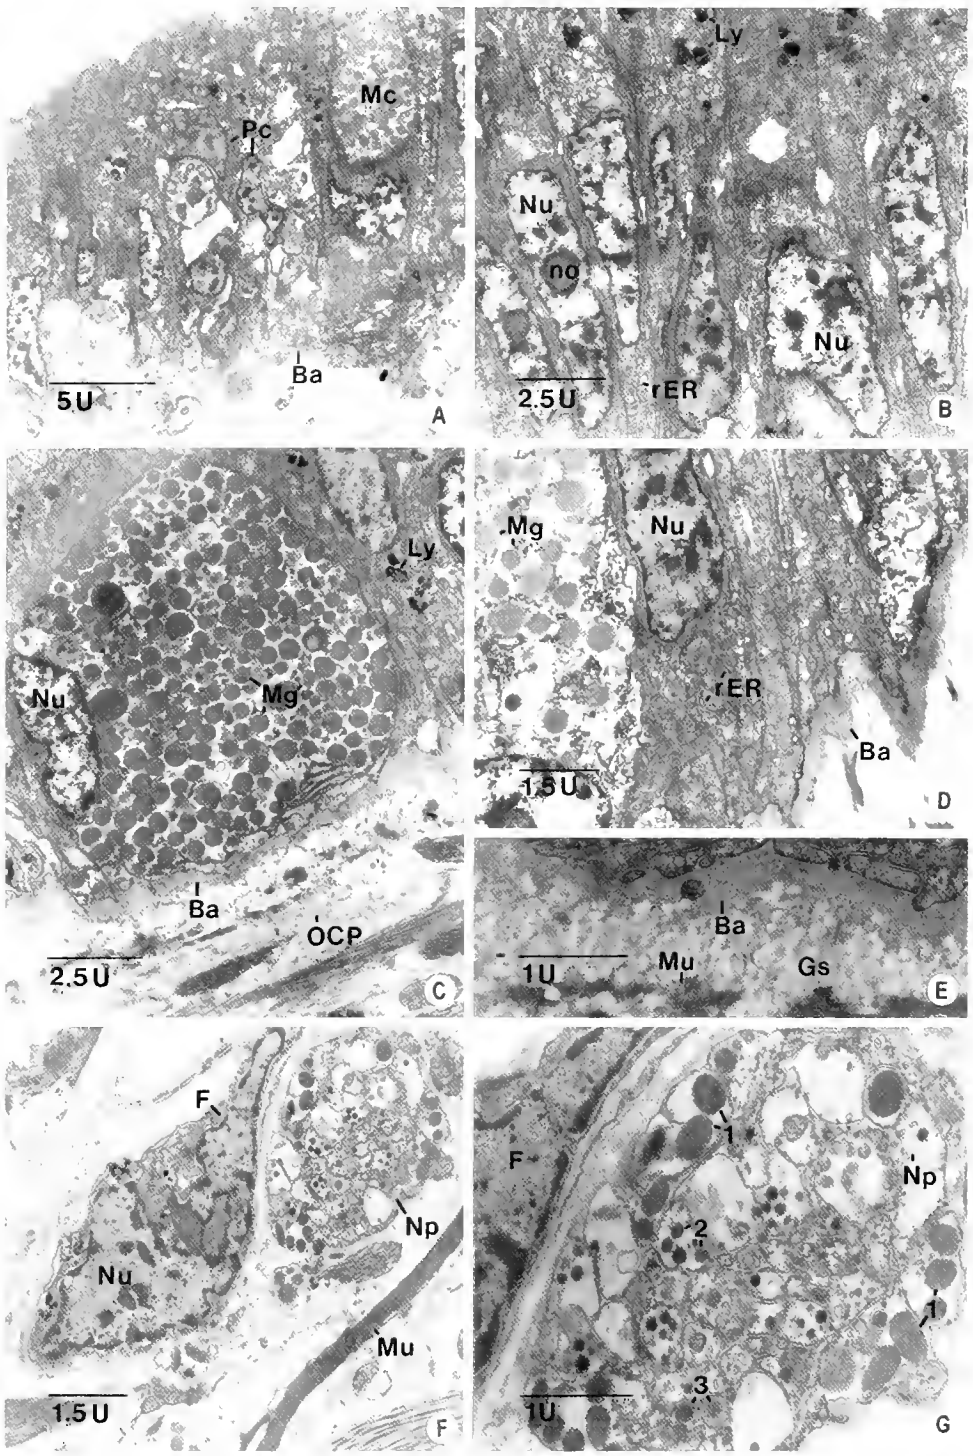

Figure 3. TEM micrographs of epithelium covering the surface of the outer capsule. (A–D) Principal cells (Pc) and mucous cells (Mc): the former are columnar or cuboidal-shaped cells tightly adhered together. Their cytoplasm contain numerous rough endoplasmic reticulum (rER) and lysosome-liked granules (Ly). Mucous cells contain abundant mucin granules (Mg) that fill up the apical cytoplasm. (E) The thick basal lamina (Ba) supporting surface epithelium, and layers of ground substance (Gs) and muscle cells (Mu). (F, G) Fibroblasts (F), and nerve bundles (Np) that innervate the outer capsule. In G, nerve processes containing dense and light spherical granules, about 165 and 150 nm in diameter (2, 3) respectively, are surrounded by processes of granulated containing large rugby-shaped granules about 270 × 550 nm in size (1).

eccentrically located toward the bottom, and they appear fairly similar to those of the first cell type. Both types of cells rest on a very thick basal lamina about 550 nm in width (Fig. 3A and D) which contains a meshwork of very fine filaments (Fig. 3E). Internal to the basal lamina are alternate layers of spindle-shaped muscle cells and the extracellular matrix which appears homogeneous and electron-lucent (Fig. 2B and Fig. 3E–3F). Among this extracellular matrix are fibroblasts, collagen fibrils, and small

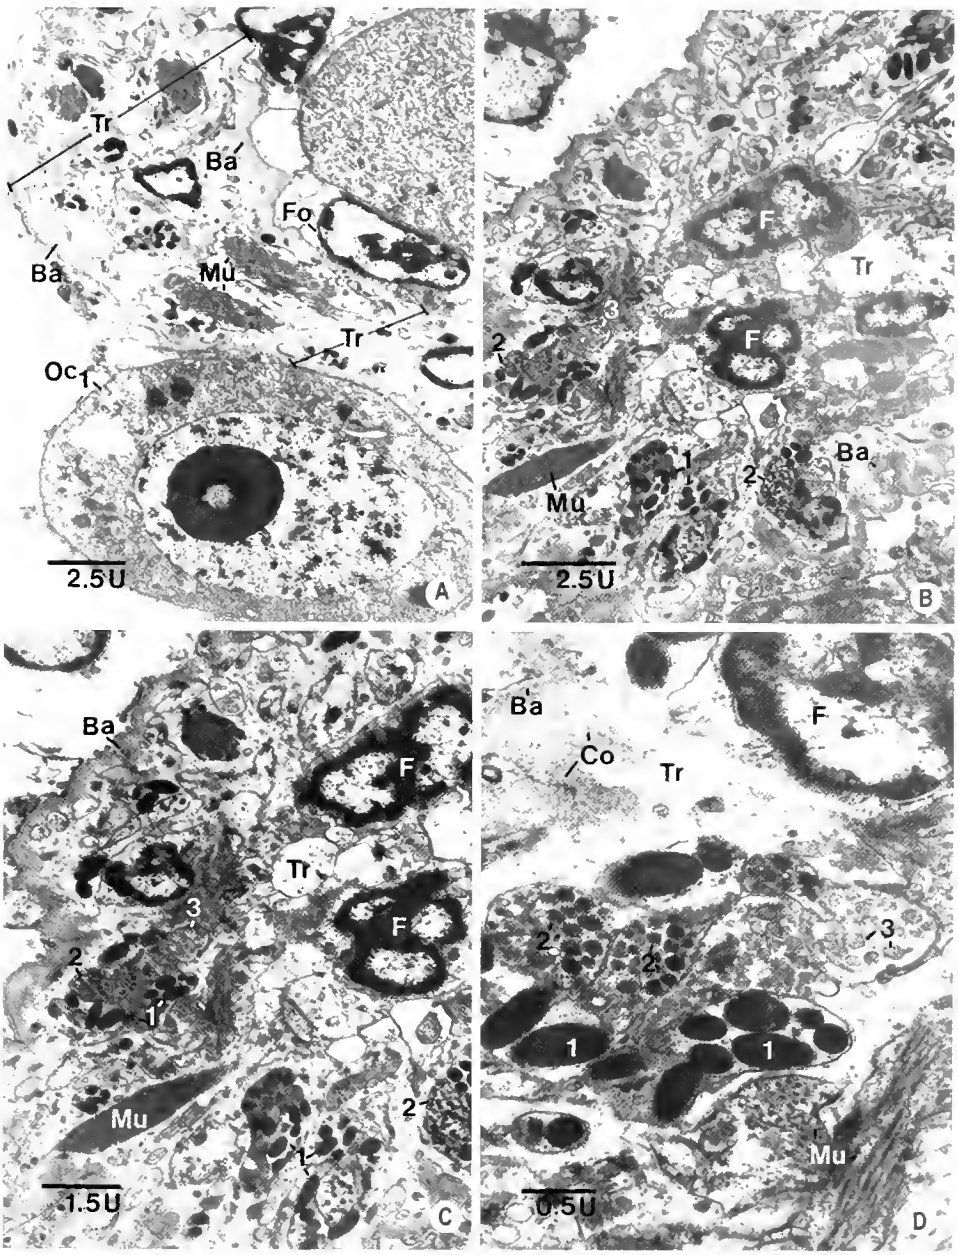

Figure 4. (A–D) TEM micrographs of a trabecula (Tr) in an ovary, which is separated from the gonadal compartment containing oocytes (Oc_1) by a thick undulating basal lamina (Ba). Within the core of each trabecula, there are collagen fibrils (Co), fibroblasts (F), muscle cells (Mu) and numerous processes of granulated cells (1) in close association with nerve processes (2, 3).

nerve bundles (Fig. 3F and G). The latter consist of nerve processes of various sizes, some of which contain electron-dense spherical granules (about 165 nm in diameter), while others contain more electron-lucent granules (about 150 nm in diameter). The peripheral part of each bundle is usually surrounded by branches of granulated cells that contain large rugby-shaped granules (about 270 × 550 nm in size). Most of the nerve bundles are situated close to the inner facet of the capsule, which is lined by a single squamous epithelium resting on another thick layer of basal lamina, that separates the capsule proper from the gonadal compartment (Fig. 2B). The inner capsule consists of a thin layer of loosely arranged connective tissues and muscle cells. It is separated from the gonadal compartment and hepatopancreatic tissue by basal laminae (Fig. 2E). The cellular constituents are composed of muscle cells, fibroblasts, and granulated cells which appear to be more abundant than in other areas of the connective tissue scaffold (Fig. 2E).

Trabecular Compartment

Each trabecula could be considered as a circumscribed compartment. As described earlier, this compartment is the continuation of the outer capsule, hence their main cellular compositions are muscle cells and fibroblasts embedded in the extracellular matrix and collagen fibrils. This compartment is partitioned off from adjacent gonadal compartments by thick convoluted basal laminae similar to those observed lining the outer and inner capsules (Fig. 4A–C). In addition, there are rows of granulated cells or their

branches at regular intervals along the trabecular sides of the basal laminae (Fig. 4A–C).

Muscle Cells

These cells are intermediate in characteristics between skeletal and smooth muscle cells of vertebrates. They have short thick filaments, each of which is surrounded by 12 to 15 long thin filaments. The thin filaments are attached to the dense bodies which are scattered throughout the cytoplasm, with some adhering to the plasma membrane (Fig. 5A–D).

Fibroblasts

These cells are similar in characteristics with their counterparts in vertebrates' connective tissues, and they are embedded within the collagen fibrils which they synthesize (Fig. 3F and Fig. 4B and C).

Granulated Cells

These cells have oval nuclei with thin rims of heterochromatin along the nuclear envelopes, and patches of heterochromatin in the center (Fig. 2E and 6A). They also have long processes that become closely associated with bundles of axons, which may come from neurons outside the gonads. As a result, there appear to be three types of granules within and around each bundle of axons and branches of granulated cells (Fig. 3F–G and Fig. 6C–F) similar to those found in the capsules. Isolated cytoplasmic branches of granulated cells containing groups of large granules are also frequently observed lying in rows near muscle cells (Fig. 5A and E), and under the undulating basal laminae that separate the trabeculae from the germ cell compartments (Fig. 4B–C and 6B). At many sites muscle cells appear in close apposition to solitary branches of granulated cells (Fig. 5E).

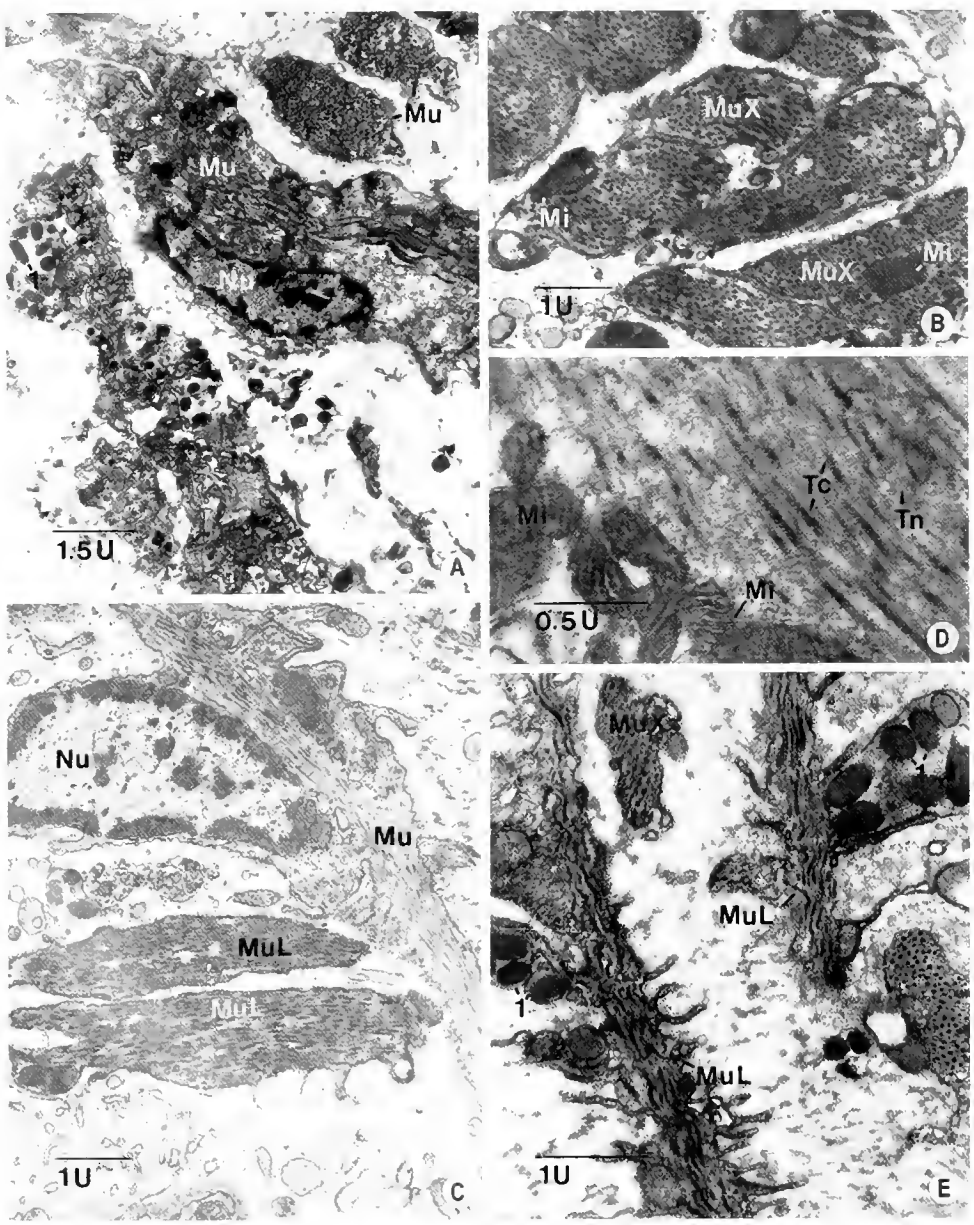

Figure 5. TEM micrographs of muscle cells, showing close association with the processes of granulated cells (1-in A, E). Cross (in B) and long sections (in C, D) of muscle cells, exhibit dense thick filaments (Tc) each of which is surrounded by numerous thin filaments (Tn). A large number of mitochondria (Mi) are also present in muscle cells.

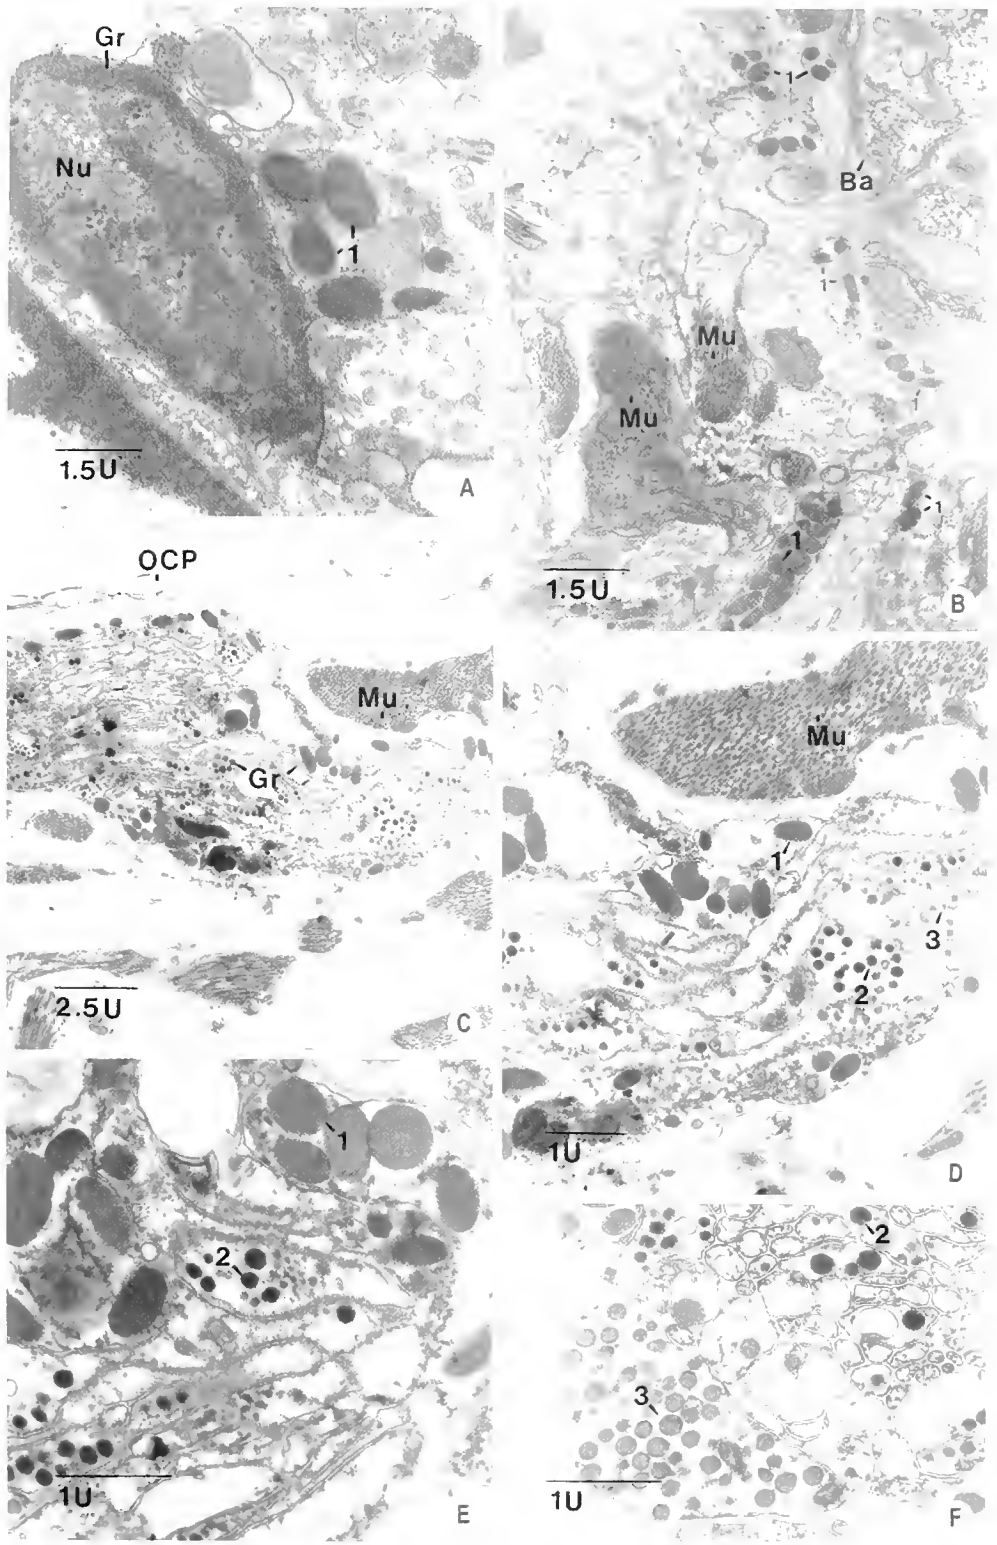

Figure 6. (A, B) TEM micrographs of a granulated cell (in A). The cell has an oval nucleus with patches of heterochromatin along the nuclear envelope and in the center. The cytoplasm contains large rugby-shaped granules about 270 × 550 nm in size, with an electron-dense matrix (1). In B, branches of granulated cells (1) are dispersed at intervals along the basal lamina (Ba). (C–F) The nerve bundles in trabeculae consist of two types of axons that contain dense (2) and light (3) spherical granules (about 165 and 150 nm in diameter). Processes of granulated cells (1) are closely associated with the periphery of each nerve bundle (in D, E).

DISCUSSION

The general histology of the gonad and classification of various types of germ cells in many species of abalone, such as, *H. tuberculata* (Stephenson 1924, Croft 1929), *H. discus hannai* (Tomita 1967, 1968), *H. cracherodii* (Webber & Giese 1969), *H. rufescens* (Young & DeMartini 1970, Martin et al. 1983), *H. diversicolor diversicolor* (Takashima et al. 1978), *H. asinina* (Apisawetakan et al. 1997, Sobhon et al. 1999) have been reported. However, most studies neglect the cellular compositions and detailed structure of the connective tissue scaffold of the gonad, apart from mentioning casually that the gonadal capsules and trabeculae are made of fibro-muscular tissues.

In our detailed studies using both light and electron microscopy, we found that the cellular compositions of connective tissue scaffold are more complex than previously thought. Within these connective tissue frameworks, which may be termed trabecular-capsular compartments, there are many types of cells that may be involved in the physiology of the gonad, including the production of reproductive hormone, and the release of mature gametes. These cells are muscle cells, fibroblasts and granulated cells.

The most striking feature is the presence of a large number of granulated cells, with large-endocrine like granules, in the trabeculae and capsules of the gonads. It is remarkable that these types of cells and their branches form an extensive network within the connective tissue scaffold of the gonad. Immunolocalization studies of abalone egg-laying hormone (aELH) performed by our group demonstrated that these cells could be one of the primary producers and/or storage sites of aELH (Chanpoo et al. 2000). Even more remarkable is that there are numerous nerve processes, which consist primarily of axons containing neurochemical vesicles, coming into close contact with branches of granulated cells. These bundles of nerve and granulated cell processes are mostly observed within the gonadal capsules. Judging from this appearance, gonads of *H. asinina* are highly innervated organs. In contrast to vertebrates, it is possible that the nervous system still play a more direct role in controlling the physiology of the gonad.

The muscle cells show typical features as present in most invertebrate species, and these characteristics are intermediate between skeletal and smooth muscle cells of vertebrates (Bennett & Threadgold 1973, Stitt et al. 1992). The thick filaments are short bundles consisting primarily of paramyosin protein (Ishii & Sano 1980) and each is surrounded by up to 12 to 15 thin filaments. This indicates that the muscle cells may be able to generate contractile force greater than that of vertebrate smooth muscle. It was found that branches of granulated cells, the putative egg-laying hormone producer, are lying close and frequently tightly adhered to the muscle cells. Immunolocalization study by our group demonstrated that aELH also binds to muscle cells in the capsules and cores of trabeculae (Chanpoo et al. 2000). It is, therefore, possible that aELH, upon being released from the granulated cells, may stimulate the contraction of muscles in the trabeculae and capsules of the gonad, and results in the release of mature gamete cells from the abalone at the time of spawning.

Fibroblasts and collagen fibrils appear to be similar in most respects to their counterparts in vertebrates' connective tissues. Thus, their functions could be primarily supportive.

ABSTRACT Connective tissue frameworks of the gonad of *H.asinina* consist of the outer gonadal capsule, flat sheets of connective tissue, called trabeculae, that extend from the former toward the inner capsules separating the gonad from the hepatopancreas. Trabeculae, thus, partition the gonad into compartments; and each trabecula acts as the axis on which growing germ cells are attached and proliferate. Each trabecula contains small capillaries in the center, surrounded by muscle cells, collagen fibers intermingled with fibroblasts, and a substantial number of granulated cells that branch extensively. Localization of abalone egg-laying hormone (aELH) was performed by immunoperoxidase technique using polyvalent antibody against recombinant aELH as a probe. Anti-aELH exhibited strong bindings, which implied the presence of aELH, to muscle cells and granulated cells within trabeculae and capsules of both male and female gonads. The cytoplasm of immature oocytes (stages 1, 2, 3) were moderately stained, while that of mature oocytes (stages 4, 5) were only weakly stained. In contrast, male germ cells were not stained.

KEY WORDS: *Haliotis asinina*, gonad, capsules, trabeculae, connective tissue, egg-laying hormone

INTRODUCTION

Donkey's ear abalone, *Haliotis asinina*, is a commercially important abalone species in Thailand because of their maximum proportion of flesh, good taste and relative abundance in Thai coastal water (Singhagraiwan & Doi 1993). The high demand for this abalone has increased pressure on natural stocks, which needed to be maintained if the population is to remain sustainable. So far, most studies have been on practical aspects of finding the optimal aquaculture system while knowledge concerning the reproductive biology of this abalone has received little attention.

A number of gastropod species have been studied with respect to the effects of the egg-laying hormones on their reproductive activities. In *Aplysia californica*, an opisthobranch, egg laying was caused by the injection of the extract from bag cells of abdominal ganglion (Arch 1976, Kupfermann 1967). Administration of the extract from caudo-dorsal cells (CDC) of cerebral ganglia in *Lymnaea stagnalis*, a pulmonate, also caused egg laying (Geraerts & Bohlken 1976). In prosobranchs, injections of crude homogenates of pleuropedal and visceral ganglia could induce spawning in *H. discus hannai* (Yahata 1973). The peptide that activated egg laying in *Aplysia* spp. had been characterized and called egg-laying hormone (ELH) (Chiu et al. 1979), whereas it was called caudo-dorsal cell hormone (CDCH) in *L. stagnalis* (Ebberink et al. 1985), and abalone egg-laying hormone (aELH) in *H. rubra* (Wang & Hanna 1998). These egg-laying hormones may be related, judging from their amino acid numbers and compositions. ELH has 36 amino acids and a molecular weight of about 4.3 kD (Chiu et al. 1979), (in comparison to CDCH, which has molecular weight about 4.5 kD (Ebberink et al. 1985), and aELH about 4.3 kD) (Wang & Hanna 1998). Genes encoding ELH, CDCH and aELH have been cloned (Scheller et al. 1983, Vreugdenhil et al. 1988, Wang & Hanna 1998). The nucleotide sequence encoding aELH of *H. rubra* was found to have a 95.4% homology with that of CDCH in *L. stagnalis*, but only 51.9% homology with that of ELH in *A. californica*. Only one amino acid difference was found between aELH of *H. rubra* and CDCH of *L. stagnalis*, while there were 19 amino acid differences between aELH of *H. rubra* and ELH of *A. californica* (Wang & Hanna 1998).

It has been suggested that ELH acts directly on muscle of the capsules and trabeculae of the gonads to initiate egg laying and sperm release in the manner analogous to the action of oxytocin on myoepithelial cells of vertebrates (Coggeshall 1972). In abalone, it remains to be studied where this hormone is synthesized, and how it is distributed in the reproductive organs. In the present study, we have investigated the distribution of this hormone in the gonads of both male and female *H. asinina* by using mouse polyclonal antibody to recombinant aELH of *H. rubra* for immunohistochemical detections.

MATERIALS AND METHODS

Experimental Animals

Sexually-mature male and female *H. asinina* more than two years old were obtained from The Coastal Aquaculture Development Center, Prachuabkirikhun Province, Thailand, during the months June to July and August to September, which are the periods when the gonads enter the proliferate and maturing-spawning phases. These abalone were reared in a land-based aquaculture system by being kept in concrete tanks, which were well flushed with sand-filtered sea water, and aerated with a mechanical air delivery system. They were given appropriate algal food, usually *Gracilaria* and *Laminaria* spp., *ad libitum*, supplemented with artificial food, and kept under a normal daylight cycle.

Samples were taken from the gonads of at least five animals of either sex at both periods of collection. The tissues were prepared

*Corresponding author.

for histological examinations by paraffin-embedded and epoxy plastic-embedded (semi-thin) methods as used for transmission electron microscopy and for detecting the distribution of aELH by immunoperoxidase method.

Paraffin and Semi-Thin Methods

For histological studies, gonadal tissues were cut into small pieces, fixed in Bouin's fixative, dehydrated and embedded in paraffin, then sectioned at 5 μm thick and stained with hematoxylin-eosin or PAS-hematoxylin. For semi-thin sections, gonadal tissues were fixed in 2.5% glutaraldehyde in 0.1 M phosphate buffer, dehydrated in ethanol, cleared in propylene oxide, and then embedded in Araldite 502 plastics. Semi-thin sections at 1–2 μm were cut with the ultramicrotome and stained with methylene blue or PAS.

Immunoperoxidase Method

Frozen sections of gonadal tissues were fixed with acetone at −10°C for 10 min. After blocking endogenous peroxidase by immersing in 3% H_2O_2 for 15 min the sections were washed with 0.05 M Tris buffer saline (TBS), pH 7.6. The sections were overlaid in moist chamber with 0.1% glycine in 0.05 M TBS, and 4% BSA in 0.05 M TBS, for 30 min each, to block non-specific bindings. Then the sections were covered for 1 h with primary antibody consisting of mouse polyclonal antibody against recombinant *H. rubra* egg-laying hormone (Wang & Hanna 1998), with dilution 1:10,000. The control sections were incubated with 0.05 M TBS in place of primary antibody. After that the sections were incubated with secondary antibody, which is biotinylated rabbit anti-mouse IgG (Zymed Co., California, USA), with dilution 1:100, for 30 min. The sections were then washed in TBS, covered with the combination of Z-avidin and biotinylated peroxidase (Zymed Co.) in the same buffer, with dilution 1:100, for 30 min. Finally, the sections were immersed in the substrate solution containing 5 ml of 0.03% (w/v) 3,3′ diaminobenzidine (DAB) plus 17 μl H_2O_2, for 15 min. Finally, the sections were washed several times with distilled water, and some were counter-stained with hematoxylin before being mounted in buffered glycerol, and observed in an Olympus Vanox microscope.

RESULTS

Connective Tissue Frameworks

Connective tissue scaffolds of the gonads in either sex consist of the outer capsule which is made of several alternate layers of muscle and collagen bundles, lined on the outside by a single layer of cuboidal epithelium (Fig. 1A, B, F). On the inside the connective tissue of the capsule extends inwards to form sheets, called trabeculae, that have straight hemolymph capillaries running in their cores. Surrounding the capillaries are muscle cells, collagen fibrils, fibroblasts, and granulated cells (Fig. 1A, B, E, F). The interior ends of trabeculae are connected with the inner capsule made of a thin loose connective tissue layer that separates gonad from hepatopancreas. Thus, trabeculae divide the gonads into small compartments, and each trabecula forms the axis on which germ cells are attached and proliferate. Early stage cells, such as spermatogonia and oogonia are seen closely bound to the connective tissue of trabeculae. Middle stage germ cells, such as spermatocytes and oocytes, are more detached and appear further away from trabeculae. Mature cells including spermatozoa and stage 5 oocytes, which are the majority of cells found in the gonads in mature phase, are completely detached from the trabeculae and fill up the lumen of the compartments (Fig. 1A, B). Of special interest is the presence of granulated cells, whose soma are large and have an ovoid shape about 10 × 18 μm in size. Each cell has a small spherical nucleus that contains mostly euchromatin. The cytoplasm contains numerous dense spherical granules about 0.3–0.6 μm in size (Fig. 1C, D, E). In PAS stained sections, the granules exhibit PAS positive substance (Fig. 1C, D). The granulated cells may give off extensive branches since in many locations only cytoplasmic processes containing dense granules were observed (Fig. 1E, F). Generally, granulated cells are present in all areas of the connective tissue scaffolds; however, they tend to be more numerous in the outer and inner capsules of the gonads.

Immunoperoxidase Staining

By using the immunoperoxidase method, the presence of brownish staining suggested that there are strong and specific bindings of anti-aELH in the trabeculae and the capsules of the gonads in both sexes. The brownish stain is distinct on the overall content of trabeculae and capsules which delimit gonadal compartments of both the ovary and testis of the mature phase abalone (Fig. 3A–D, Fig. 4A, B), in contrast to the control sections which are completely unstained (Fig. 2A). Within each trabecula, there are more intensely stained spots or streaks, which at high magnification, appear to be muscle cells and granulated cells that contain large brownish granules in the cytoplasm (Fig. 3B, D, Fig. 4B, C, D). The latter cells are similar in appearance and general distribution with the granulated cells observed in paraffin and semithin sections, which exhibit better cellular morphology. The positively stained granulated cells were observed in both the outer and inner capsules and the trabeculae. However, there appear to be a higher concentration of these positive cells in the inner capsule that separates gonads from the hepatopancreas (Fig. 2B, C, Fig. 4A, B), in both proliferate (Fig. 2B–D) and mature phases (Fig. 4A–D) of the gonadal cycle. Connective tissue in the trabeculae and in the capsules are moderately stained, but they appear more intense in the mature than the proliferate phase of the gonadal cycle (Fig. 2B, 3A). In the ovary, the cytoplasm of early oocytes (stages 1, 2, 3), which are the majority of cells in the proliferate phase, is moderately stained (Fig. 2A, B), while the cytoplasm of mature oocytes (stages 4, 5) which the majority of cells in the mature phase, is only weakly stained (Fig. 3A, B, C). In contrast, there is no staining of either early male germ cells or spermatozoa in the testis (Fig. 4A, B, C).

DISCUSSION

The expression of the egg-laying peptide gene in the bag cells of the abdominal ganglion, atrial gland, and pleural ganglion of *A. californica* has been detected by *in situ* hybridization, using radiolabeled cDNA probes to ELH mRNA (McAllister et al. 1983). Some work had also been done to locate the ELH receptor within the ovotestis of *A. californica*. ELH binding-protein from the ovotestis was purified by ELH affinity column chromatography, and antibodies were produced for localizing this protein in *A. californica* gonads (Choate et al. 1993). It was revealed that the cytoplasm of oocytes is the only site of immunoreactivity, which was never detected in spermatocytes and spermatozoa. In *L. stagnalis*, *in situ* hybridization experiments with cDNA probes revealed a high level of CDCH mRNA expression in caudodorsal cells in the cerebral ganglia. The observed expression pattern correlated with immunocytochemical data which implied that CDCH

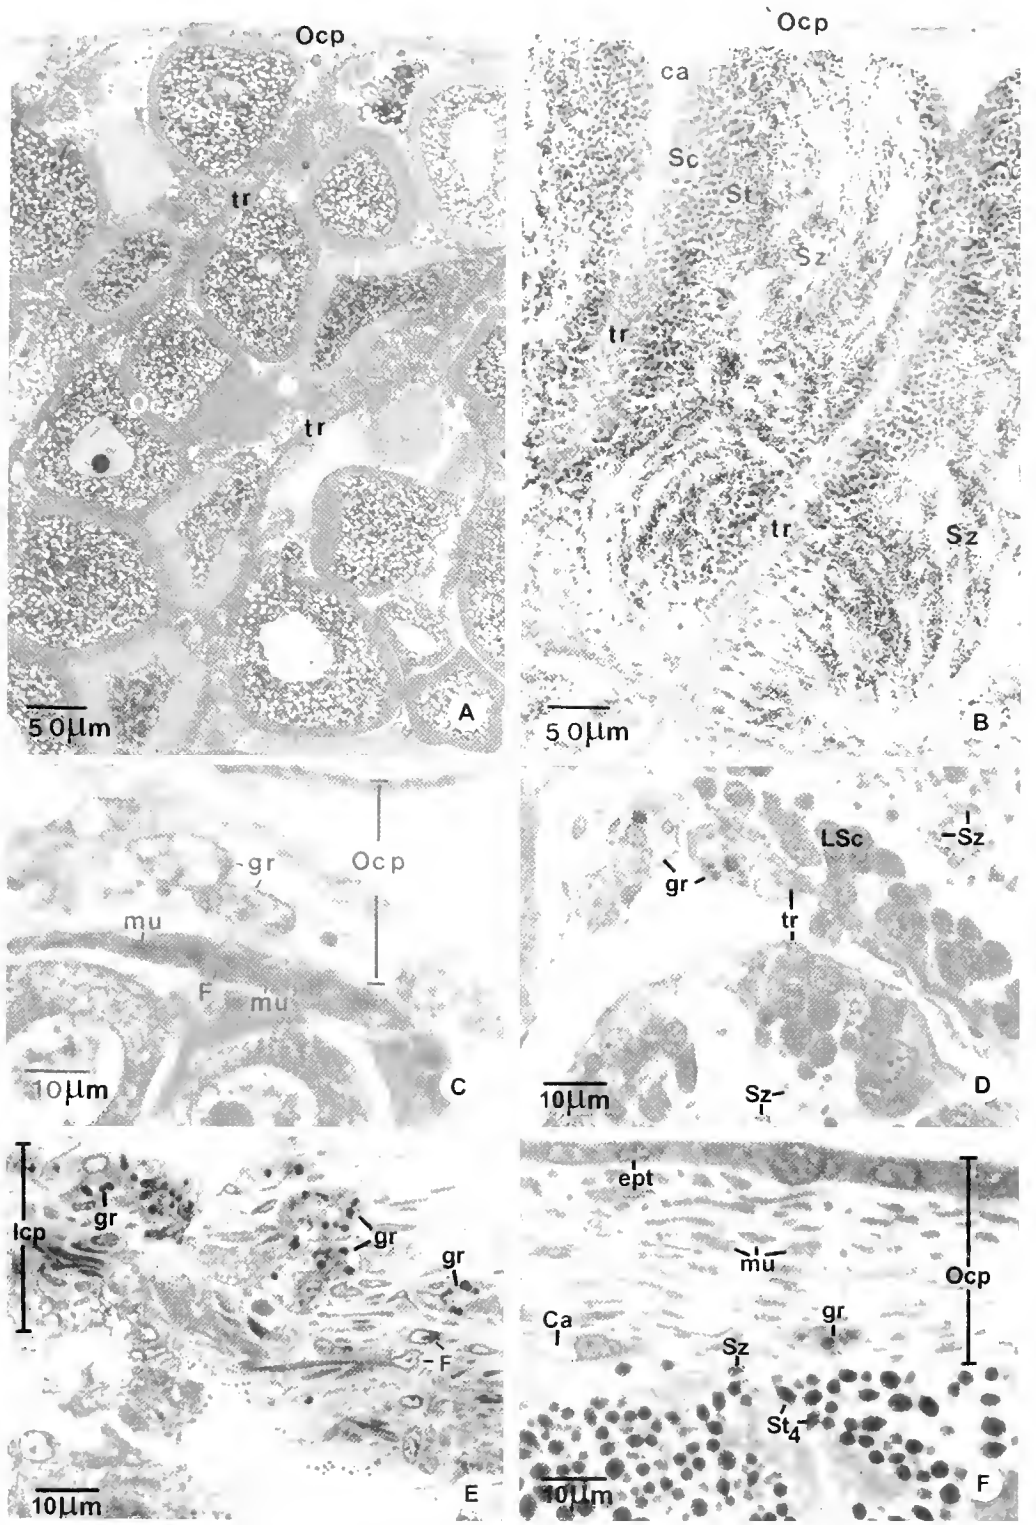

Figure 1. (A, B) Light micrographs of PAS-hematoxylin stained paraffin sections of *H. asinina* ovary (A) and testis (B) in the mature (prespawning) phase, where there are abundant mature stage V oocytes (Oc_5) with fully formed jelly coats (jc) in the ovary (in A), and numerous spermatozoa (S_z) with dense nuclei in the testis (in B). The connective tissue scaffolds of the gonads in both sexes consist of the outer capsule (Ocp), the trabeculae (tr) and the inner capsule (not shown). In the core of each trabecula, there is a small hemolymph capillary (Ca). Sc = spermatocytes, St = spermatids. (C, D) High magnification micrographs showing the granulated cells containing PAS positive granules (gr-in C) in the outer capsule of the ovary (Ocp) and in a trabecula (tr) of the testis (gr-in D). F = fibroblasts, LSc = leptotene spermatocyte, mu = muscle cells, Sz = spermatozoa. (E, F) The semi-thin plastic sections of the ovarian inner capsule (Icp- in E) and the testicular outer capsule (Ocp-in F) showing the granulated cells with their ellipsoid nuclei (gr-in E), and their attenuated processes containing dense granules (gr-in F). Ca = haemolymph capillary, ept = epithelium, F = fibroblast, mu = muscle cells, St_4 = spermatid stage 4.

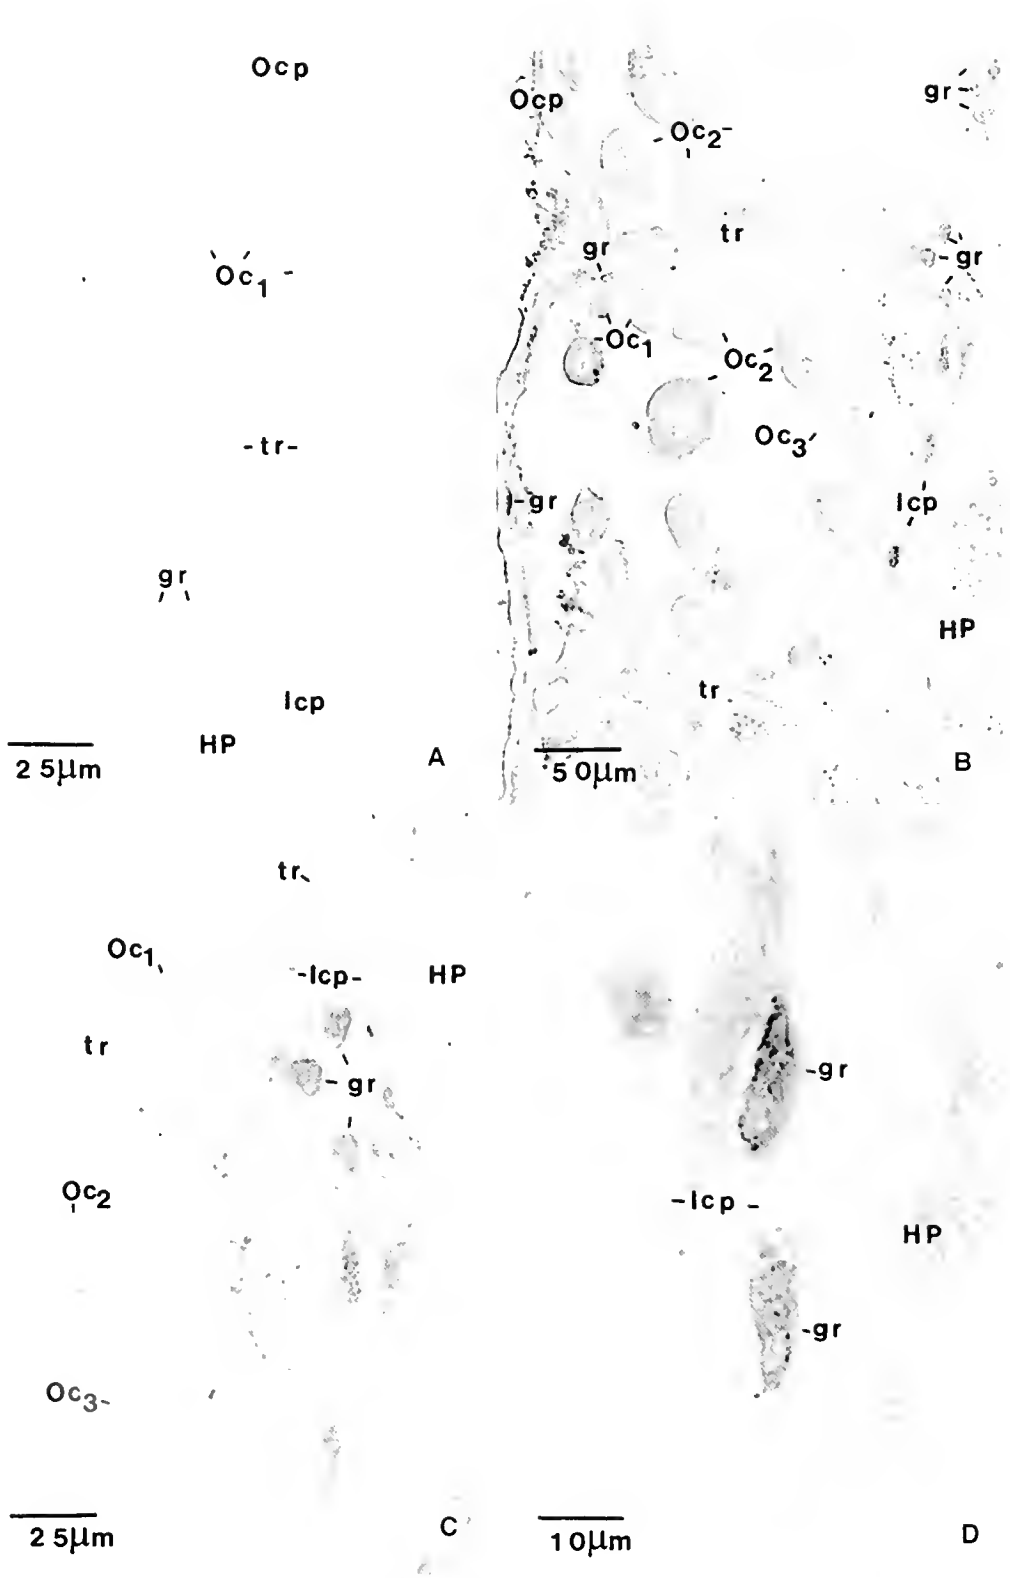

Figure 2. Light micrographs of the ovary in the proliferate phase, stained with anti-aELH by the immunoperoxidase method. (A) Control section shows no staining in the ovarian tissue. (B–D) Sections stained with anti-aELH, showing intense staining in granulated cells (gr) within the inner (Icp) and the outer capsules (Ocp), while moderate staining is seen in the connective tissue proper of trabecula (tr), both capsules (Ocp & Icp), and the cytoplasm of immature oocytes (Oc_1, Oc_2, Oc_3). HP = hepatopancreas.

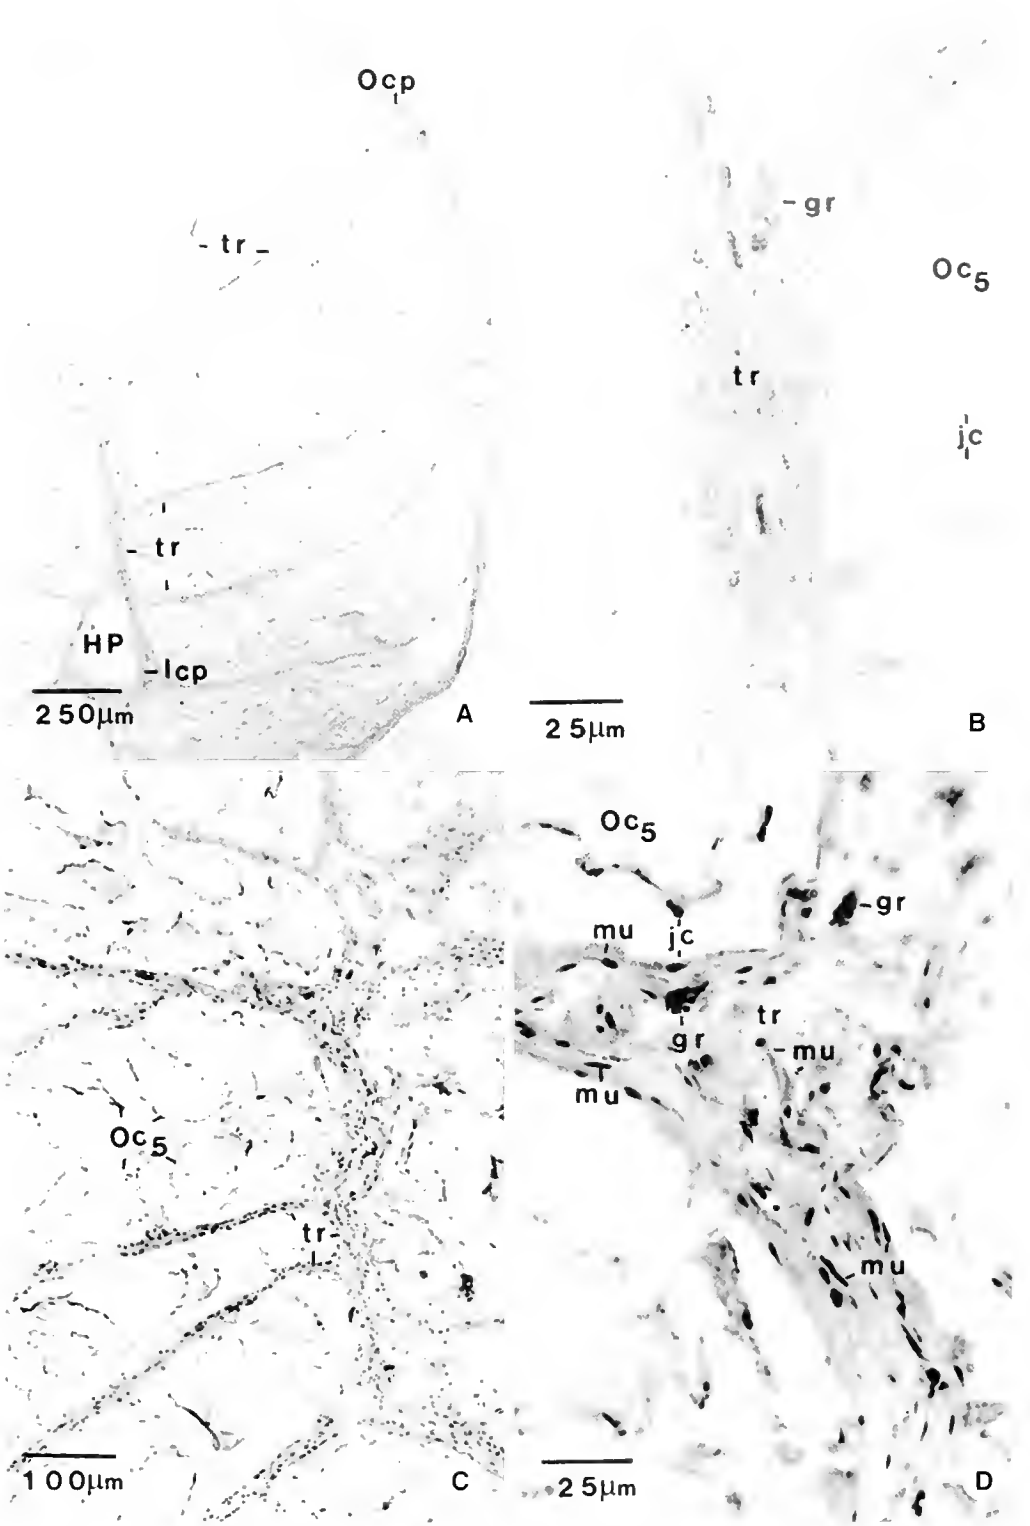

Figure 3. Light micrographs of the ovary in the mature phase, stained with anti-aELH by the immunoperoxidase method. (A, B) In A, anti-aELH exhibits staining in the trabeculae (tr) and both capsules (Ocp, lcp) of the gonad. In B, granulated cells (gr) in a trabecula are intensely stained. The cytoplasm of late stage oocytes (Oc_5) surrounded by a thick jelly coat (jc) is not stained. (C, D) Sections stained with anti-aELH and counter-stained with hematoxylin. In C, the connective tissue of the trabeculae (tr) is positively stained in comparison to oocytes (Oc_5). In D, which is higher magnification of an area from the trabeculae in C, granulated cells (gr) and muscle cells (mu) are intensely stained.

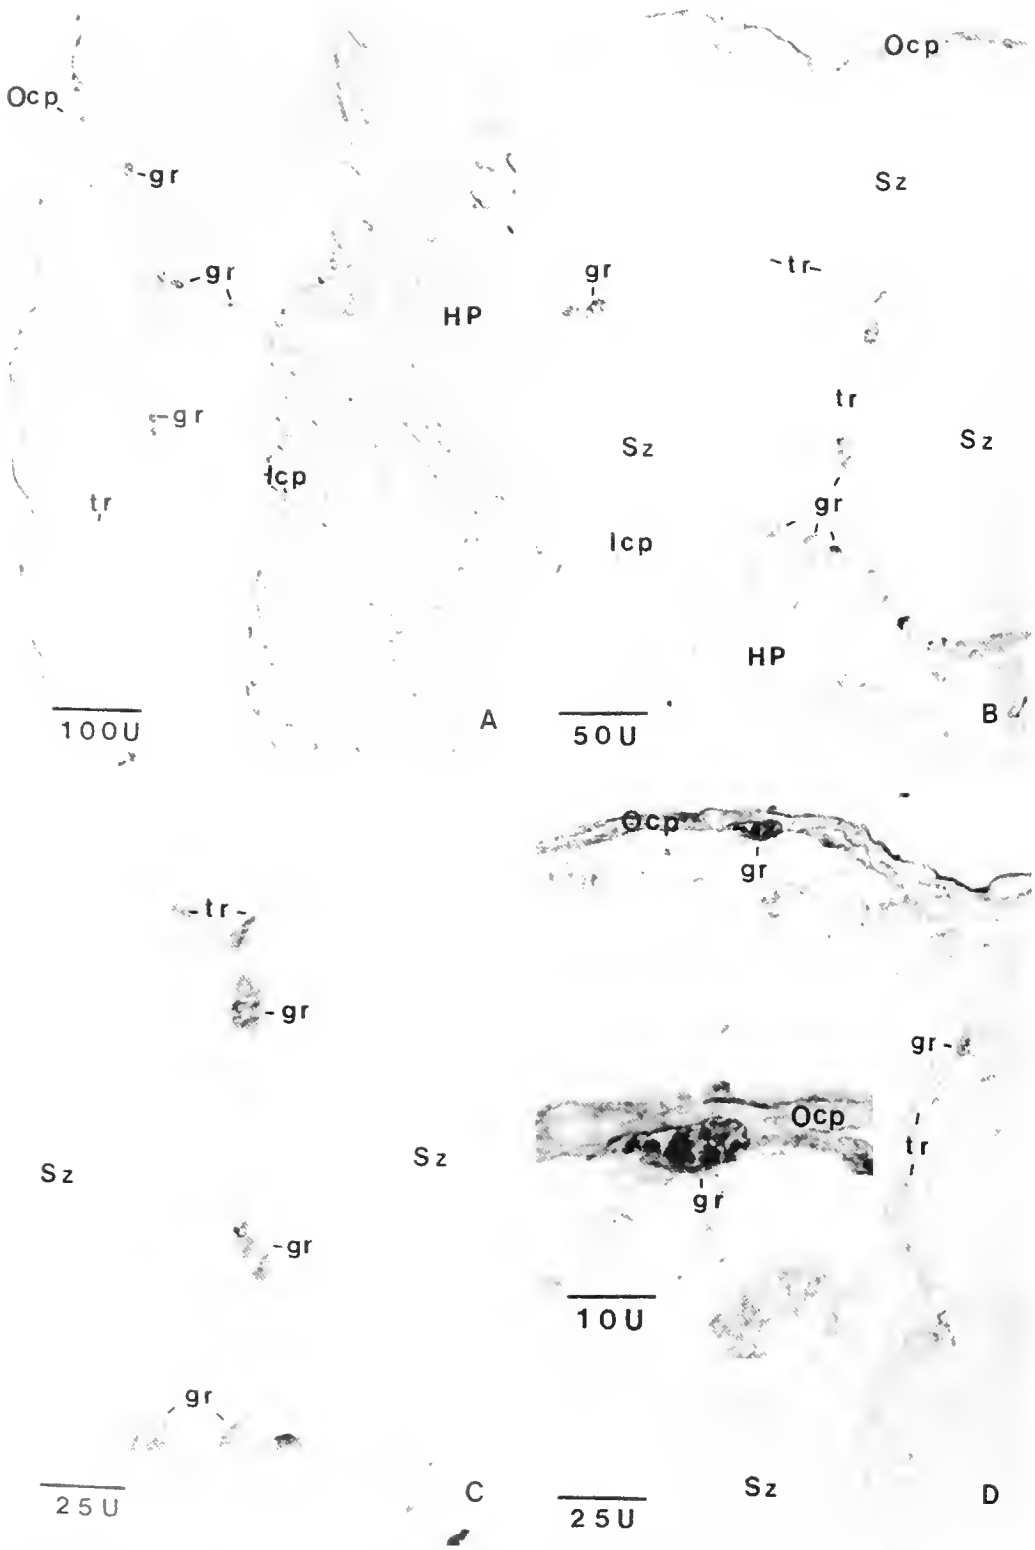

Figure 4. Light micrographs of the testis in the mature phase, stained with anti-aELH by the immunoperoxidase method. (A–D) Sections stained with anti-aELH, showing strong staining of the trabeculae (tr), both the outer and inner capsules (Ocp, Icp). In C, and D inset, which are high magnifications of a trabecula and the outer capsule, granulated cells (gr) with large granules in their cytoplasm are intensely stained, while spermatocytes and spermatozoa (Sz) are not stained.

is transported through the axon and released by exocytosis to the hemolymph (Dirks et al. 1989, Dirks et al. 1993, Van Minnen et al. 1988). Expression of CDCH was not restricted to the CNS alone, but was also found in the reproductive tract, including the oothecal gland, muciparous gland, and pars contorta, which are female accessory sex glands in *Lymnaea stagnalis*. In these glands the processes of positively labeled neurons terminated on the secretory cells, suggesting that they controlled the activities of these tissues (Van Minnen et al. 1988). CDCH immunoreactive material has also been found in secretory cells of the prostate gland and sperm duct (Van Minnen et al. 1989). In contrast to CDCH little is known about the origin of egg-laying hormone in abalone. Histological studies in the Japanese abalone, *Haliotis discus hannai*, showed that the number of neurosecretory cells, especially type 1 and 7, in pleural-pedal ganglia was correlated with the induction of spawning (Hahn 1992). Injections of pleural-pedal and visceral ganglion crude homogenates, or the combination of both, caused female *H. discus hannai* to spawn (Yahata 1973). The quantity of eggs being spawned was significantly greater with the injections of homogenates from visceral ganglion or the combination of pleural-pedal and visceral ganglion, when compared with the injection of pleural-pedal ganglion alone (Yahata 1973). In our preliminary study of *H. asinina* visceral ganglia, neurosecretory cells type 1 were also positively stained with anti-aELH (unpublished observation). Hence, existing evidence implies that abalone egg-laying hormone is mostly produced by neurosecretory cells of the nerve ganglia, particularly pleuropedal and visceral ganglia.

In the present study, we found that anti-aELH from *H. rubra* showed strong cross reaction with *H. asinina* gonadal connective tissues, and this implied that aELH may also be produced and stored in the granulated cells within the trabeculae and capsules of the gonad. Similarly, muscle cells in these connective tissue scaffolds were also stained with the anti-aELH, which suggested that this group of cells also bind aELH. Coggeshall (1972) suggested that, in *Aplysia*, ELH acted directly on muscle cells to induce their contraction, which caused the expulsion of ripe oocytes from the ovary. From the evidence gathered in the present study we, therefore, would like to suggest that the granulated cells in the trabeculae and the capsules of gonads in both sexes of abalone can synthesize aELH. After being released from the granulated cells, this hormone could bind to muscle cells in trabeculae and capsules and cause them to contract, which results in the expelling of ripe oocytes or spermatozoa from the gonads. The significance of the binding of anti-aELH to early stage oocytes is not known, but this hormone may also participate in the developmental process of germ cells. In contrast aELH did not bind to male germ cells thus its role in the male abalone may be limited to controlling the release of spermatozoa as has recently been demonstrated by our group (unpublished observation).

ACKNOWLEDGMENTS

We sincerely thank Associate Professor Peter J. Hanna, School of Biological & Chemical Sciences, Deakin University, Geelong, Australia, who kindly supplied mouse polyclonal antibody against aELH of *H.rubra*. This work was supported by the Thailand Research Fund (Senior Research Scholar Fellowship to P. Sobhon).

ULTRASTRUCTURE OF NEUROSECRETORY CELLS IN THE CEREBRAL AND PLEUROPEDAL GANGLIA OF *HALIOTIS ASININA* LINNAEUS

A. THONGKUKIATKUL,[1,*] P. SOBHON,[2] E. S. UPATHAM,[3,4] M. KRUATRACHUE,[4] C. WANICHANON,[2] Y. P. CHITRAMVONG[3] AND T. PUMTHONG[5]

ABSTRACT The ultrastructure of all three types of neurosecretory cells (NS_1, NS_2 and NS_3) in the cerebral and pleuropedal ganglia of *Haliotis asinina* was studied. NS_1 cells contained a euchromatic nucleus, and the cytoplasm contained RER, Golgi complexes, mitochondria and ribosomes. There were two types of neurosecretory granules in the NS_1 of cerebral ganglia, type 1 were large osmiophilic membrane-bound granules and type 2 were small electron-dense spherical granules. The NS_1 cells of pleuropedal ganglia only had one type of round cytoplasmic granule with a moderate to strong electron-dense matrix. NS_2 cells contained blocks of heterochromatin in the nucleus. The cytoplasm of the NS_2 of cerebral ganglia contained the usual organelles similar to those of NS_1 cells and large membrane-bound granules containing crystalline structures embedded in a moderately dense osmiophilic matrix. The NS_2 cells of pleuropedal ganglia contained one type of granule that had a dense matrix. NS_3 cells were smaller than NS_1 and NS_2. The nucleus contained thick heterochromatin strands. The organelles in the cytoplasm appeared to be fewer than those of NS_1 and NS_2. The secretory granules of NS_3 of both cerebral and pleuropedal ganglia were composed of aggregates of dense osmiophilic globules of various sizes.

KEY WORDS: *Haliotis asinina*, neurosecretory cells, cerebral ganglia, pleuropedal ganglia, ultrastructure

INTRODUCTION

Neurosecretory cells present in the cerebral ganglia of prosobranchs have not been extensively studied, and consequently little is known about them. The neurosecretory cells in the cerebral ganglia of *Bithynia tentaculata* Linnaeus were stained with phloxine (Andrews 1968). They were found to be unipolar and their nuclei were usually concave on one side. Neurosecretory material accumulated in the periphery of the cytoplasm and the axon hillock (Andrews 1968). In *Haliotis discus hannai* Ino and *Nordotis discus* Reeve, two cell types in the cerebral ganglia were identified as neurosecretory cells. They were large and medium sized cells with euchromatic nuclei and contained neurosecretory granules in the cytoplasm (Yahata 1971, Hahn 1994).

More recently, in the cerebral ganglia of *Haliotis asinina* Linnaeus, two types of neurosecretory cells were found (Upatham et al. 1997). These cells are either large or medium in size and stained positively with chrome-hematoxylin-phloxine and paraldehyde-fuchsin. The large sized cells contain a round nucleus with euchromatin and a distinct nucleolus. The medium sized cells also contain a round nucleus with patches of heterochromatin. Neurosecretory granules are present in both cell types (Upatham et al. 1997).

Most studies on the ultrastructure of neurosecretory cells in gastropods have concentrated on pulmonates and opisthobranchs with only a few on prosobranchs. In the cerebral ganglia of *Lymnaea stagnalis* (Linnaeus), two groups of neurosecretory cells have been described (Joosse 1964, Boer 1965, Boer et al. 1968). The cytoplasm of these cells contain electron-dense granules, which had a mean diameter of 20 nm, extremely elongated mitochondria, rough endoplasmic reticulum, free ribosomes, polyribosomes, Golgi complexes, multivesicular bodies, neurotubules and cytosomes. Bonga (1970), using the alcian blue-alcian yellow staining technique, reported that there was only one type of neurosecretory cells *i.e.* dark green cells in the pleuropedal ganglia of *L. stagnalis*. At the electron microscopic level, the dark green cells appear to contain a large quantity of elementary granules with a mean diameter of 20 nm. Numerous Golgi complexes were found to be evenly distributed in the cytoplasm, and there was extensive rough endoplasmic reticulum. A low number of cytosomes were present. In *Achatina fulica* (Bowdich), neurosecretory cells in the cerebral ganglia contain a round shaped nucleus with patches of heterochromatin and a conspicuous single large vacuole in the cytoplasm. In addition, electron-dense granules with a mean diameter of 16nm are associated with extensive Golgi complexes and rough endoplasmic reticulum (Kruatrachue et al. 1994).

In the prosobranchs, the ultrastructure of neurosecretory cells and neurons has been described in *B. tentaculata* (Andrews 1971) and *Haliotis rufescens* Swainson (Miller et al. 1973). In *B. tentaculata*, there are three types of neurosecretory cells, viz. S1, S2 and S3. In the cytoplasm of these cells, there are well-developed rough endoplasmic reticulum and Golgi complexes, mitochondria, lysosomes, glycogen granules, neurofibrils, and neurosecretory granules (Andrews 1971). Miller et al. (1973) describe that most of the neurons of *H. rufescens* contain the usual cytoplasmic organelles along with large membrane-bound inclusions. A few neurons contain small dense granules, which are similar in appearance to typical neurosecretory granules.

It was, therefore, apparent that an extensive investigation of the ultrastructure of neurosecretory cells in *Haliotis* was needed. Hence, the aim of the present study was to describe the ultrastructure of different types of neurosecretory cells in the cerebral and pleuropedal ganglia of *H. asinina*.

MATERIALS AND METHODS

Cerebral and pleuropedal ganglia from mature *H. asinina* were fixed in a mixture of 4% v/v glutaraldehyde and 2% v/v paraform-

*Corresponding author. E-mail address: amporn@bucc4.buu.ac.th.

aldehyde in 0.1M Millonig buffer (pH 7.8) at 4°C for 24 h, washed several times with the same buffer, and postfixed in 1% OsO_4 in 0.1M Millonig buffer. The specimens were dehydrated in a graded series of ethanol, infiltrated in acetone and embedded in Araldite 502-epoxy resin. Sections were cut on a Sorvall MT2 ultramicrotome, stained with saturated uranyl acetate and lead citrate, and viewed with a Hitachi H-300 TEM, operating at 75KV.

RESULTS

Based on ultrastructural characteristics, there are three types of neurosecretory cells in the cerebral and pleuropedal ganglia of *H. asinina*. These are: type 1 neurosecretory cell (NS_1), type 2 neurosecretory cell (NS_2), and type 3 neurosecretory cell (NS_3).

NS_1 cells are round to oval (15–20 μm in dimension) and contain round nuclei (6–8 μm in diameter) (Fig. 1, Fig. 2). The

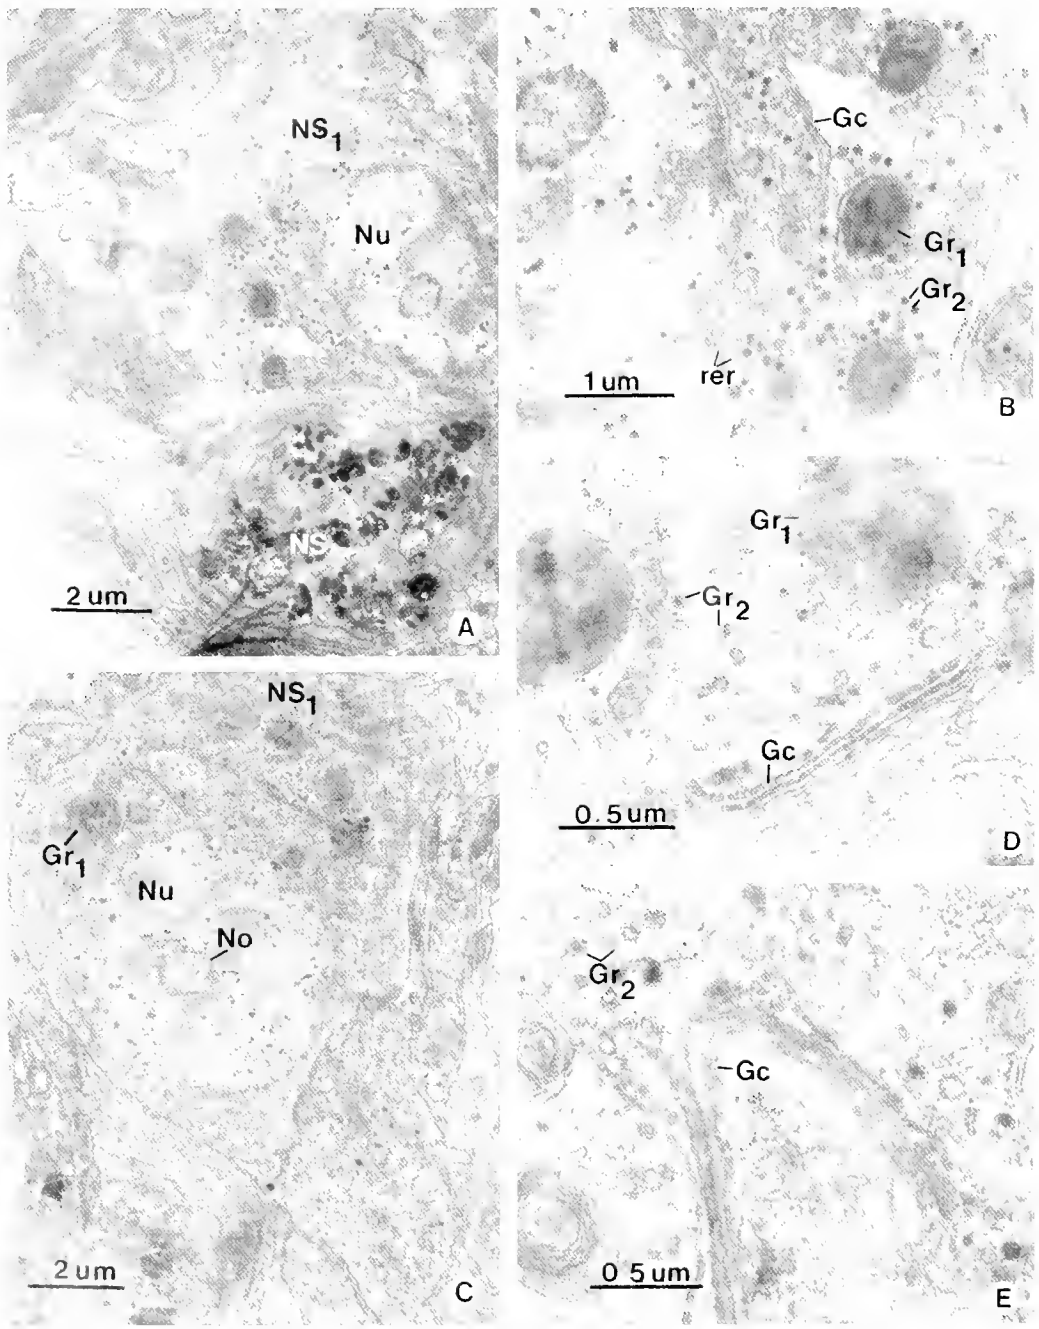

Figure 1. TEM micrographs of NS_1 cells of cerebral ganglia. (A, C) Medium power micrographs of the NS_1 showing the round nucleus (Nu) which contains a thin rim of heterochromatin (He) near the nuclear envelope. The nucleolus (No) is round, large and very distinct. There are abundant secretory granules in the cytoplasm. NS_1, type 1 neurosecretory cell; NS_3, type 3 neurosecretory cell; Gc, Golgi complex; Gr_1, type 1 granule. (B, D, E) High magnifications of the cytoplasm of the NS_1 demonstrating abundant rough endoplasmic reticulum (rer), Golgi complexes (Gc) and secretory granules. Type 1 granules (Gr_1) are large spherical membrane bound granules whereas type 2 granules (Gr_2) are small and round, containing electron-dense cores.

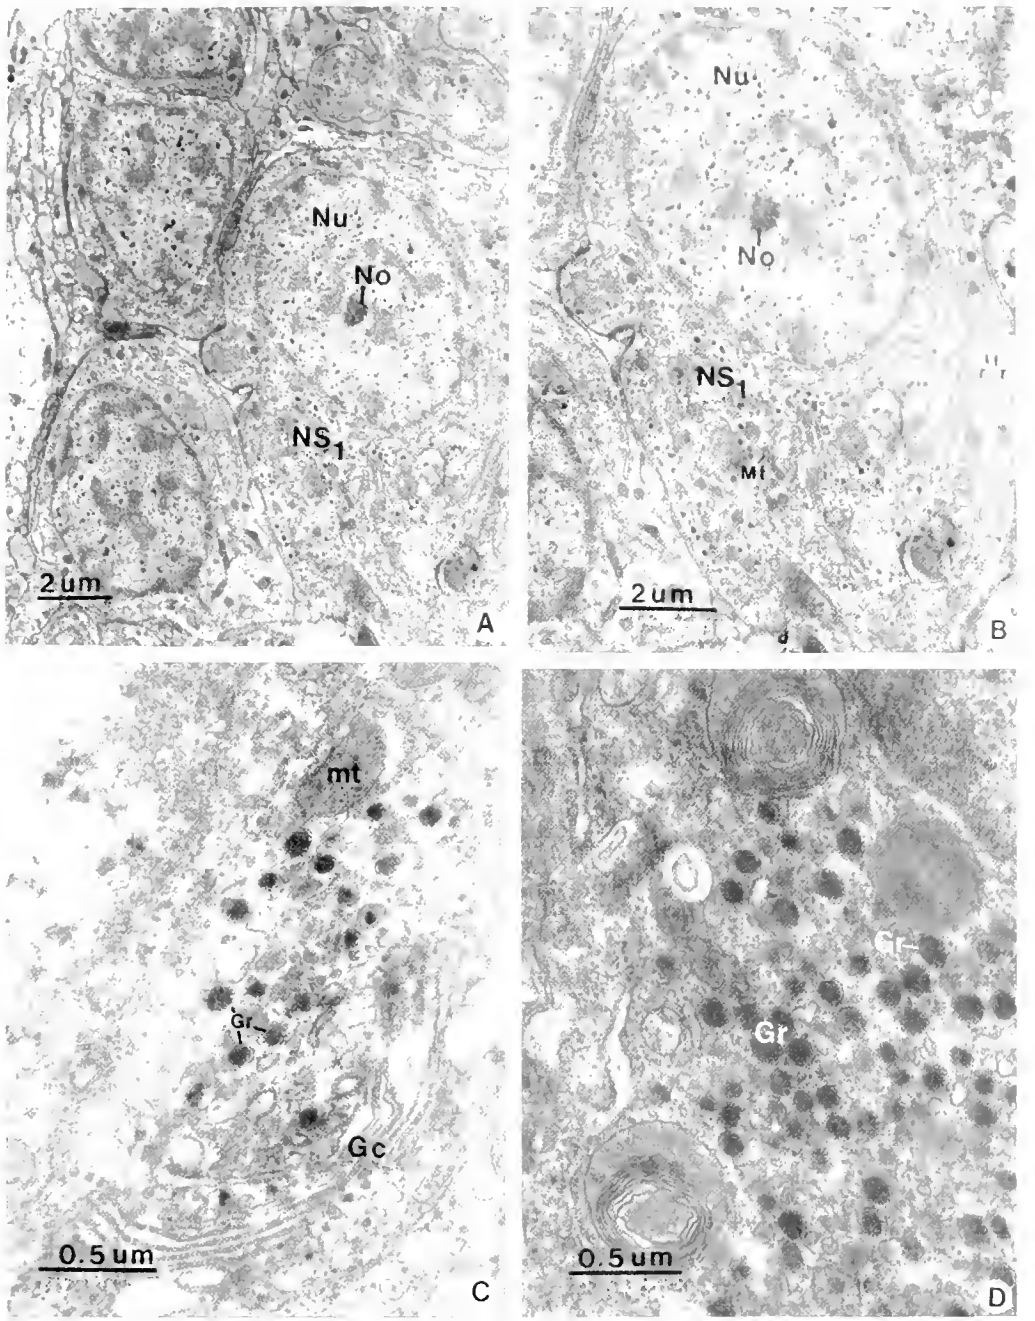

Figure 2. TEM micrographs of NS_1 cells of pleuropedal ganglia. (A, B) Low and medium power micrographs of NS_1 showing a round nucleus (Nu) which contains a thin rim of heterochromatin (He) near the nuclear envelope. The nucleolus (No) is round and very distinct. The cytoplasm contains rough endoplasmic reticulum (rer), mitochondria (Mt), Golgi complexes (Gc) and secretory granules (Gr). (C, D) Enlarged view of A & B exhibiting the cytoplasm of NS_1 containing mitochondria (Mt), extensive Golgi complexes (Gc) and electron-dense granules (Gr) near the maturing face of the Golgi complexes.

nucleus contains a thin rim of heterochromatin near the nuclear envelope. Small patches of heterochromatin are scattered in the central region of the nucleus, while the rest of the nucleoplasm contains finely dispersed euchromatin. The nucleolus is large, round and very prominent (Figs. 1A, C, Figs. 2A, B). The cytoplasm shows abundant rough endoplasmic reticulum consisting of many large stacks of membrane in straight arrays (Fig. 1D, Fig. 2C). Golgi complexes are extensively developed and each consists of four to five elongated and slightly bent cisternae and saccules, which are often surrounded by dense vesicles (Fig. 1D, Fig. 2C). There are mitochondria and abundant polyribosomes in the cytoplasm. Two types of secretory granules are present in the NS_1 of cerebral ganglia. Type 1 are large, membrane-bound, spherical granules (Figs. 1B, C). Their diameter is about 500–800 nm and they contain moderately osmiophilic material. There are few granules present, and these are usually dispersed around the maturing face of the Golgi complexes (Fig. 1D). Type 2 are small membrane-bound spherical secretory granules, containing electron-

dense matrices. Their diameter is about 60 nm, and they are scattered throughout the cytoplasm (Figs. 1B, D). The newly synthesized granules indicated by their light matrices are concentrated mainly in the maturing face of the Golgi complexes (Figs. 1D, E). In the NS_1 of pleuropedal ganglia, only one type of secretory granule is present. These granules are round and have a mean diameter of 120 nm. They contain moderate to strong electron-dense matrices (Figs. 2C, D).

NS_2 cells are round or oval (10–12 μm in dimension) (Fig. 3, Fig. 4). Their nucleus is round (6–8 μm in diameter) with a thin rim of heterochromatin near the nuclear envelope, and large blocks of heterochromatin are scattered in the central region (Fig. 3A, Fig.

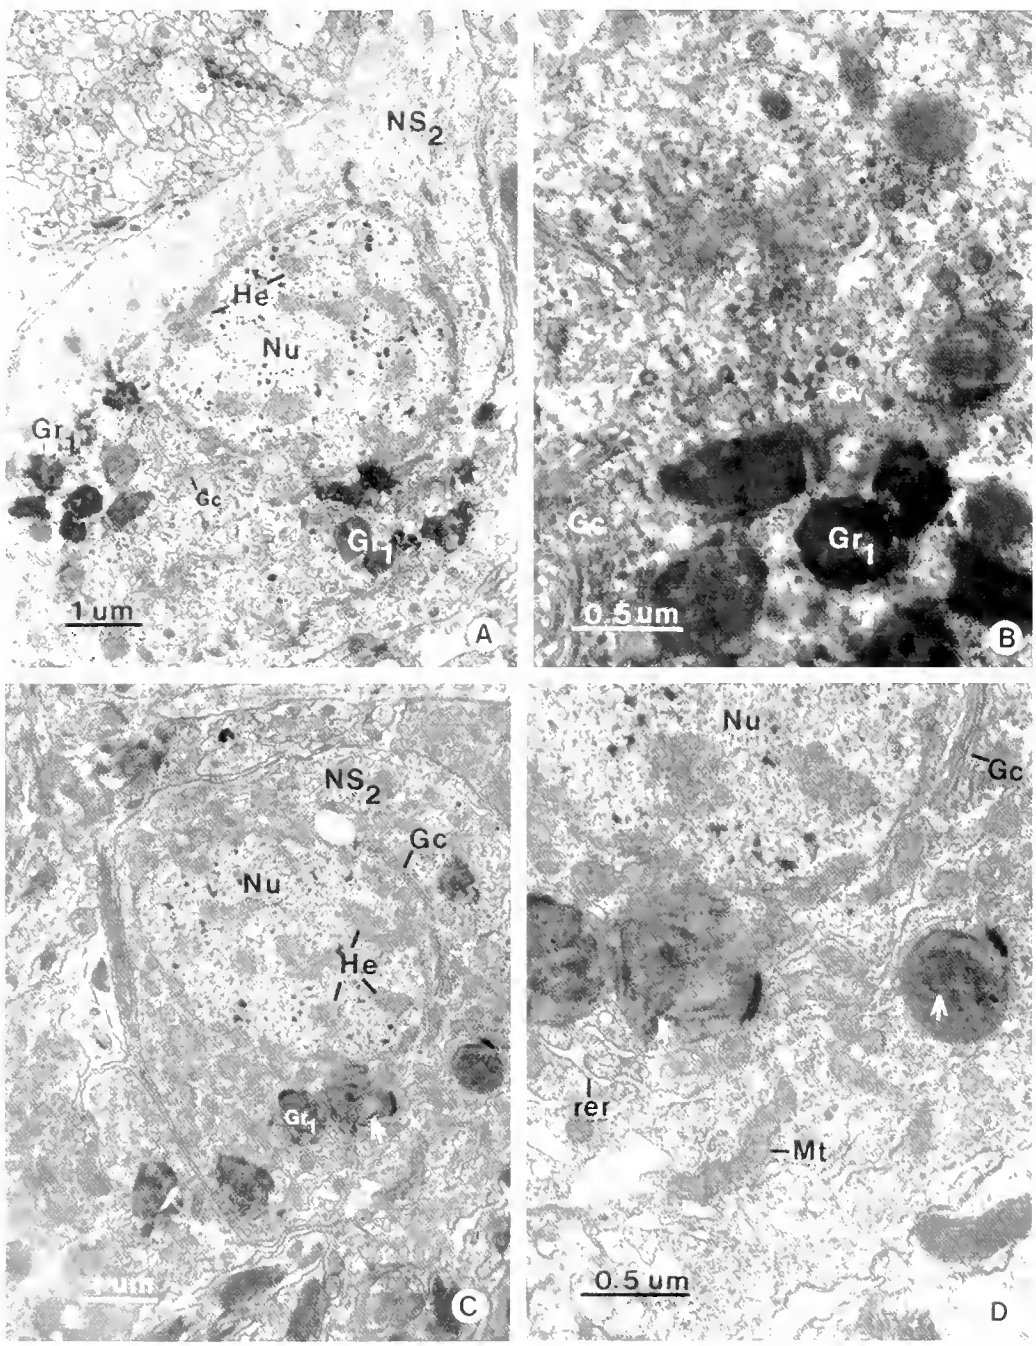

Figure 3. TEM micrographs of NS_2 cells of cerebral ganglia. (A, C) Medium power micrographs of NS_2, exhibiting the round nucleus (Nu) with a thin rim of heterochromatin (He) attached to the nuclear envelope and large blocks of heterochramatin scattered in the central area of the nucleus. The cytoplasm possesses rough endoplasmic reticulum, mitochondria, Golgi complexes (Gc), and type 1 granules (Gr_1) containing a crystalline structure (arrow). (B, D) Enlarged view of C exhibiting the cytoplasm of the NS_2 containing Golgi complexes (Gc), rough endoplasmic reticulum (rer), mitochondria (Mt), condensing vesicles (Cv) and secretory granules. Type 1 granules (Gr_1) contain a crystalline structure (arrow) embedded in a moderately osmiophilic matrix. Nu, nucleus.

(A) An electron micrograph of subtype a of NS_2 showing round nucleus (Nu) with a thin rim of heterochromatin (He) along the periphery and in the central region of the nucleus. The nucleolus (No) is very prominent. Mt, mitochondria; rer, rough endoplasmic reticulum. (B, C) Enlarged view of A, exhibiting the cytoplasm of NS_2 containing Golgi complexes (Gc), mitochondria (Mt), multivesicular bodies (mvb) and secretory granules (Gr). Nu, nucleus. (D) An electron micrograph of subtype b of NS_2, exhibiting a cytoplasm filled with a large number of spherical secretory granules (Gr). Nu, nucleus; He, heterochromatin. (E) An enlarged view of the spherical secretory granules (Gr) with dense matrices.

4A). The cytoplasm of the NS_2 cells in the cerebral ganglia possesses extensively developed rough endoplasmic reticulum, and has numerous mitochondria (Fig. 3D). There could be more than one Golgi complex per cell. Each Golgi complex usually consists of four to six elongated cisternae and saccules, which are often surrounded by dense vesicles (Fig. 3B). The most prominent granules appear large and round, membrane-bound, and about 500 to 800 nm in diameter. Each granule contains crystalline structures of various sizes, embedded in moderately dense osmiophilic matrices (Figs. 3B, D). These granules are concentrated at the maturing face of Golgi complexes (Fig. 3D).

The NS_2 cells of the pleuropedal ganglia contain abundant cell organelles, i.e., mitochondria, rough endoplasmic reticulum, Golgi complexes, multivesicular bodies (Figs. 4B, C), and small spherical secretory granules with dense matrices about 240 nm in diameter (Figs. 4D, E). NS_2 cells can be divided into two subtypes, viz subtypes A and B. Subtype A contains few neurosecretory granules, which are mostly concentrated at the Golgi complexes, and

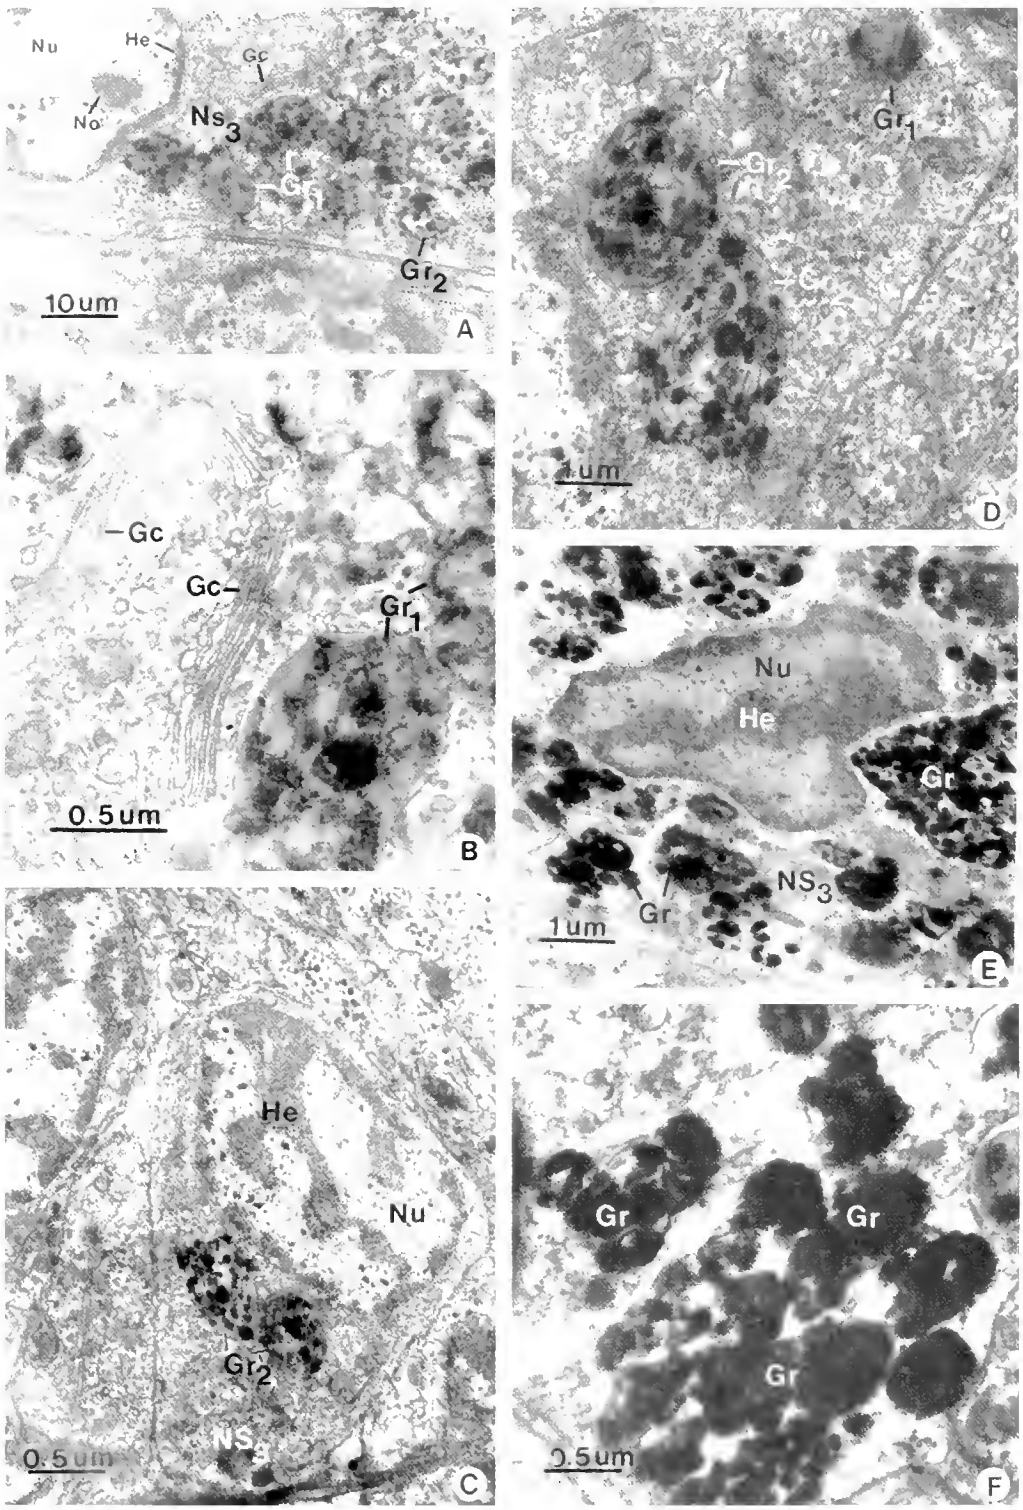

Figure 5. TEM micrographs of NS_3 cells of cerebral ganglia. (A) Medium power micrograph of NS_3 showing an oval nucleus (Nu) which contains thick strands of heterochromatin (He) near the nuclear envelope. The nucleolus (No) is very distinct. The cytoplasm contains rough endoplasmic reticulum, mitochondria, Golgi complexes (Gc) and secretory granules. Type 1 granules (Gr_1) are composed of strong osmiophilic material. Type 2 granules (Gr_2) are composed of highly condensed osmiophilic globules. (B) A high magnification of the cytoplasm of NS_3 showing extensive Golgi complexes (Gc) and type 1 granules (Gr_1). (C) Medium power micrograph of NS_3 showing an oval nucleus (Nu) containing thick strands of heterochromatin (He) near the nuclear envelope and blocks of heterochromatin passing through the center of the nucleus. (D) A high magnification of the cytoplasm of NS_3 containing type 1 granules (Gr_1) and type 2 granules (Gr_2). (E) Medium power micrograph of NS_3 showing an indented nucleus (Nu) which contains thick strands of heterochromatin (He) near the nuclear envelope and blocks of heterochromatin passing through the center of the nucleus. The cytoplasm contains aggregated granules (Gr). (F) An enlarged view of E exhibiting aggregated granules (Gr).

there is a large amount of rough endoplasmic reticulum, numerous mitochondria and extensively-developed Golgi complexes. Hence, they show evidence for high secretory activity (Figs. 4A, B). In contrast, cytoplasm of subtype B is filled mostly with neurosecretory granules and has few additional organelles (Fig. 4D). These cells appear to be in a storage phase where granules are ready to be discharged.

NS_3 cells are smaller (8–10 μm in size) than NS_1 and NS_2 (Fig. 5, Fig. 6). The nuclei are oval (about 5–6 μm in dimension) and some are indented (Figs. 5C, E, Figs. 6A, C, D). They contain a

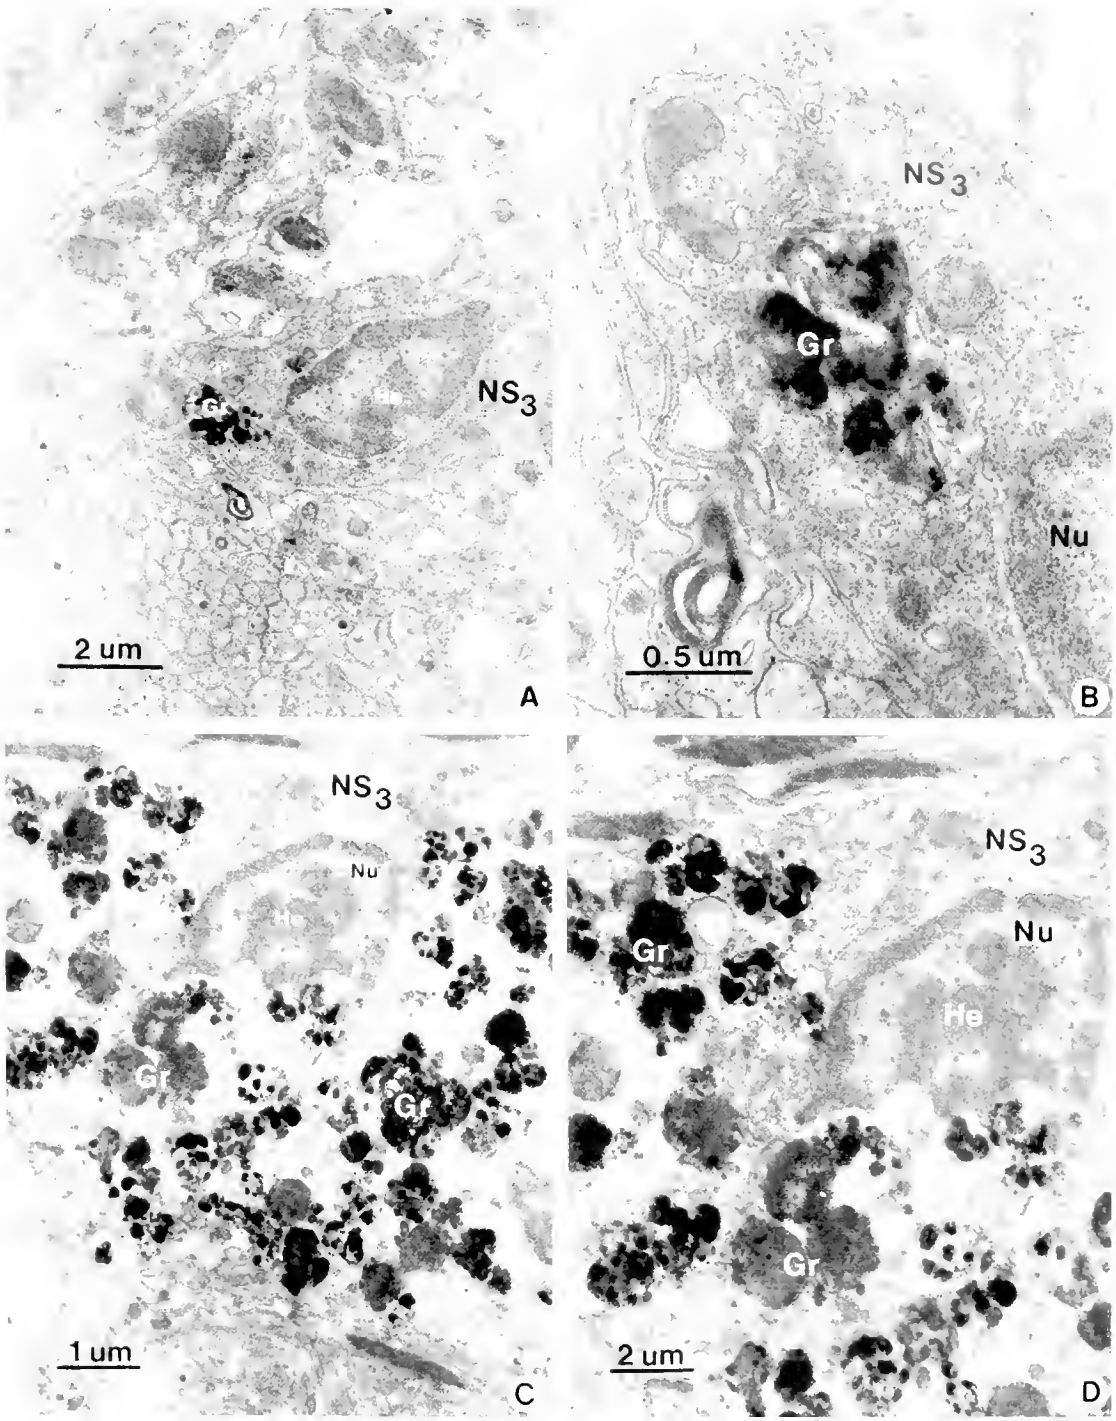

Figure 6. TEM micrographs of NS_3 cells of the pleuropedal ganglia. (A, B) Low and high power micrographs of NS_3 subtype 1 showing oval nuclei (Nu) which contain thick strands of heterochromatin (He) at the nuclear envelope and in the central region. The cytoplasm contains few large secretory granules (Gr). (C, D) Low and high power micrographs of NS_3 subtype 2, showing an oval nucleus (Nu) which contains thick strands of heterochromatin (He) near the nuclear envelope and in the central region. The cytoplasm contains aggregated granules (Gr).

thick rim of heterochromatin near the nuclear envelope, and a thick strand of heterochromatin in the center (Figs. 5C, E, Fig. 6D). In the NS_3 cells of the cerebral ganglia, the cytoplasm contains rough endoplasmic reticulum, mitochondria, and Golgi complexes, but these organelles are less abundant, and of smaller sizes, than those in NS_1 and NS_2 cells. Much cytoplasm is filled with secretory granules (Figs. 5A, D). These granules are large (2000–7000 nm in diameter), membrane-bound, and contain dense, osmiophilic globules of various sizes that are aggregated together. When examined in detail, these granules are divided into two subtypes. Type 1 secretory granules are composed of strongly osmiophilic crystalline material in a clear ground substance (Figs. 5A, B), and type 2 secretory granules are composed of highly condensed osmiophilic globules aggregated together (Figs. 5D, E, F). It is possible that type 2 secretory granules are developed from type 1 secretory granules.

In the NS_3 cells of pleuropedal ganglia, the cytoplasm contains less rough endoplasmic reticulum, fewer mitochondria, and fewer Golgi complexes, than those of NS_1 and NS_2. NS_3 cells are divided into two subtypes. Subtype 1 cytoplasm contains few, but large secretory granules, with a strong osmiophilic substance within a clear ground matrix (Figs. 6A, B), and subtype 2 cytoplasm contains numerous large secretory granules, each composed of strong osmiophilic globules aggregated together in a homogeneous ground substance (Figs. 6C, D). It is possible that neurosecretory cells of subtype 1 develop from subtype 2 through the condensation and dehydration of the osmiophilic substance.

DISCUSSION

The ultrastructural study of the neurosecretory cells in the cerebral ganglia of *H. asinina* revealed that there are three types of neurosecretory cells (i.e. NS_1, NS_2, NS_3). This is in contrast to only two types reported by Upatham et al. (1997) using light microscopy. The pleuropedal ganglia also contain three types of neurosecretory cells. The details of the heterochromatin and euchromatin in the nuclei of cerebral and pleuropedal ganglia neurosecretory cells were revealed by light microscopy and confirmed by the extra resolution of TEM. The NS_1 nucleus contains mostly euchromatin, while large amounts of heterochromatin were present in NS_2 and NS_3 cells. In general, the cytoplasm of these cells resembles that of neurosecretory cells described in other gastropods, such as *B. tentaculata* (Andrews 1971), *H. rufescens* (Miller et al. 1973), *A. fulica* (Kruatrachue et al. 1994) and *L. stagnalis* (Boer et al. 1968).

The main differences between the neurosecretory cells of the cerebral ganglion and those of the pleuropedal ganglion are the type and size of neurosecretory granules. In the cerebral ganglia, the NS_1 cell contains 2 types of secretory granules (large and small) while the NS_1 cell of the pleuropedal ganglion contains only one type (small granules). In addition, the NS_2 cells of the cerebral and pleuropedal ganglia both contain one type of secretory granule. However, they are different both in size and content. The NS_3 of both ganglia appear to contain one type of secretory granule that contains aggregates of dense globules.

In the cerebral ganglia, the NS_1 cytoplasm is composed of cell organelles, including numerous mitochondria, rough endoplasmic reticulum, Golgi complexes and secretory granules, which reflects a highly active secretory function. Golgi complexes are extremely large and there may be several present in a cell. Small electron-dense secretory granules are associated with the maturing face of Golgi complexes. These granules were later widely distributed throughout the cytoplasm. Hence, this indicates that the Golgi complexes in the neurosecretory cells of *H. asinina* have a similar role in packing of electron-dense material, to those of neurosecretory cells reported in other gastropods (Boer et al. 1968, Kai-Kai & Kerkut 1979).

The ultrastructural characteristics of the NS_1 of the cerebral ganglia indicate that it is a highly active synthetic cell. In comparison, the cytoplasm of NS_2 and NS_3 contains only one type of granule, which are large and round in NS_2 and polymorphic in NS_3. These granules bear crystalline structures in NS_2 and in NS_3 and are composed of aggregates of dense osmiophilic substances. The similarity between granules in NS_2 and NS_3 tends to indicate that the two cells could be of the same group. While the NS_2 appears to be in a more active secretory phase, the NS_3 has reached the fully differentiated state, in which hormonal product is already produced in abundance, stored, and ready for release.

In the present study, the cytoplasms of NS_1 and NS_2 cells in the pleuropedal ganglia of *H. asinina* exhibit characteristics which imply that they have actively synthetic features. These are the numerous mitochondria, rough endoplasmic reticulum, Golgi complexes, multivesicular bodies and secretory granules, and numerous small clear vesicles that may be transport vesicles in the cytoplasm. Rough endoplasmic reticulum and Golgi complexes are well developed. The electron-dense secretory granules are probably formed from the Golgi complex. This process is similar to that described in neurosecretory cells in the pleural ganglia of *L. stagnalis* (Bonga 1970).

INTERACTIONS AMONG RED ABALONES AND SEA URCHINS IN FISHED AND RESERVE SITES OF NORTHERN CALIFORNIA: IMPLICATIONS OF COMPETITION TO MANAGEMENT

KONSTANTIN A. KARPOV,[1]* MIA J. TEGNER,[1]† LAURA ROGERS-BENNETT,[2] PETER E. KALVASS,[1] AND IAN K. TANIGUCHI[3]

[1]*California Department of Fish and Game, Fort Bragg, California 95437;* [2]*California Department of Fish and Game, Bodega Marine Laboratory, Bodega Bay, California 94923;* [3]*California Department of Fish and Game, Los Alamitos, California 90720*

ABSTRACT Red abalones (*Haliotis rufescens*), red sea urchins (*Strongylocentrotus franciscanus*), and purple sea urchins (*S. purpuratus*) share similar food and habitat requirements in northern California. Red abalones and red sea urchins also support important fisheries. Here we explore spatial interactions and apparent competitive effects among these species at an area where fishing has large impacts on both taxa, and at unfished reserve sites in which invertebrate density and food availability differ. There was an inverse correlation between adult red abalone and red sea urchin abundance at the scale of our transects when density of either or both species was high. In the poorest habitat for macroalgae, red abalones seldom occurred on the same transects with red urchins. The results suggest that differences in density, depth, and food availability play an important role in the observed spatial patterns of red abalones and red sea urchins. Purple sea urchins were not correlated to either of the other two species' distributions. An intense fishery for red sea urchins appears to have had a positive effect on kelp availability, and abalone growth and abundance. Aerial photographs during the period of intense urchin fishing (from 1982 to 1989), showed a dramatic increase in the surface canopy. Similarly, during this period, size frequency distributions of fished red abalones show an increase in the number of individuals in larger size classes. Modal progression in abalone size frequency distributions suggests a faster growth rate during this period when compared with a growth study, at the same location, conducted during the pre-urchin fishery years. Ultimately, red sea urchin removal apparently led to an increase in red abalone abundance even at a site that was heavily fished by recreational abalone fishers. Meanwhile, at a nearby reserve site where kelp populations are lower, red abalones have declined in abundance as red sea urchins increased. Our results suggest the need for multi-species ecosystem-based approaches to management of these valuable resources.

KEY WORDS: reserves, *Haliotis rufescens*, *Strongylocentrotus franciscanus*, *Strongylocentrotus purpuratus*, competition, spatial exclusion, ecosystem-based management

INTRODUCTION

Red abalones (*Haliotis rufescens*), red sea urchins (*Strongylocentrotus franciscanus*) and purple sea urchins (*S. purpuratus*) share similar food and habitat preferences in kelp forest communities along the California coast. In northern California, red abalones are found in rocky intertidal and shallow subtidal areas in high abundance at 7–8-m depths, but also occur down to 25 m in areas where drift algae accumulate in surge channels. Red and purple urchins are found from mid- to low- intertidal zones to depths in excess of 50 m. Both species prefer rocky substrates, particularly ledges, crevices and surge channels, and avoid sand and mud (Schroeter 1978, Kato & Schroeter 1985). In areas of high predation, red abalones show a preference for crevice habitat (Hines & Pearse 1982). Red abalones and red and purple urchins feed primarily on the same species of macroalgae (Leighton & Boolootian 1963), and have been described as potential competitors for food and space (Leighton 1968, Tegner & Levin 1982). Both urchins and abalones feed primarily on drift kelp, but sea urchins are well known for their destructive grazing on attached plants when drift becomes limiting. Schroeter (1978) presented evidence that red urchins out compete purple urchins for food and habitat, suggesting that the red urchin fishery could lead to an increase in populations of its smaller congener. Several authors have considered the potential of sea urchin populations being released from competition as abalones were fished down in southern California (North & Pearse 1970, Tegner 1980, Tegner & Levin 1982, Tegner & Dayton 2000). No one has examined the effects of red urchin removal in areas where red abalones are still abundant.

Red abalones and red sea urchins are both fished intensively in northern California. Red abalone take is restricted to recreational fishers who are prohibited from using SCUBA. Karpov et al. (1998) reported that this results in a "defacto" refuge for red abalone at depths greater than 8.4 m. Since 1985, Red urchins have been subjected to an intense commercial fishery at all depths (Kalvass & Hendrix 1997). Purple sea urchins are essentially unfished, comprising less than 1% of the total urchin landings.

The red abalone, the largest member of the genus, attains sizes of up to 312 mm in northern California (Department of Fish and Game -DFG- unpublished data). Legal minimum size for the recreational-only abalone fishery is 178-mm shell diameter. Red sea urchins, characterized by long spines in relation to test diameter (TD), attain sizes of 140 mm TD, and were first protected by a minimum size limit of 89-mm TD in 1991. Purple sea urchins have short spines relative to their TD, and maximum TD is about 85 mm. In northern California macroalgae are highly seasonal as a food source (Tegner et al. 1992). Wave energy is markedly higher in northern compared to southern California, and thus is likely to be a more important factor affecting the distribution of abalone and urchins (Deacon 1973).

Fishing effects, both direct and indirect, make field studies of competition difficult to conduct. Here we take advantage of three locations in northern California, one fished and two reserves closed to sport and commercial fishing, to examine biological and fishery interactions between red abalones, red sea urchins, and purple sea urchins. Differences in fishing regimes constitute a natural experiment, which offers an opportunity to examine the factors structuring this nearshore community, the potential produc-

†Deceased.

tivity of the three grazers, and the ecosystem effects of fishing. We compare observations of densities, size-frequency distributions, and spatial distributions of the three grazers and kelp populations over time. Two major questions are asked in this study: (1) Has intense red urchin removal by the fishery had an affect on the abalone resource, and (2) are there significant differences by habitat, density, or depth that indicate spatial exclusion between sea urchins and abalones.

Materials and Methods

Our study is focused in northern California on a fished area, Van Damme State Park (VDSP), and two unfished "control" areas: Bodega Marine Life Refuge (BMLR) and Point Cabrillo Marine Reserve (PCMR)(Fig. 1). VDSP is highly impacted by both the sport only abalone fishery and the commercial red sea urchin fishery. In this study, we used the same 120 dive stations examined for changes in emergent abalone abundance and size distributions during 1986, and from 1989–1992 by Karpov et al. (1998). In 1999, we added 34 more stations that were at comparable locations to those surveyed during earlier years. Red urchins were surveyed throughout these periods; purple sea urchins were added in 1989. As in the previous study (Karpov et al. 1998), we stratified our sampling into two strata, "shallow" and "deep", using 8.4 m as the dividing depth because free divers seldom dive deeper than 8.4 m to collect abalone. Thus, the VDSP study area represents a treatment of large-scale continued removal of red urchins at all depths and red abalones from shallow water. Two no-take reserves were also surveyed, PCMR and BMLR (Fig. 1). Parker et al. (1988) first surveyed 30 stations at PCMR in 1986. PCMR was re-sampled in 1988 for sea urchins at 14 stations and again in 1999 at 30 stations. About half of the 1999 stations were in close proximity to locations sampled in 1986. Sampling was normally conducted during late summer months. Station depths throughout the study period ranged from 2 to 18 m. Sampling was conducted along 2 × 30 m transects randomly placed on rocky habitat. Transects were not sampled if they were placed on substrate with more than 50% sand.

PCMR, first established as a "no-take" reserve in 1975, is located 9 km north of VDSP. PCMR provides both a site for comparing spatial correlation for high densities of red and purple sea urchins to high densities of red abalone, as well as a nearby unfished control for comparison with the fished VDSP site. BMLR, located 130 km south of VDSP, was established as a no take reserve in 1966 (Fig. 1). In 1999, 33 stations at BMLR were sampled to examine spatial correlation in an area with no surface canopy of kelp in more marginal abalone and urchin habitat. We also examined this area on a smaller spatial scale. Stations were grouped into three sites of distinct habitat, designated Horseshoe Cove, Cave, and Points (North and South Point combined) (Fig. 2).

To compare the relative availability of food at each study area, percent cover of algae was estimated by divers on each quadrant and averaged in all three of the study sites during 1999. Algae and cover were classified in five categories: encrusting, coralline algae turf, foliose, understory, or canopy kelp. Understory kelp included brown algae such as *Pterygophera californica* and *Laminaria dentigera*. The primary canopy species in northern California was the annual kelp, *Nereocystis luetkeana*. Percentage cover at times exceeded 100%.

Size frequency distributions, weighted for density, were examined for patterns of recruitment of red sea urchins and red abalones at VDSP and PCMR. Size frequency distributions of red urchin catches were obtained from commercial samples. Estimates of

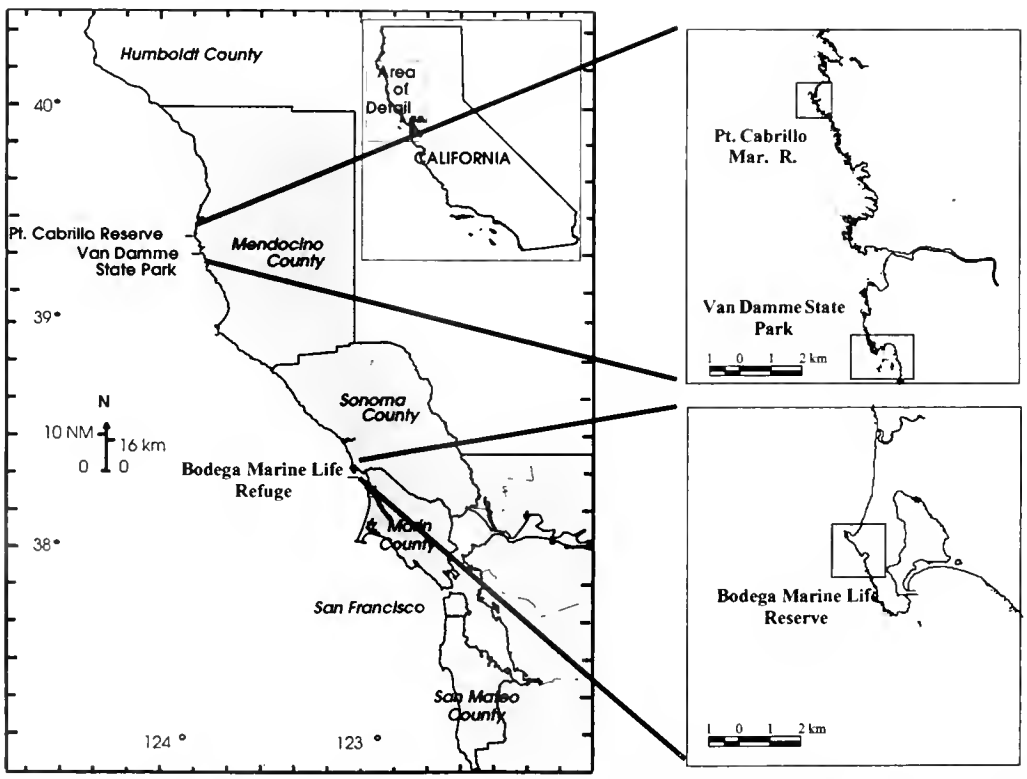

Figure 1. Location of Point Cabrillo Marine Reserve (PCMR), Van Damme State Park (VDSP), and Bodega Marine Life Refuge (BMLR) study areas in northern California.

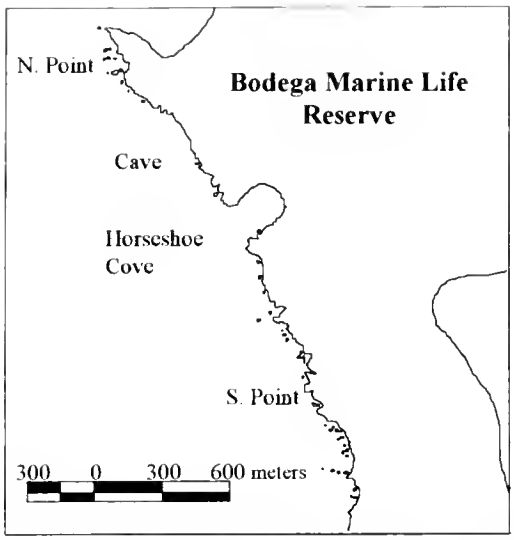

Figure 2. Detailed view of BMLR showing sampling areas.

urchin catch at VDSP were made from fishery logbook data. Creel surveys of sport-caught red abalones conducted during spring minus-tides from 1977 to 1994 at VDSP were used to construct size frequency distributions of the sport take.

Estimates of kelp surface canopy were obtained at VDSP from aerial infrared photographs taken each October from 1982 to 1991. Surface areas estimates were constructed from polygons drawn visually in Arc View GIS software.

Statistical Comparison

Red abalone and red sea urchin counts from 2 × 30 m transects at VDSP and PCMR were compared using two-way ANOVAs testing differences between year and depth strata. Densities were transformed using the method of Pearse and Hines (1987) (transformed density = ln (density + 1)). The non-parametric Spearman Rank Correlation test was used to examine inter-specific spatial correlation. Paired counts of each of the three species were used. The test produces a correlation coefficient (r_s) range 1–1. Transects with zero counts were excluded from these comparisons to avoid inappropriate habitat.

We used 1986 PCMR data to examine the effect of transect size on the observed inverse correlation between red abalones and red sea urchins. Since data that year were recorded on a finer scale, subdividing the 2 × 30 m transect into six 1 × 10 m segments, we examined spatial correlation by randomly selecting a 10, 20, and 60 m^2 segment from each of 26 shallow and deep transects. The inverse relation was significant at both 20 ($r_s = -0.55$, $P = 0.004$) and 60 m^2 ($r_s = -0.43$, $P = 0.03$) transect sizes, but not significant at 10m^2.

Red abalone and sea urchins were classified as having either low or high abundance at each of the three locations across the years examined, depth strata, and habitat types. This classification was used to create a matrix allowing the significance of the correlation coefficients related to high or low density of any of the species to be examined. The abundance of red abalone, red sea urchin, and purple sea urchin was considered high at greater than 0.4, 1.0, 1.0 m^{-2}, respectively. Similarly, inter-specific spatial correlation was examined at each of the three habitat types at BMLR and between the three study areas. Finally, correlation was also examined at VDSP and PCMR over time to determine if fishery related abundance changes reflected spatial exclusion. Significance for all tests was set at $\alpha = 0.05$.

RESULTS

During the 1999 survey, BMLR had the least macro-algae of the three study areas. While relative cover of foliose algae was comparable to the other two study areas, canopy was absent and understory much less abundant (Table 1). Horseshoe Cove had the largest standing stock of understory in BMLR. VDSP had the highest algal cover of all three study areas. Surface canopy covered 65% to 79% of shallow and deep stations. Understory and foliose algae were more abundant at shallow than deep stations. PCMR was intermediate between BMLR and VDSP in macro-algae abundance, with the highest abundance at the shallow stations.

BMLR

Red abalone were low in abundance throughout BMLR. They were the most abundant at Horseshoe Cove (0.4 abalone m^{-2} SE = 0.1), followed by Cave (0.2 m^{-2} SE = 0.1) and Points (0.1 m^{-2} SE = 0.03) stations (Fig. 3). Almost all abalones were found at shallow stations, with only three encountered at deep (>8.4 m) stations. Red sea urchin densities were low in Horseshoe Cove (0.6 red urchin m^{-2} SE = 0.2) but higher at both the Cave (1.2 m^{-2} SE = 0.3) and Points (1.1 m^{-2} SE = 0.2). Purple sea urchins were found in very low abundance throughout this reserve. No significant correlation in counts was found between purple urchins and either red abalones or red urchins at any of the three BMLR sites. Red urchin and red abalone counts, however, were negatively correlated on transects at each of the three sites (Fig. 3). Plots of the distribution of counts by station showed marked segregation by species at almost all the stations, with few containing both species. Patterns of segregation were similar among the three locations in the reserve irrespective of relative density decrease for abalones or increase for sea urchins.

PCMR

While generally higher than BMLR, red abalone densities at PCMR declined in both shallow water (from 1.2 SE = 0.2 to 0.6 m^{-2} SE = 0.1) and in deep depths (1.2 SE = 0.2 to 0.1 m^{-2} SE = 0.1) during this 13-year interval (Fig. 4, Fig. 5). ANOVA comparison showed the difference in density to be significant by

year, depth, and interaction (Table 2). Red sea urchin densities were significantly greater at depth and in 1999 (interaction was not significant). Size distributions reveal very little differences with large proportions of animals at both depths at or above legal sizes for both species (Fig. 6). Deep water red urchins showed evidence of recruitment in both years with bimodal distributions of YOY (<30mm) or small juveniles and large adults. Purple sea urchins, not surveyed in 1986, were at greatest abundance at shallow depths in 1999 (3.2 m^{-2}, SE = 1.0, Fig. 4 and Fig. 5).

Purple sea urchins at PCMR were not significantly spatially correlated to the other two species at the scale of our transects. Correlation comparisons between red abalones and red sea urchins were significantly negative in both 1986 and 1999, when shallow and deep stations were combined. Comparisons at shallow depths were significantly negative in 1986 and 1999 (Fig. 4). Graphical comparison of correlation revealed more overlap or concurrence of both species on the same transects than observed at BMLR. At deep stations in 1986 the correlation was negative but not significant (Fig. 5). PCMR was the only area where high densities of both red abalones and red urchins were found in our study. Under these high densities both species were significantly negatively correlated ($r_s = -0.52$ $P < 0.0001$, Table 3).

VDSP

In 1986 red abalone densities at VDSP were low in deep (0.1 m^{-2} SE = 0.1) and shallow depths (0.4 m^{-2} SE = 0.1), while red sea urchin densities were low at shallow (0.4 m^{-2} SE = 0.1) and high at deep stations (1.7 m^{-2} SE = 0.3) (Fig. 7, Fig. 8). Abalone densities had increased significantly to 0.8 (SE = 0.1) at shallow stations, and to 0.9 m^{-2} (SE = 0.2) at deep stations by 1992. Karpov et al. (1998) examined this difference using ANOVA and found the increase to be significant between years and depths (Table 2). During the same period, red urchin densities underwent significant decline by year and depth (P = 0.04 and 0.0001 respectively). By 1999, deepwater red urchin abundance had recovered to 2.4 m^{-2} (SE = 0.5), while red abalones had declined to 1986 levels (0.1 m^{-2} SE = 0.1). Repeating the ANOVA comparison revealed that the change in red urchin abundance was no longer significant by year, but still significant by depth. Purple sea urchins, first examined in 1989, underwent significant increases by depth and by year, increasing primarily at deep stations to 1.8 m^{-2} (SE = 0.7) in 1992 (Fig. 7, Fig. 8, Table 2).

VDSP data allowed comparison of species correlation at various combinations of density for each of the species (Table 3). Except at low densities of each, red abalones and red sea urchins were significantly inversely correlated ($P < 0.04$). Again, as in the other two study areas, no significant correlation was observed for purple sea urchins when counts were paired to either of the other two species.

Size distributions of both red abalones and red sea urchins at VDSP weighted for abundance were compared for evidence of recruitment by depth (Fig. 9). Red abalone size frequencies showed a clear pulse of juveniles at shallow depths in 1989. The mode in deep water appeared later, and grew into sizes larger than the sport size limit by 1992. In 1999, the deep water abalones remaining included few juveniles and resembled the 1986 and 1989 distribution. In shallow water, the distributions showed a large buildup of large adults over all previous years, with less evidence of recent juvenile recruitment than had been apparent in 1989 through 1992.

Size distributions of red sea urchins, first measured in 1990, showed a deep water peak at the minimum commercial legal size

limit of 76 mm, first imposed in 1989 (Fig. 9). That mode declined through 1992 with little evidence of recruitment at either depth during that period. In 1999, a large cohort of red urchins, analogous to the earlier event for shallow water red abalones, had become established at deep depths with the peak, knife-edged, at the new 89 mm legal size limit, first imposed in June 1990.

Apparent Competitive Effects

Commercial landings of red sea urchins were first reported at the Van Damme area in 1985 (Fig. 10). Landings peaked at 800 mt in 1987, and declined along with CPUE (kg per diver day) through 1993. Size distributions of red urchins remained essentially flat from 1987 through 1990, becoming increasingly positively skewed by 1994 with few animals taken below the newly imposed size in 1990, and a decreasing number of animals larger than 120 mm taken (Fig. 11).

Surface kelp canopy at the VDSP area increased dramatically from 3 to 45 ha between 1982 and 1987. This coincided with increased red sea urchin removal (Fig. 10). *Nereocystis luetkeana* was the dominant kelp but the canopy also included *Macrocystis integrifolia*.

While the level of sport take was not monitored at VDSP, telephone surveys conducted from 1986 to 1989 estimated that there were 30,000 to 40,000 sportsmen in the northern red abalone fishery (CDFG unpublished). In 1998, a $12 stamp was instituted for the abalone sport fishery; 32,000 were sold in 1998, and 35,000 in 1999. VDSP is among the most highly utilized sport fishing sites in northern California. Creel surveys conducted at this site during spring and early summer since 1977 reveal continued high use with no decline in CPUE throughout our study period.

Red abalone size distributions from diver creels at VDSP can be segregated into pre- and post-onset of the sea urchin fishery. The first period, from 1977 through 1985, shows little change (Fig. 11). Size distributions during this period were highly skewed to the right, with the mode adjacent the sport legal size of 178 mm. Two of these years, 1983 and 1984, had the most positively skewed distributions with the lowest mean size of 188 mm. The second period (1986 to 1994) is characterized by dispersal into a flat distribution and an apparent modal progression from 182 mm in 1987 through 206 mm in 1992.

DISCUSSION

Spatial Interactions

There was a significant negative correlation between red abalones and red sea urchins at all sites and depths with the exception

of deep-water stations at PCMR in 1999. This positive correlation is an artifact of data from only two stations; abalone were absent from 10 of 12 deep stations. The consistent negative correlation for all other comparisons suggests spatial interspecific exclusion between these two species. Deacon (1973) found a similar negative correlation between red abalones and red urchins in Sea Ranch, a northern California location between BMLR and VDSP. In 2000 we completed an additional 24 emergent transects, 13 deep and 11 shallow, at Salt Point State Park, located north of BMLR and south of VDSP (Bennett unpublished). Red urchins and red abalones were again negatively correlated in an area of high red abalone (0.84 m^{-2}) and low red urchin (0.90 m^{-2}) densities. Once more, red urchins were most abundant at deep and red abalones at shallow stations. Our finding of significant negative correlation at all but low densities of both red abalones and red urchins suggests that the observed spatial exclusion is density related. The increase in abalone abundance occurred during a period of increased surface

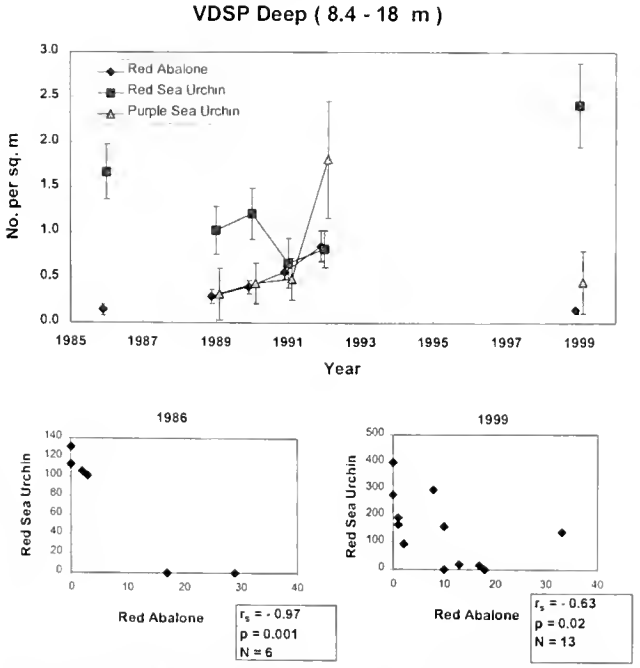

Figure 8. Red abalone, red sea urchin, and purple sea urchin densities (± se) at VDSP deep depth stations in 1986, 1989 to 1992, and 1999 with paired comparison of counts by species at each station with Spearman Rank correlation coefficients (r_s), statistical significance, and number of stations in 1986 and 1999.

canopy and therefore increased food abundance. Karpov et al. (1998) reported on the increase in abalone populations at VDSP at both depths from 1986 to 1992. Mechanisms responsible for this increase could include large-scale removal of potential competitors by the urchin fishery and positive effects on abalone growth due to increased kelp production.

The most profound lack of co-occurrence between red abalones and red sea urchins was at BMLR, the site with the least available macroalgae. This suggests competitive exclusion is greatest in habitat where food is limiting. It is likely that high silt loads from the Russian River (8 km to the north) and urchin grazing may limit kelp productivity in this area. Tegner et al. (1992) described areas adjacent to San Francisco Bay as marginal habitat, largely influenced by sediment loads from the bay. et al. (1997) reported comparable habitat to BMLR, with an absence of canopy and lack of understory algae below 13-m depth, off Fitzgerald Marine Reserve (another area near San Francisco Bay) in 1993. Canopy and understory kelps are the primary source of drift needed to support abalone as well as sea urchin populations (Deacon 1973, Tegner & Dayton 1991, Tegner et al. 1992).

The lack of correlation (positive or negative) between purple sea urchins and the other two species, at the scale of our transects, suggests that the spatial distribution of this species is not strongly correlated to the other two species. We note, however, that Schroeter (1978) found that the longer-spined red urchins exclude purple urchins from the most desirable habitat (within the m^2 scale) by spine fencing. The mechanism responsible for the increase in purple urchin abundance at both shallow and deep stations in VDSP may have been a release from competition for space as red sea urchin stocks declined due to fishing, or a strong coincident recruitment event. Off Sea Ranch, northern California, Deacon (1973) found a significant positive correlation between red urchins and purple urchins but no significant correlation between purple urchins and red abalones. Tegner et al (1989) observed significant increases in purple urchins at Johnson's Lee, Santa Rosa Island, an area that had also been subjected to intense fisheries for both red urchins and red abalones. Lafferty and Kushner (pers. comm.) reported periodic rapid increase and collapses of purple urchin populations off the northern Channel Islands in southern California from 1983 to 1998, with decreases due to starvation and disease following warming events. Our results and those of Tegner et al (1992) and Ebert and Russell (1988) are consistent with strong episodic recruitment for this species but do not clarify whether this follows release from competition for space.

Sea urchins are more adapted to periods of starvation than abalones, persisting for long periods on drift and microflora after macroalgae have disappeared from an area (Leighton 1968, Shepherd 1973, Tegner & Levin 1982). In spite of the overlap in their diet, red sea urchins have a more generalist feeding strategy than abalone (Leighton 1966). Abalones are essentially drift feeders, while sea urchins can act as drift feeders or can form feeding fronts that actively graze attached kelps when food is extremely limited (Harrold & Reed 1985). At both PCMR and VDSP, we found understory algae to be least abundant at deep depths, suggesting that food is more limiting at deeper depths. More drift algae at shallower depths have been observed at other sites in northern California (Rogers-Bennett et al. 1995).

The significant difference in red abalone and red sea urchin abundance by depth at VDSP and PCMR suggests differences in habitat preference between the two species. Greater numbers of red urchins were found at deeper stations and conversely greater num-

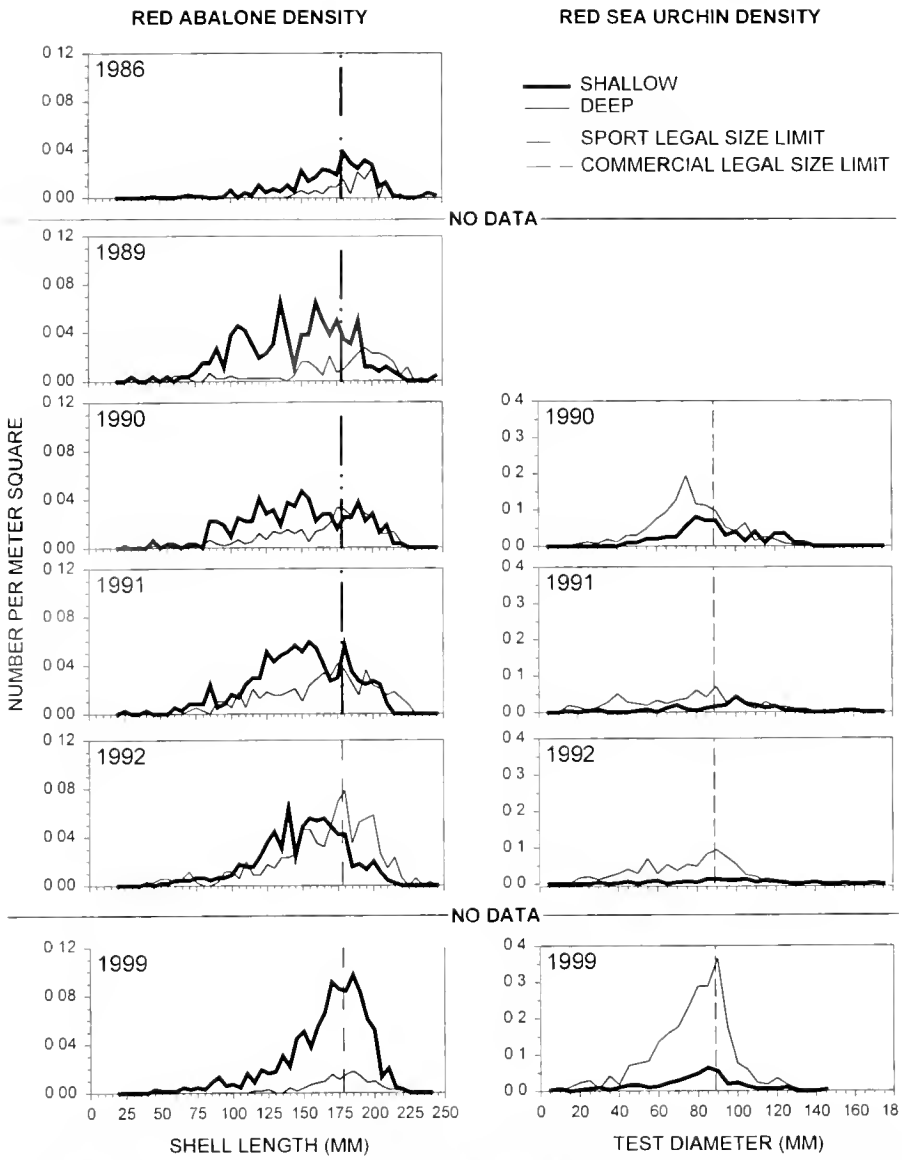

Figure 9. Red abalone and red sea urchin size density from emergent dive transects at VDSP at both shallow and deep depths. Years compared for red abalones are 1986, 1989-1992, and 1999; and for red urchins 1980-1992 and 1999. Vertical Lines represent minimum legal size for red abalone (178 mm) and red urchin (89 mm).

bers of red abalones at shallower depths. The absence of red abalones was most pronounced at deep depths off BMLR where food is most limiting, but was also apparent for abalones at VDSP, in spite of intense fishing pressure for abalone at shallow depths. The increased red abalone densities observed in deep stations at VDSP during the 1989 to 1992 period did not persist into 1999 and declined significantly following an increase in abundance of red urchins. A greater abundance of abalones at shallow depths in northern California may reflect their morphological adaptation to the high surge conditions found in shallow waters (Cox 1962, Deacon 1973). While both species prefer crevice habitats, especially in areas of high predation such as the sea otter range (Hines & Pearse 1982), urchins are more easily dislodged by wave action (Dayton 1973), and would be most vulnerable outside of crevices at shallow depths. In New Zealand, manipulative experiments reducing sea urchin densities enhanced the recruitment, survival, and growth of abalones (Andrew et al. 1998).

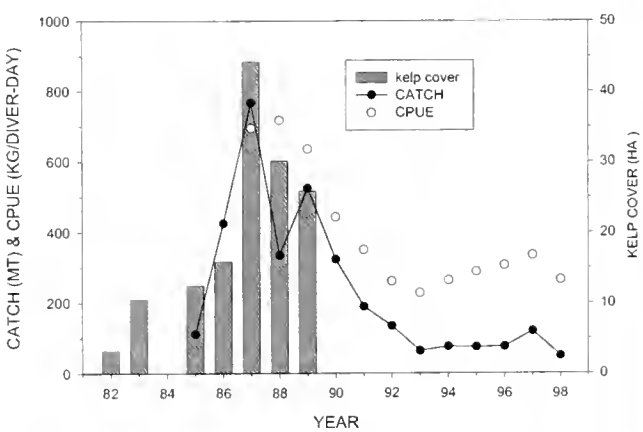

Figure 10. Commercial landings of red sea urchins, catch per unit effort (CPUE), and kelp canopy cover in the VDSP area.

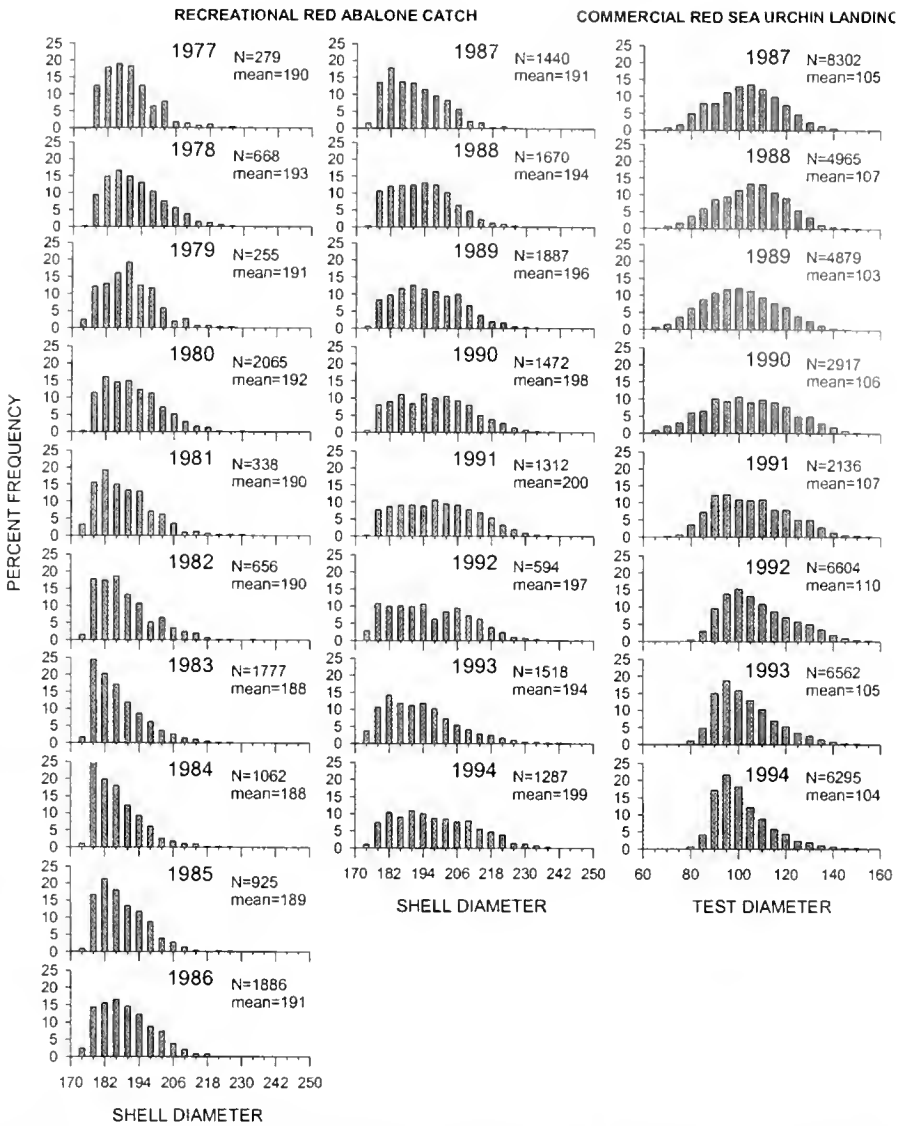

Figure 11. Size frequency distribution of commercial red sea urchins taken from the VDSP area from 1987 to 1994 with size of sport-diver-landed red abalones from 1977 through 1994. Legal minimum sizes are 178 mm for red abalones and 89 mm for red sea urchins.

Apparent Competitive Effects and Fishery Changes

Karpov et al. (1998) reported on the strong recovery in abalone populations in both depths at VDSP from 1986 to 1992. Both red sea urchin removal and enhanced abalone growth with increases in algal food are likely to have contributed to this increase in abalone abundance. Low kelp abundance observed at VDSP in 1982 and 1983 probably reflected the effect of grazing by an unfished population of red urchins. The rapid increase in kelp cover concurrent with high levels of urchin removal suggests kelp productivity and abundance increased along with removal of the sea urchins. Unfortunately, surface canopy aerial photographs were discontinued following 1989. Continued low levels of CPUE and increasingly skewed urchin size distributions in the fishery show that intense fishing continued throughout our study period.

Red abalone growth appears to be somewhat plastic and able to respond to increased food availability (Haaker et al. 1998). Modal progressions observed in size frequency distributions of sport-caught red abalones in the VDSP vicinity between 1987 and 1993 imply a growth rate of about 4 mm per year for abalone greater than about 180 mm shell length (SL) (Fig. 11). This growth rate is greater than observed in previous tag and recapture studies in northern California (Tegner et al. 1992) and southern California (Haaker et al. 1998). A DFG (unpublished) study at Van Damme from 1973 to 1977 based on 275 recaptured tagged red abalone showed an annual growth rate of <1 mm at sizes above 178 mm SL. While this is an area for more rigorous research, we propose a mechanism for this empirical observation of increased abalone growth at VDSP.

The importance of sea urchin grazing to the structure of kelp communities is well known (Nicholson 1970, Lawrence 1975, Harrold & Pearse 1987). Removal of an estimated 2,878 mt of red sea urchins from the VDSP area (approx. 3.5 km of coastline) from 1985 to 1993 coincided with an explosive increase in kelp canopy from 12.5 ha in 1985 to 44.2 ha in 1987 (Fig. 10). Concomitant with these events was a reduction in the larger size classes of red urchins. Red urchins ≥120 mm TD comprised 24.9% of the Mendocino County catch in 1992 (Mendocino County is used as a

proxy for the VDSP sea urchin catch, because of inadequate sampling at that location). By 1998, these sizes made up only 9.5% of the catch. This suggests a mechanism for the observed abalone growth rate increase, whereby removal of significant amounts of a primary macro-benthic grazer like sea urchins, as well as a continuing vigorous fishery for the abalones themselves, allowed release of the kelp canopy as well as subsurface kelps from grazing. This led to increased food availability for the remaining kelp grazers.

Red sea urchin size distributions by density at deep stations in 1999 showed peaks at 85–99 mm TD at PCMR and 80–94 mm TD at VDSP (Figs. 6 & 9). Based upon a combination of observational and experimental evidence, these peaks appear to be comprised primarily of a cohort that settled during the 1992–93 El Niño. Significant settlement events of red urchins were noted on artificial substrates monitored since 1990 at shallow subtidal stations at PCMR and Westport (about 30 km north of PCMR) in late spring and early summer 1992 and spring 1993 (Ebert et al. 1994). Subtidal surveys in the vicinity of PCMR in fall 1994 noted a strong cohort averaging 18 mm TD, 16 months following the spring 1993 artificial substrate settlement event (Kalvass & Hendrix 1997). Ebert (1997) developed a growth transition matrix for California red urchins with annual probabilities of transfer between 10 mm size groups. We applied these probabilities to the observed 1994 10–20 mm cohort and estimated that 63% would grow to the 80–100 mm size groups by the time we observed them in 1999 at both PCMR and VDSP. Growth of the observed cohort in 1994, from significant settlement events in 1992 and 1993, might account for much of the peak near the commercial red urchin minimum size limit of 89 mm TD observed in 1999 (Fig. 9).

Mechanisms

Our finding that red abalones are displaced from deep but not shallow depths at VDSP, combined with the negative correlation observed in abalones and red sea urchins at comparable densities in 1986, strongly suggests that competitive exclusion of red abalones has occurred. Disappearance of red abalone in deep water could have resulted from other mechanisms including illegal take (Daniels & Floren 1998), a major mortality event from disease (Lafferty & Kuris 1993), or movement to shallow depths during a period of successful red urchin recruitment.

Temporal changes in density at PCMR support the trend of exclusion of red abalones in deeper water but need to be interpreted cautiously. Densities where compared between two years bracketing a thirteen year interval and not a time series as sampled at VDSP. In addition, since only half of the same locations were resampled in 1999, spatial variations in habitat could have exaggerated (or underestimated) actual temporal differences in abundance (Thrush et al. 1994).

Red sea urchins in northern California appear to be much less mobile than red abalones. Ebert et al. (1999) tagged thousands of red urchins at 20 locations between southern California and southeast Alaska, for growth analysis. Recovery rates at these sites after approximately one year ranged from 13% to 76% for internally tagged urchins. These high recovery rates indicate that red urchins are relatively sessile. Conversely, red abalone tagging studies indicated abalone can move considerable distances. In a study at PCMR, Ault and DeMartini (1987) found that in an area of high abundance 11% of the tagged population moved over 90 m, with one animal moving 0.6 km. Similarly, high numbers of tagged red urchins (16–38%) were recovered after one year from sites in Salt Point in northern California. Twice as many urchins were recovered from a shallow site compared with a deep site, suggesting urchins in shallow water are more sedentary (Rogers-Bennett 1994). Deacon (1973) also found that the vast majority of red urchins moved far less than red abalone, during movement experiments at Sea Ranch. In the spring of 1998 starving red abalone were reported by divers south of Noyo Bay, 14 km north of VDSP (Haaker & Karpov, unpub. obs.). They observed a marked absence of understory kelps with evidence of abalone undergoing unusual movements over foliose algae in search of food. One possible explanation for the decline in deep-water abalones off VDSP could be recent movement to shallow depths in search of food.

Continued low numbers of red sea urchins at shallow depths in Van Damme are expected, given the high density of red abalone remaining at shallow stations in 1999. Urchins could only survive at shallow depth in crevice areas protected from extreme sea conditions (Deacon 1973), and it is unlikely that red urchins could displace red abalones from such habitat once occupied. While we found that the removal of red sea urchins at shallow depths in VDSP appeared to enhance the abundance of adult red abalones, juvenile abalones are known to shelter under the spine canopy of red sea urchins, complicating the relationship between red abalones and red sea urchins (Tegner & Dayton 1977, Rogers-Bennett & Pearse 2001).

CONCLUSIONS

Our results suggest that spatial competition between red abalones and red sea urchins is density related and appears to be most pronounced in habitats where macroalgae are scarce. In kelp beds these species co-occur on transects more frequently but are negatively correlated when either species is in high abundance. Intense red urchin fishing at VDSP coupled with a major recruitment event of red abalones appears to have enhanced abalone density in both shallow and deep depths through 1992. This release from inter and intraspecific competition for space and food resulted in a large surplus abalone population at refuge depths through the early 1990s. However, significantly lower densities of abalone are now apparent at depth. A major recruitment event for red sea urchins appears to have depressed abalone populations at depth. We cannot rule out the possibility of movement, mortality, or poaching of deep water red abalones as causes for the decline. In the absence of fishing for both species, densities of red abalones at an adjacent PCMR reserve site are now below those found at the intensely fished area, while sea urchins have increased to greater numbers than fished abundance. With its high urchin abundance, PCMR kelp populations are also lower than at nearby VDSP. Together this suggests that fishing of both red urchins and red abalones at VDSP enhanced abalone densities. We therefore suggest that an ecosystem approach that takes into account multispecies interactions, should be an important consideration in managing these fisheries in northern California.

ACKNOWLEDGMENTS

We especially wish to thank Neville Sweijd and Peter Cook for making presentation of our work possible. We thank Carolyn Friedman, Jerry Kashiwada, Mike Prall, and Kristen Riser for their contributions to the analysis. We also wish to thank the many research divers and biologists who over many years have contributed their time and efforts in field collections used in our study. Thanks to Sonoma County Fish and Wildlife Advisory Board for supporting travel expenses for L. Rogers Bennett.

ABSTRACT Declines in landings of Southern California abalone fisheries and the eventual collapse of many stocks over the last two decades coincided with a period of greatly increased environmental variability. This included massive storms, an increase in the frequency of warm-water El Niño events after 1976, and an interdecadal-scale increase in sea surface temperatures. Kelp populations may be decimated by severe storms or warm water. Because of the strong inverse relationship between nitrate availability and water temperature, temperature is a good indicator of nitrate availability or stress SINCE kelp growth ceases in warm nutrient-depleted water, tissue decays, and standing stocks may be greatly reduced. Abalones are affected by the availability of the drift kelp on which they feed. Anomalously warm temperatures may affect reproduction, and altered current patterns may affect larval dispersal. Because water temperature varies with location in Southern California and each of the five exploited abalone species has its own thermal preferences, we chose to evaluate the role of environmental variability on populations of red abalone (*Haliotis rufescens*) on three northern Channel Islands spanning a temperature gradient. We compared water temperature regimes and anomalies, monthly aerial surveys of canopies of giant kelp (*Macrocystis pyrifera*), and field evidence of poor abalone growth and reproduction during El Niño events. The severity of El Niño disturbances and long-term changes in kelp standing stocks both correlated with the temperature gradient. Declines of red abalone total landings and area-specific landings on the warmer Santa Cruz and Santa Rosa Island began a decade after the large 1957–1959 El Niño. The subsequent collapse of many populations appears related to warm anomalies after the 1976–1977 regime shift, kelp declines, and poor reproduction coupled with fishing-induced declines in adult abalone density. Red abalone populations have persisted on cooler San Miguel Island where thermal anomalies had less effect and kelp canopy biomass has been more stable. Southern California abalones evolved in this disturbance regime, but the combination of extended periods of increased environmental variability with intense fishing pressure may have led to the loss of local populations, especially in warmer areas.

KEY WORDS: El Niños, *Macrocystis*, storms, ocean climate, reproduction, stock collapse

INTRODUCTION

Declines in the landings of Southern California abalone fisheries and the eventual collapse of many abalone stocks over the last two decades (Karpov et al. 2000) coincided with a period of changing ocean climate (McGowan et al. 1998). Since 1976 to 1977, there has been an increase in the frequency, duration, and intensity of warm-water El Niño events and a corresponding decrease in cold-water La Niña events (Fig. 1). Frequently described as a regime shift, this has been accompanied by a significant interdecadal-scale increase in sea surface temperature (Roemmich & McGowan 1995), and a shifting in the mean location of sea surface isotherms to the north along the West Coast of North America (Fig. 2). Furthermore, large waves in Central and Southern California are strongly associated with El Niño events, and there has been a marked increase in the number of broad area wave events exhibiting very large waves (Seymour 1996).

El Niños and large wave events are important agents of disturbance to kelp forest communities, with severities that vary with latitude and exposure (Tegner & Dayton 1987, Seymour et al. 1989). El Niño storms, such as those that produced the extraordinary number of large wave events in winter 1983, may decimate exposed kelp populations along the entire coast of California. Storms also kill abalones directly (Cox 1962). The effects of the warm, nutrient-depleted waters, however, are stronger in the southern portion of the range of giant kelp, *Macrocystis pyrifera*, the major source of productivity and structure in this community (Tegner & Dayton 1987). Sea surface temperature is the best predictor of harvestable *Macrocystis* biomass (Tegner et al. 1996). Because of the strong inverse relationship between nitrate availability and water temperature, temperature is a good indicator of nitrate availability or stress, as kelp growth ceases in warm nutrient-depleted water, tissue decays, and standing stocks may be greatly reduced. Community effects of the 1982 to 1984 El Niño were apparent long after the anomalous oceanographic conditions, as manifested by increased abundance of understory kelps relative to that of *Macrocystis* (Tegner et al. 1997). The long-term increase in temperatures since 1977 is associated with a 2/3 decrease in the median size of giant kelp plants (measured as a decline in number of stipes) and thus a decrease in drift kelp availability (Tegner et al. 1996). Furthermore, because strong El Niño events are adding to the secular increase in ocean temperatures, the 1997 to 1998 event was warmer than the very strong 1982 to 1984 event.

While the effects on kelps are relatively well understood, the impacts of these changes in ocean climate on consumers are poorly known. Temperature affects animals directly, and temperature and storms both affect the food supply of grazers. The west coast of North America supports eight species of abalones, and their geographic and depth distributions are largely determined by temperature (Leighton 1974). Thus, effects may be apparent in distribution as well as physiology. *Macrocystis* is the dominant source of drift kelp in Southern California (Tegner & Dayton 1991), and the major food for abalones (Tutschulte 1976). With up to 60% of the biomass of a healthy *Macrocystis* forest in its canopy (North 1968), the loss of that canopy and varying degrees of plant mortality lead to a corresponding decrease in drift availability. Understory kelps produce far less drift per unit area than *Macrocystis*. Drift availability is very low after major storm disturbance, juvenile giant kelp populations produce little drift, and thus drift production may remain low for months to years after an El Niño event (Tegner & Dayton 1991). Furthermore, warm, nutrient-depleted

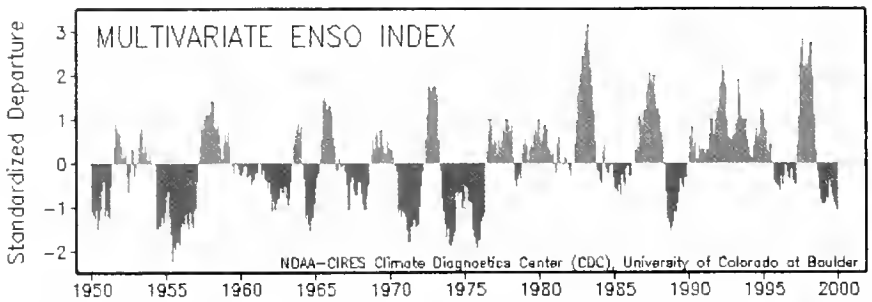

Figure 1. Multivariate El Niño-Southern Oscillation Index (courtesy of National Oceanographic and Atmospheric Administration's Climate Diagnostic Center). Downloaded in January 2000 from http://www.cdc.noaa.gov/ENSO.mei_index.html). El Niño events are positive, La Niña events are negative. This is a tropical index; events strong enough to affect the California Current region exceed some threshold about the mean.

conditions also lead to a decrease in the nitrogen content of kelps (Tegner & Dayton 1987), resulting in both the quantity and quality of abalone food being altered.

Previous observations indicate that abalones are affected by environmental variability. Cox (1962) noted that "during 1957, 1958, and 1959, the main food supply of abalones off California practically disappeared when an unseasonal influx of warm water destroyed all of the kelp beds. During this starvation period, the gonads of the abalones did not increase in size during their regular spawning season and many probably were unable to spawn." He also observed that growth was minimal or nonexistent, and that body tissues appeared to shrink. The flesh of abalones that did enter the fishery was shrunken and watery. Haaker et al. (1998) later quantified strong interannual variability in growth rates, including a dramatic reduction in the growth rate of *Haliotis rufescens* (red abalone) during the 1982 to 1984 El Niño event. Vega et al. (1997) observed an inverse correlation between sea surface temperature anomalies and total catch of abalones from Baja California which they related to impacts on algal food abundance. On the other hand, Shepherd et al. (1998) found total abalone catch at La Natividad, Mexico, to be positively correlated with mean sea surface temperature anomalies with a lag of eight years, but also reported evidence for recruitment failure during severe El Niños.

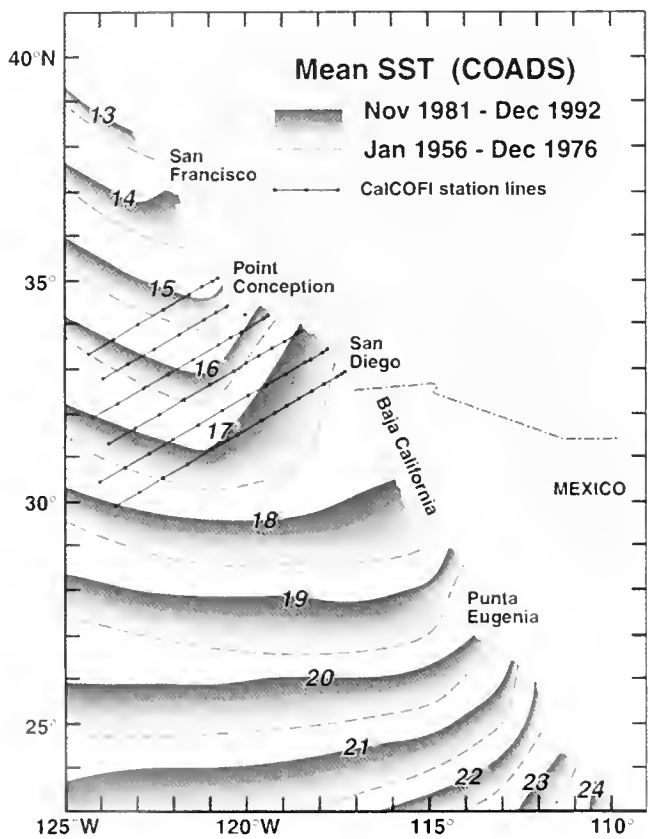

Figure 2. Changing isotherm locations along Baja California (Mexico) and California (USA). The Southern California Bight extends from Point Conception to just below the Mexican Border. The present California Cooperative Oceanic Fisheries Investigations (CalCOFI) grid is illustrated by station lines. The range of *Macrocystis pyrifera* is from just south of San Francisco to the region just south of Punta Eugenia. COADS (Comprehensive Ocean Atmosphere Data Set, http://www.cdc.noaa.gov/coads/) data were used to determine the location of the annual mean sea surface temperature (SST) isotherms before and after the mid 1970s regime shift. The dashed line represents the position 1956 to 1976 and the solid line represents 1981 to 1992.

Field studies on the Palos Verdes Peninsula (33°46′ N, 118°25′ W) near Los Angeles during and after the strong 1982 to 1984 El Niño event suggest that anomalies in both temperature and food availability affect abalone reproduction and recruitment. We followed gonadal development of green (*H. fulgens*) abalones from February 1982 through September 1983. Normally these animals spawn in both the spring and the fall. El Niño storms in January 1983 removed all *Macrocystis*; the abalones had little if any food until kelp recruitment in May. Gonadal development in spring 1983 began much later than in 1982, was very low in comparison with the previous year, and it is unlikely that there was significant spawning (Tegner & Dayton, 1987, Fig. 9). The green abalone is a warm-water species near the northern end of its range at Palos Verdes (Cox 1962) and winter-spring 1983 was before the major temperature anomalies associated with this ENSO; thus the observed depression in reproduction may have been primarily caused by lack of food. Size-frequency distributions of cool-temperate red and warm-temperate pink (*H. corrugata*) abalones collected in 1986 at Palos Verdes suggested that El Niño conditions affected these congenors quite differently. There was a near absence of two and three year old red abalones, animals that would have been spawned in 1983 and 1984; virtually all the pink abalones were in these size categories (Tegner & Dayton, 1987, Fig. 10). These data suggest that temperature anomalies may have favored pink abalones over the colder water reds during the ENSO event. We cannot exclude large-scale alterations in current patterns during El Niño events (Tegner & Dayton 1987) also affecting abalone recruitment, but this seems unlikely given the short larval period (McShane 1992). On smaller scales, the devastation of kelp forests and con-

comitant reductions of their effects on flow could increase local dispersal of larvae (Tegner & Dayton 1987).

While it is likely that all abalone species are affected by variability in ocean climate, the effects will vary with species and location. Because Southern California is a mixing ground between cool temperate waters of the California Current coming from the north and warm-temperate flow from the south (Fig. 3), comparisons of how populations in thermally distinct habitats respond to interannual variability may offer insights into the relative effects of different factors. Here we compare red abalone populations across the thermal gradient from colder San Miguel Island to Santa Rosa Island to warmer Santa Cruz Island. We use long-term records of temperature, kelp canopy biomass, field assessments of abalone populations, and fisheries statistics to explore hypotheses relating environmental variability to the decline of the red abalone fishery and the collapse of many local stocks.

MATERIALS AND METHODS

Historically the red abalone is the most important species in the California abalone fishery by virtue of its large size, wide distribution, and long harvest history. Its range extends over 16° of latitude from Coos Bay, Oregon to Bahia Tortugas, Mexico (Cox 1962). From Southern California south, however, it is limited to the northwestern Channel Islands which are heavily influenced by the cold waters of the California Current (Fig. 3), and to mainland locations where strong upwelling moderates temperatures (Tegner et al. 1992). Leighton (1974) reports that he found fecund, spawnable red abalones every month of the year (1969–1971) at Estero Bay in Central California, whereas in Southern California he obtained laboratory spawnings in January, February, April, September, November, and December. Before the fishery was closed in 1997, size limits were 178 mm and 197 mm for the recreational and commercial harvests, respectively.

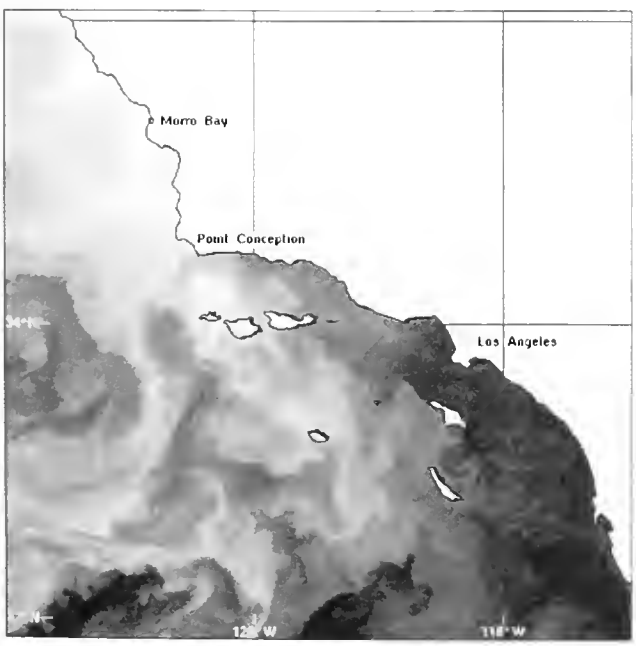

Figure 3. This satellite image illustrates thermal variability along the Central and Southern California coastline on November 21, 1996. The coldest temperatures are white and the warmest are black. Note the cold waters of the California Current flowing south past Point Conception and the warm waters of the Southern California Eddy flowing north along the mainland; mixing of these two water masses creates temporal and spatial variability within the Southern California Bight. The three islands immediately below Point Conception are, from west to east, San Miguel, Santa Rosa, and Santa Cruz Island. NOAA AVHRR (Advanced Very High Resolution Radiometer) sea surface temperature data provided by the NOAA Coastwatch Program for and displayed in Windows Image Manager.

Channel Island sea surface temperature data (courtesy of Jack Engle, Tatman Foundation, University of California, Santa Barbara) were generated from regional satellite-derived isotherm maps of the California coast posted several times a week by the National Weather Service (http://www.nws.mbay.net/sst1.gif). Data are interpolated to 0.5 C, and averaged by month for each island. Mean monthly temperatures calculated for the period 1982–1998 were used to determine temperature anomalies through time.

Biologists from International Specialty Products (formerly Kelco) have been making approximately monthly aerial estimates of *Macrocystis* biomass available for harvesting (California law allows removal of the upper 1.2 m of the canopy) for more than three decades. As these estimates are made by a very small number of observers and continually refined against the actual harvest tonnage, we believe that these estimates are quite accurate. There were no estimates made during 1992 and 1993. To protect proprietary harvest information and to eliminate the effect of the large differences in size among the islands, data are presented as a proportion of the maximum observed in the time series for each island. Linear models for all three islands were fitted with the percent of maximum annual relative canopy biomass as the response variable and year as the predictor variable. The error distributions of the relative annual canopy biomass data were determined to be normal according to visual analysis of residual-fit spread plots and normal quantile plots of residuals. These assured that all of the three fitted models adequately explain the variation in the data (Cook & Weisberg 1982, McCullagh & Nelder 1989).

Sex ratio was assessed visually (Ebert & Houk 1984) at San Miguel Island in May 1997. Red abalones of varying sizes were collected from several locations on San Miguel Island with a target goal of 30 per sample. Animals were brought to the surface and gonad color was scored by at least two observers: dark colored (green to black) for females and light colored (cream to light brown) for males.

Size-frequency distributions of red abalones from a single location on Santa Rosa Island and from four locations on San Miguel Island were collected in June 1999. The data were summed for the San Miguel Island sites.

RESULTS

Temperature Records

Mean monthly temperatures for the three islands for the period 1982 to 1998 are plotted in Figure 4. It is apparent that San Miguel Island is consistently colder than Santa Rosa Island, which is consistently colder than Santa Cruz Island. The differences are minimal in the winter and maximal in late summer. Monthly averages were compared using Friedman's two-way ANOVA. The results showed significant differences between sites ($P < 0.001$) and an a posteriori test (Nemenyi 1963) indicated that each island's temperature regime was significantly different from the others'. Note that this data set begins after the 1977 regime shift.

Time series of ambient temperature in comparison with the mean monthly values and the anomalies for 1982 to 1998 are

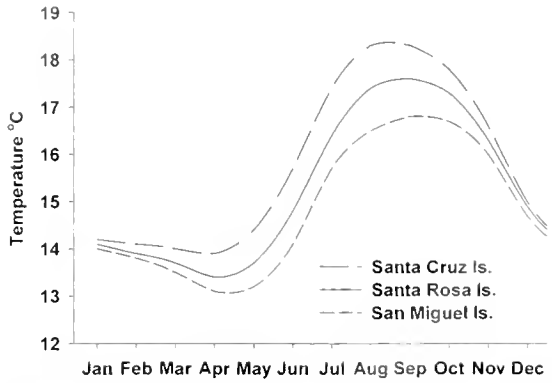

Figure 4. Mean monthly temperatures, 1982 to 1998, for San Miguel, Santa Rosa, and Santa Cruz Island.

plotted in Figure 5. Note the 1982 to 1984, 1992 to 1993, and 1997 to 1998 El Niño warm anomalies. La Niña events took place in 1988 to 1989 and 1999 (Fig. 1). The timing and magnitudes of the anomalies were remarkably similar among the three islands, but the summer values were higher at Santa Cruz Island and the winter values lower at San Miguel Island because of the difference in average temperatures.

Macrocystis Canopy Biomass

Time series of aerial estimates of giant kelp canopy biomass (Fig. 6) exhibit the strong interannual variability characteristic of *Macrocystis* populations (e.g. Tegner et al. 1996). Many of the peaks and depressions are common to all three islands, for example the regrowth in 1984 and 1985 after the winter 1983 storms and the 1983 to 1984 El Niño warm anomaly disturbances. Because some of the within-year decreases in canopy biomass are due to natural disturbance and some to harvesting, the annual maximum biomass estimates for each island are compared in Fig. 7. Some of the patterns are strikingly similar in timing and magnitude, including the decline in canopy at all three islands from 1978 to the low 20% of maximum biomass from 1986 through 1999. San Miguel Island, the coldest of the three, had a higher relative canopy biomass than intermediate temperature Santa Rosa Island from 1995 through the end of 1999.

Regressions of maximum annual relative canopy biomass against time were used to determine whether (a) kelp populations on the different islands had declined, (b) whether the regression coefficients changed at the time of the 1976 to 1977 regime shift, and (c) whether the islands were different from each other. (a) Analysis of variance indicated that two of the three slopes were significantly different from zero. Relative canopy biomass declined significantly at Santa Rosa Island (slope −0.011, $r^2 = 0.19$, $P = 0.04$), and at Santa Cruz Island (slope −0.014, $r^2 = 0.28$, $P = 0.001$) from 1968 to 1999. (b) T tests comparing regression coefficients before and after the 1976 to 1977 regime shift were not significant for any island. (c) Analysis of covariance, however, found significant differences in the elevations of the regressions ($P = 0.02$). Multiple comparisons (Tukey test) of the elevations of the regressions indicated that San Miguel Island canopy biomass was significantly different from that at Santa Cruz Island, but Santa Rosa Island canopy biomass was not significantly different from either San Miguel or Santa Cruz Island canopy biomass. Thus, kelp canopy biomass has persisted better at San Miguel Island relative to Santa Cruz Island.

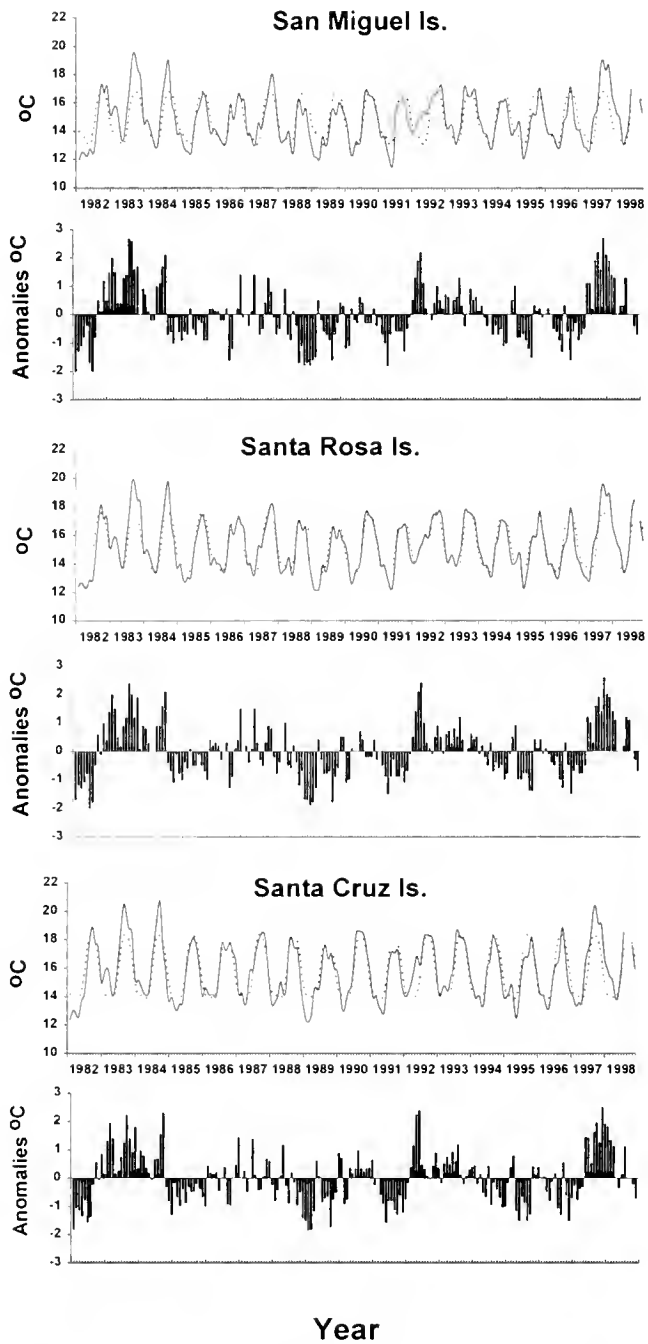

Figure 5. Time series of monthly average temperatures (solid lines) in comparison with mean monthly temperatures (dotted lines) for the period 1982 to 1998 (upper panels). Monthly anomalies (bars) from mean monthly temperatures, 1982 to 1998 (lower panels). See text for details. San Miguel, Santa Rosa, and Santa Cruz Island.

Abalone Field Data

In May 1997, red abalone sex ratios (assessed visually) on San Miguel Island were heavily skewed toward females. The sex ratio was 5.8:1 (female:male) on the west side of the island ($n = 34$), 5.7:1 on the south side of the island ($n = 60$), and 5.6:1 on the north side ($n = 33$). At this time near the onset of the 1997 to 1998 El Niño, the surface temperature on San Miguel Island was about 1°C above normal (Fig. 5) and kelp canopy biomass was only 10%

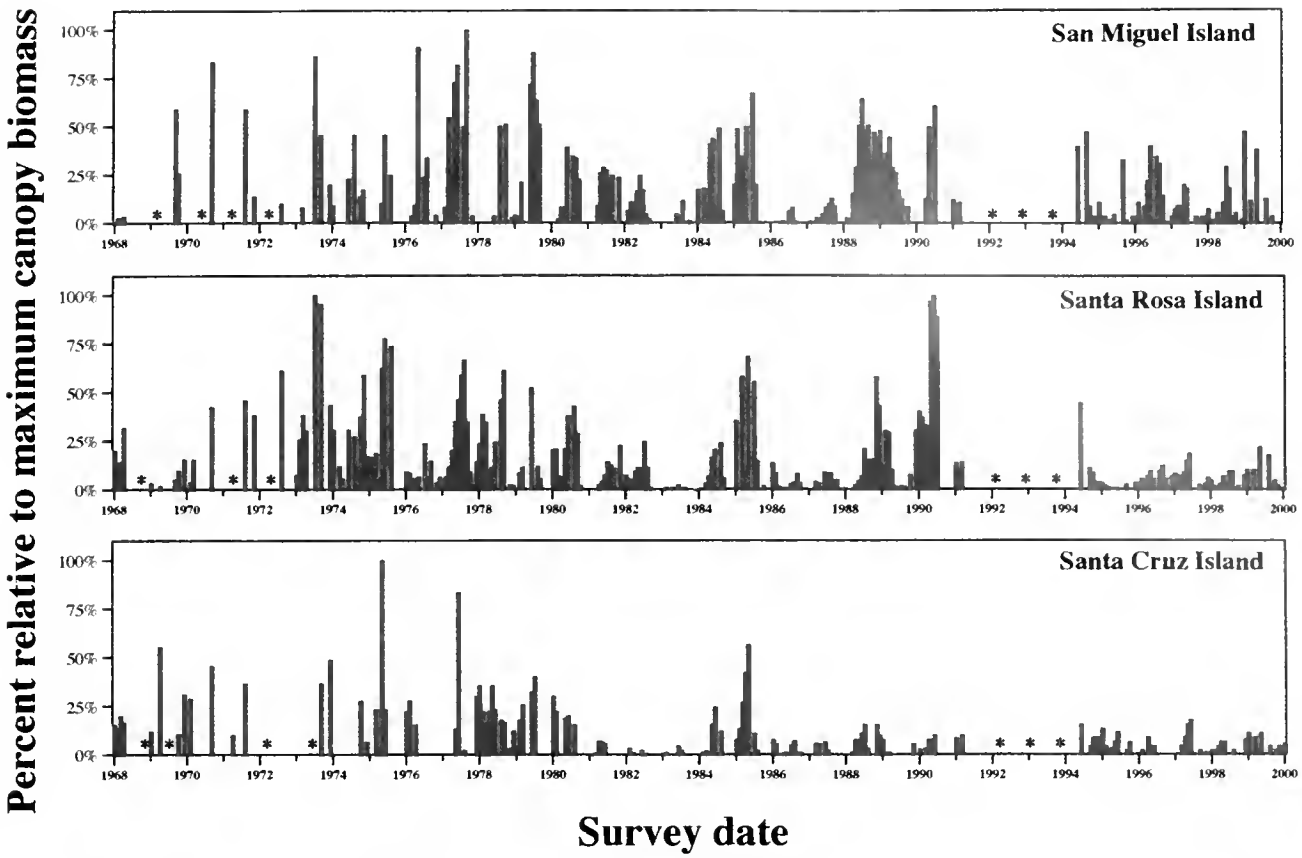

Figure 6. Monthly aerial estimates of *Macrocystis pyrifera* canopy biomass from San Miguel, Santa Rosa, and Santa Cruz Island An asterisk (*) indicates no survey.

of maximum (Fig. 6). The sexes of 15 animals could not be determined. Observers noted that sex determination was more difficult than in February 1997, when temperatures were slightly below the long-term mean.

The red abalone size-frequency distribution on San Miguel Island in June 1999 was strongly bimodal (Fig. 8). The near absence of sizes representing two and three year old individuals suggests poor reproduction and recruitment in 1997 and 1998. The strong mode at 20 mm suggests that reproduction quickly followed the onset of the La Niña and cooler temperatures in November 1998; the kelp canopy recovered to 47% of maximum by January 1999 (Fig. 6). Limited size-frequency data collected at San Miguel Island in 1993 revealed very few recruits; a collection from Castle Rock on western San Miguel Island in 1994 after the 1992 to 1993 El Niño found a burst of small animals (Haaker unpub. data). The small 1999 sample from Santa Rosa Island, where red abalone densities are very low (Fig. 8), suggests that reproduction and recruitment have not been successful on this island for the last four years.

DISCUSSION

Snapshots of sea surface temperature (Fig. 3), mean monthly temperatures (Fig. 4), and biogeographic differences in species composition (e. g., Murray et al. 1980) all indicate that there is a significant thermal gradient across the northern Channel Islands from coldest at San Miguel Island in the west to warmest at Santa Cruz Island in the east. Temperatures are highly variable in time, but the data in Figure 5 suggest that approximately constant average temperature differentials among the three islands are maintained through El Niño and La Niña events, as well as interdecadal scale changes. Temperature is directly important to abalone physiological processes and larval survival (Leighton 1974), to harvestable *Macrocystis* biomass (Tegner et al. 1996), and to the quantity and quality of drift *Macrocystis* (Tegner & Dayton 1987), the major food source of abalones (Tutshulte 1976).

Because of the strong inverse relationship between temperature and nitrogen availability, *Macrocystis* populations are very sensitive to extended periods of warm water. Warm water *per se* does not harm giant kelp which, if provided with abundant nutrients, grows well even at 25°C (reviewed by North & Zimmerman 1984). There are negligible amounts of nitrate above 15°C (Jackson 1977, Gerard 1982, Zimmerman & Kremer 1984) but giant kelp thrives at 14°C, so very small differences in temperature can have important community effects. *Macrocystis* can build internal N reserves when external concentrations are high, and then use these reserves to maintain relatively rapid growth for up to a month in the absence of significant external nutrients (Gerard 1982, Zimmerman & Kremer 1986). When kelp tissue N drops below 1% (dry weight), internal reserves are depleted, and N starvation will lead to rapid deterioration. During most summers when surface temperatures exceed 16°C, upwelling and internal wave-induced thermocline motions provide nutrient input to maintain giant kelp populations (Zimmerman & Kremer 1984). During strong El Niño events, the thermocline is often depressed to levels too deep for

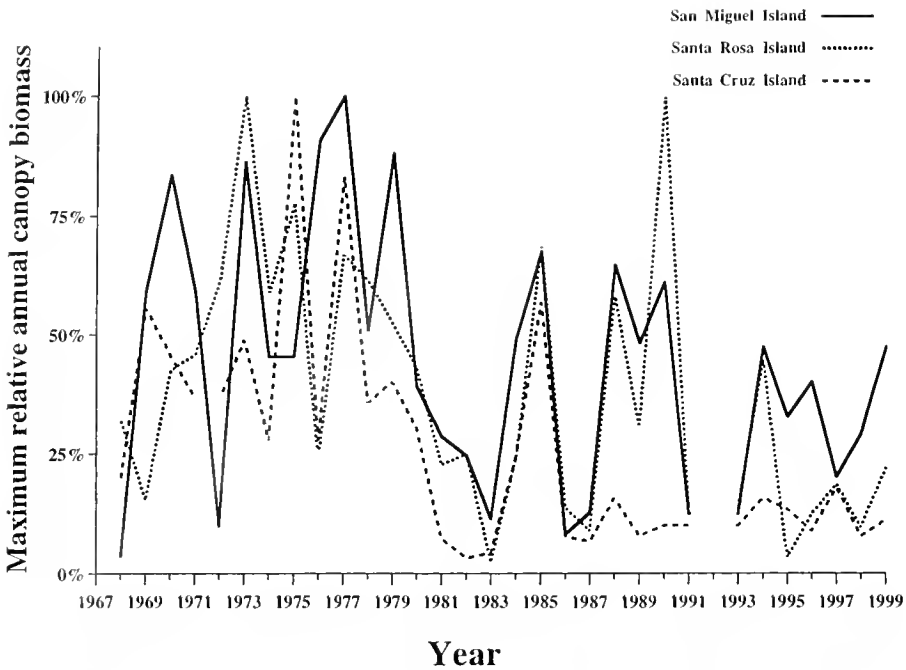

Figure 7. Maximum annual estimates of *Macrocystis* canopy biomass from San Miguel, Santa Rosa, and Santa Cruz Island.

these processes to be effective (Zimmerman & Robertson 1985). *Macrocystis* canopies were completely lost on the southern-most Santa Catalina and San Clemente Islands and along the southern-most counties, Orange and San Diego, in California during the 1982 to 1984 El Niño (Tegner & Dayton 1987). Further to the north, given temperature decrease with latitude, the warm anomalies added to lower temperature bases and there was some degree of giant kelp canopy formation. Conversely, *Macrocystis* thrives during the cold water and enhanced upwelling of La Niña events (Tegner et al. 1997).

Santa Cruz, Santa Rosa, and San Miguel Island experienced temperature anomalies during recent El Niño events that were remarkably similar in timing and magnitude; the difference is that the anomalies added to a different temperature base at each island. Thus, the anomalies were more likely to make the environment unsuitable for *Macrocystis* at Santa Cruz Island, and that may explain low standing canopy biomass estimates at that island from the mid 1980s through 1999 (Figs. 6, 7). There were significant declines in relative canopy biomass at Santa Cruz and Santa Rosa Island, but not at cooler San Miguel Island. We stress, however, that aerial surveys cannot detect sea urchin barrens, another potential explanation for poor performance of giant kelp. Because up to 60% of the biomass of a healthy *Macrocystis* population is in the canopy (North 1968), we can safely infer that poor canopy condition is reflected in low drift availability (Tegner & Dayton 1991) for grazers.

Several lines of evidence suggest that red abalone reproduction and recruitment are depressed by warm temperatures and lack of food. Cox (1962) reported the lack of gonad development and the low probability of spawning during 1957 to 1959, a warm anomaly that only later would be recognized as a strong El Niño event. There was a near absence of animals of the size classes that would have been spawned in 1983 and 1984 in a 1986 size-frequency distribution from the Palos Verdes Peninsula (Tegner & Dayton 1987). Visually assessed sex ratios from San Miguel Island were highly skewed toward females in 1997, near the onset of the 1997 to 1998 El Niño. A 1:1 sex ratio is expected in abalones, but when gonads are poorly developed, it is impossible to distinguish the grayish-brown digestive gland from an enveloping dark-green ovary (Ebert & Houk 1984). Later histological examination of 97 of these animals revealed a 1:1 sex ratio (C. S. Friedman unpub. data), indicating that many adult red abalones stressed by environmental conditions at San Miguel Island had undeveloped gonads. Finally, size-frequency data from San Miguel Island in 1999 (Fig. 8) suggests little to no recruitment during the 1997 to 1998 El Niño. Warm temperature anomalies of the magnitude observed in 1983 to 1984 and 1997 to 1998 were also observed in 1992, and that anomaly persisted into early 1994 (Fig. 5). Furthermore, McGowan et al. (1998) illustrate regional sea surface temperature anomalies of about 2°C in 1977 and 1978, and about 1°C in 1980, a period of the decline in *Macrocystis* canopy biomass at all three islands (Fig. 7). Thus, there have been a large number of warm events since 1977 that may have affected red abalone reproduction and recruitment.

Haaker et al. (1998) assessed the annual growth of tagged red abalones on Santa Rosa Island from 1978 to 1982, and revisited the site in 1984, a two year hiatus that included the strong 1982 to 1984 El Niño event. Growth parameters changed significantly throughout the study period, with L_∞ generally declining during each successive period. Warm anomalies in 1977, 1978, and 1980 (McGowan et al. 1998) followed by the 1983 El Niño winter storms (Tegner & Dayton 1987) were associated with a substantial decline in *Macrocystis* canopy biomass from 1978 to 1983 at all three islands (Fig. 7). Kelp recruited in 1983, but with the thermal stress of the El Niño, canopy formation was not significant until 1984. Thus, the very slow abalone growth observed during 1983 to 1984 can be attributed to thermal stress (Fig. 5), low kelp biomass (Fig. 6, Fig. 7), and the low drift production of a young *Macrocystis* stand (Tegner & Dayton 1991).

Statewide commercial red abalone landings began a significant

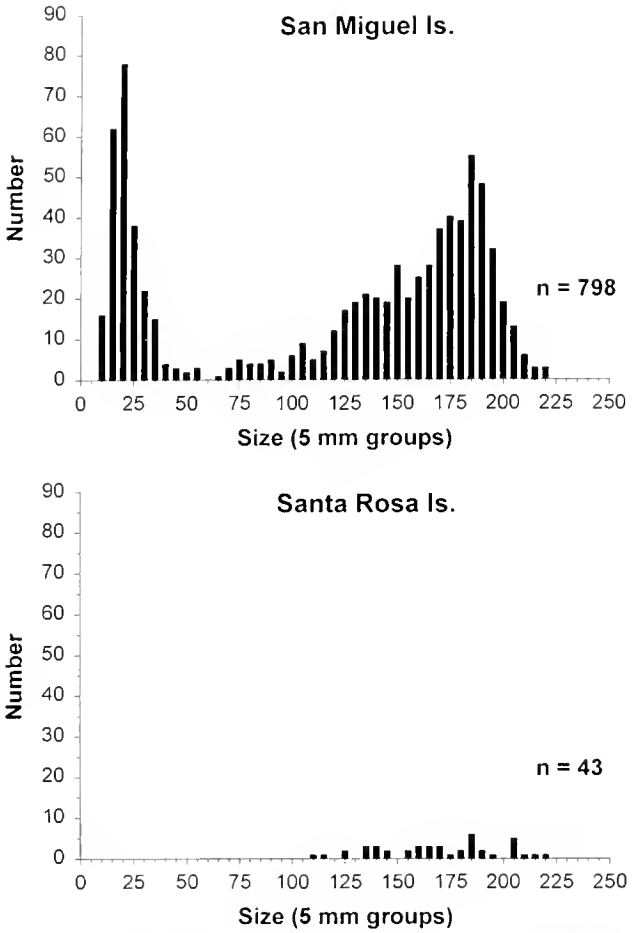

Figure 8. Red abalone size-frequency distribntions from San Mignel and Santa Rosa Island, June 1999.

decline in the late 1960s (Fig. 9). When commercial fishing was closed in 1997, total red abalone landings were at 87 metric t, almost a 90% decline from the historic peak in the early 1960s. Karpov et al. (2000), analyzing area-specific landings, showed a spatial trend with higher catches coming from the mainland or nearshore islands, shifting over time to more remote areas. Catch from Santa Cruz Island, the closest to shore, peaked before Santa Rosa Island; at the time of the closure, catch on the two islands was 1 and 3% of their respective peaks. In contrast, San Miguel Island was the source of 82% of the red abalones landed in 1996, and these represented 23% of the peak catch on this island. Fishery-independent abundance estimates collected from 1983 to 1998 confirmed that populations declined in conjunction with the catch (Fig. 9). Red abalone population estimates in Santa Cruz Island study sites (see Davis 1989 for site locations and survey techniques) went to zero in the late 1980s; Santa Rosa Island had higher initial abundance and density estimates that also declined to low levels by the end of the 1990s. Abundance estimates at San Miguel Island mirrored the continuing catch until the fishery was closed in 1997 (Karpov et al. 2000).

The temperature, kelp, and abalone reproduction and recruitment data suggest that environmental variability contributed to the decline of the fishery and the subsequent collapse of some stocks. If, as Cox (1962) reported, there was little to no recruitment of red abalones during 1957 to 1959, there would have been a corresponding decline of animals entering the fishery 10 to 15 years later. The decline in statewide landings and in the Santa Cruz and Santa Rosa Island catches in fact began about 1968 (Fig. 9). Under intense fishing pressure, few abalones exceed commercial size limits in natural populations (Tegner et al. 1989) and aggregations are fewer and smaller (Shepherd & Partington 1995). As the reduced or missing age classes passed through the size-frequency distribution to fishable size, stocks would experience a corresponding decrease in density and egg production. While stock-recruitment relations are poorly known for abalones, it appears that major environmental disturbances such as the 1957 to 1959 El Niño coupled with continued intense fishing pressure establish the conditions for recruitment overfishing. Shepherd and Partington (1995) report that below densities of 0.15 to 0.2 m^{-2}, abalone populations are increasingly vulnerable to recruitment failure. Fishery independent data (Fig. 9) indicate that the Santa Cruz Island red abalone population was below this threshold in 1983, at the beginning of a strong El Niño event, and these animals disappeared from the study sites within four years. At Santa Rosa Island, the 1983 abundance estimate was 0.15 m^{-2}, but this study population did not survive the environmental disturbances of following years. Fig. 8 indicates that there are still red abalones on Santa Rosa Island, but the lack of recruitment during conditions in late 1998 through 1999 which produced strong recruitment at San Miguel Island suggests that Santa Rosa Island densities are below the threshold for successful fertilization.

Once all three of these northern Channel Islands were highly productive red abalone habitat (Karpov et al. 2000). San Miguel Island populations have persisted not only because it is the furthest of the three islands from ports, but because its ocean climate has apparently buffered recent environmental variability relative to the warmer islands. Indeed, fishermen find it easier to get to San Miguel Island than Santa Rosa Island by following the mainland coast to Point Conception before crossing the Santa Barbara Channel (J. Colgate pers. comm.). The role of climate in exacerbating overfishing is supported by catch statistics from other locations. Red abalone catch from the San Diego region, apparently heavily impacted by the 1982 to 1984 El Niño (Tegner & Dayton 1987), dwindled to very low levels in the late 1980s, whereas Point Conception stocks were still productive when the fishery was closed in 1997 (California Department of Fish and Game 1997).

One of the most disturbing implications of El Niño events and interdecadal scale increase in temperatures for abalones involves Withering Syndrome (WS), a disease first identified in black abalones (*H. cracherodii*) and now observed in other California species as well. Elevated temperatures accelerate mortality rates (Friedman et al. 1997), and Tissot (1995) suggests that temperature is the single most important factor influencing population recovery. WS is now progressing through Central California (Altstatt et al. 1996). During the elevated temperatures of the 1997 to 1998 El Niño, several abalone farms in California experienced a dramatic increase in the proportion of red abalones showing clinical signs of WS (Moore et al. 2000).

Management of California abalone fisheries was heavily based on the high fecundity of these gastropods; a size limit large enough that the animals would reproduce several times before entering the fishery was considered adequate to protect the stocks. Later egg-per-recruit analysis indicated that the size limits allowed for healthy egg production, even at high fishing mortality rates (Tegner et al. 1989). The implicit assumptions of the size-limit approach, however, didn't consider extended periods of environmen-

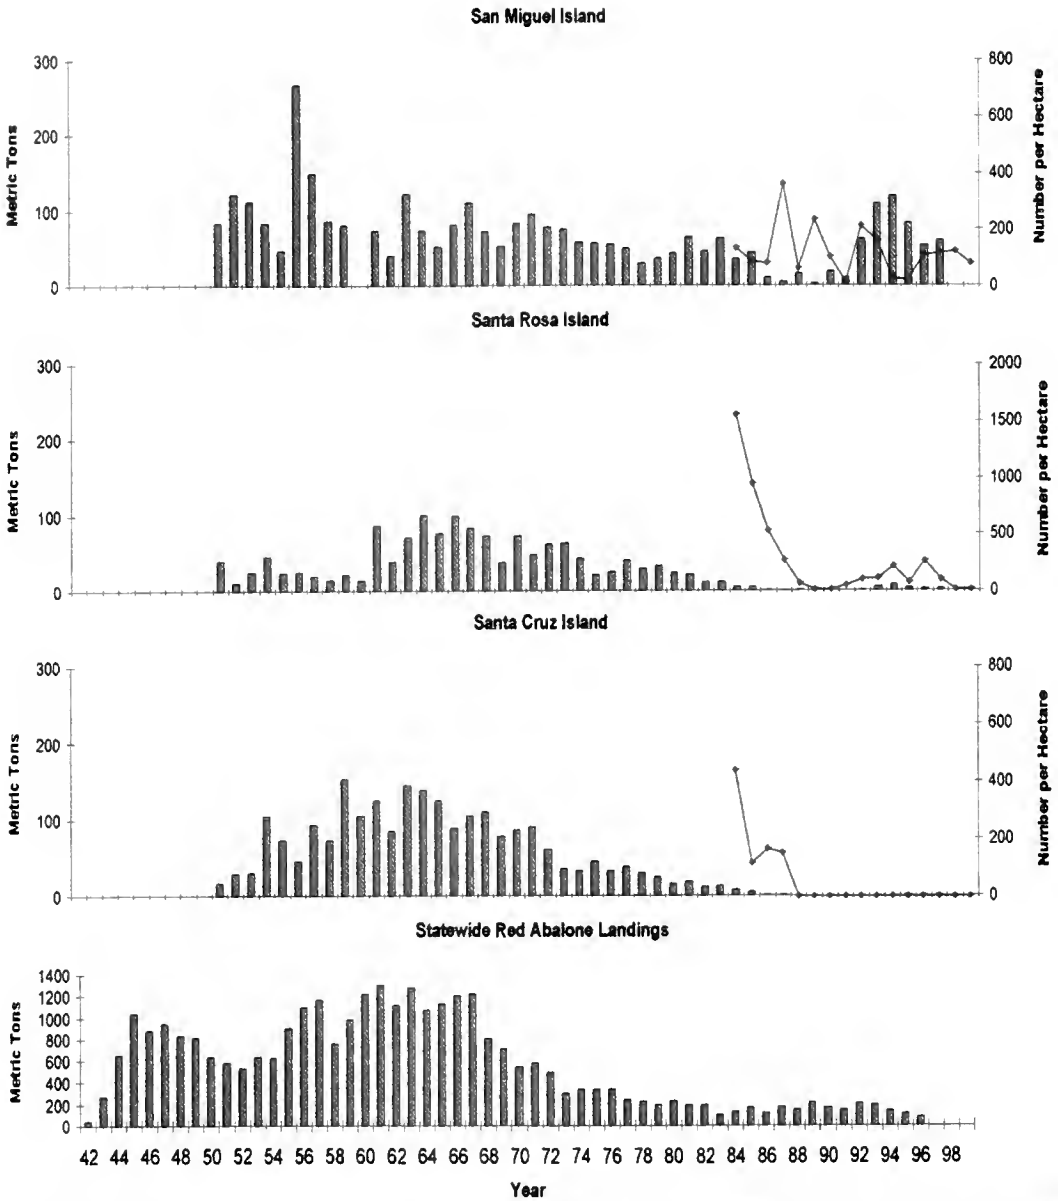

Figure 9. Red abalone harvest (metric tons) from San Miguel, Santa Rosa, and Santa Cruz Island, 1952 to 1996, and non-invasive population counts on 60 m^2 transects from the Channel Islands National Park annual monitoring program, 1983 to 1998. Statewide landings, 1942 to 1996. Note the change in scale on the vertical axis. Adapted from Karpov et al. (2000).

tal variability leading to protracted recruitment failure or Allee effects on fertilization (Shepherd & Partington 1995). The organisms of west coast kelp communities are adapted to environmental variability on scales including episodic El Niño and La Niña events, and interdecadal regime shifts. The Scripps pier temperature record reveals three regimes since the beginning of the data set in 1916: a warm period until about 1940, a cool period lasting until 1976, followed by the present warm period (McCall 1996). Red abalone reproduction and growth may be depressed during periods of warm water, but most animals survive the adverse environmental conditions; the addition of intense fishing pressure onto climate disturbances, however, makes population decline almost inevitable. To be successful, future management must take both environmental variability and Allee effects into account; no-take reserves to protect aggregations of brood stock are probably the only way to reduce Allee effects. Our data suggest that remote monitoring of temperature and kelp canopy biomass could be calibrated to offer an inexpensive and practical approach to incorporate environmental variability into management of abalones and other grazers.

ACKNOWLEDGMENTS

We thank Mati Kahru for the satellite image, Jack Engle for the island temperature data, Dale Glantz and Keith Ullrich of International Specialty Products for the kelp data, Kon Karpov for the red abalone landings data, Alistair Hobday and two anonymous reviewers for their comments on the manuscript, and the Pew Fellows Program in Marine Conservation for financial support.

POPULATION GENETICS OF THE YELLOW ABALONE, *HALIOTIS CORRUGATA*, IN CEDROS AND SAN BENITO ISLANDS: A PRELIMINARY SURVEY

MIGUEL A. DEL RÍO-PORTILLA[1]* AND JOSÉ G. GONZÁLEZ-AVILÉS[2]

[1]*Departamento de Acuicultura, Centro de Investigación Científica y de Educación Superior de Ensenada, Km 107 Carr. Tijuana-Ensenada, Ensenada, B.C. México, A.P. 2732, Ensenada, B.C. México 22800;* [2]*S.C.P.P. Pescadores Nacionales de Abulón, S.C. de R.L., Ryerson 117 Col. Centro, Ensenada, B.C. México 22800*

ABSTRACT The yellow abalone, *Haliotis corrugata*, is one of the principal species caught in Central Baja California, Mexico. Around the Cedros and San Benito Islands, the yellow abalone is mainly distributed in three zones: the North (Punta Norte) and South (San Agustin) of Cedros Island and around the small islands of San Benito. The main goal of this work was to characterize genetically the populations of the yellow abalone in these three zones as a baseline to help the fishery. Allozyme electrophoresis at eight loci was carried out with six samples from two years in the three localities. The average number of alleles per locus was 2.3 with a 67% polymorphism. Mean unbiased heterozygosity ranged from 0.15 to 0.25, which is similar to that of other abalone species. Only three out of 34 cases did not agree with the Hardy-Weinberg equilibrium and there was no tendency for either heterozygote excess or deficit. It was concluded that *H. corrugata* shows differentiation between localities and these may be considered as independent populations for fishery management.

KEY WORDS: abalone, *Haliotis corrugata*, population genetics, allozymes, Cedros Island, San Benito Islands

INTRODUCTION

In Mexico, *Haliotis corrugata* is known as the yellow abalone because of the color of its foot. It is distributed from the Coronado Islands near the border with the United States to Margarita Island, and in depths from 10 to 20 m (Guzmán del Próo 1992). The yellow abalone together with the blue abalone, *Haliotis fulgens*, are the principal products from the Mexican fishery with annual production about 709 t (meat weight) in 1998 (SEMARNAP 1999). Along the Peninsula of Baja California, *H. corrugata* represents about 13% of the fishery's production (León & Ramírez 1992).

The Cooperative "Pescadores Nacionales de Abulón" (PNA) capture abalone from the Cedros and San Benito Islands (Fig. 1) and the annual production in the past 11 y is shown in Table 1. In these islands, abalone is mainly distributed in three zones: (a) the North and (b) South of Cedros Island, and (c) around the small islands of San Benito.

There are few studies on abalone population genetics on the Pacific Coast of North America (Gaffney et al. 1996, Kirby et al. 1998, Gutiérrez-González 2000, Hamm & Burton 2000, Zúñiga et al. 2000), but to our knowledge there are no studies on population genetics of the yellow abalone. Therefore, the aim of this study was to carry out a preliminary genetic characterization of the yellow abalone, *Haliotis corrugata*, population at the Cedros and San Benito Islands using allozyme electrophoresis, to determine the population genetic structure and to obtain initial genetic data for fishery management and for population enhancement.

MATERIALS AND METHODS

Adults of *H. corrugata* were sampled from the commercial catch and from a population evaluation program. These abalone were caught from six localities: "El Faro," "La Bandera," "Anegados," and "El Chual" during 1997, and "Punta Norte" and "San Agustin" during 1998 (Fig. 1). Their shell length was measured and locality mean shell lengths were compared with a one-way ANOVA, followed by an *a posteriori* Tukey test. Gill and digestive gland samples were individually frozen in 1.5-ml tubes and transported to the Laboratory of Genetics at Centro de Investigación Científica y de Educación Superior de Ensenada, B.C. (CICESE) and preserved at −70 °C until electrophoresis analysis. Abalone tissues were homogenized individually with 0.5 ml of TME buffer (0.1 M Tris, 0.1 M maleic acid, 0.01 EDTA, and 0.01 $MgCl_2$, pH 7.8), and allozyme electrophoresis on 12% starch gels was carried out for 11 enzymatic systems: aspartate aminotransferase (AAT, 2.6.1.1), glucose phosphate isomerase (GPI, 5.3.1.9), glutathione reductase (GSR, 1.6.4.2), hexokinase (HK 2.7.1.1), isocitrate dehydrogenase (IDH, 1.1.1.42), leucine amino peptidase (LAP, 3.4.11. −), malic enzyme (ME 1.1.1.40), malate dehydrogenase (MDH 1.1.1.37), mannose-phosphate isomerase (MPI, 5.3.1.8), 6-phospho-gluconic dehydrogenase (PGD, 1.1.1.44), and phospho-glucomutase (PGM, 2.7.5.1). Gels were run in the TME buffer (pH 7.8) and staining was performed using standard procedures (Harris & Hopkinson 1976), except for LAP which was stained according to procedures described by Beaumont et al. (1983). Meldola blue (0.8%) was used instead of PMS (Turner & Hopkinson 1979). When more than one locus was observed, the most cathodical locus was named as '1.' The most common allele was designated as "100" and the rest were designated according to their relative mobility to the 100 allele.

Allele frequencies, polymorphism, unbiased and direct count heterozygosity, heterozygote deficiency (D), and Nei's (1978) genetic distances were evaluated using the Biosys-1 (Swofford & Selander 1981), and an unweighed pair group method with arithmetic means (UPGMA) phenogram was built. Deviations from the agreement with the Hardy-Weinberg (H-W) equilibrium were tested with the Genepop's exact test (Raymond & Rousset 1994). Wright's (1951, 1965) F (F_{IS}, F_{ST}, and F_{IT}) statistics were evaluated using Weir and Cockerham's (1984) estimators by jacknifing and their significances were tested by bootstrapping with the Fstat program (Goudet 1994). Pairwise comparisons among all populations were done using exact tests (Miller 1997). Whenever there

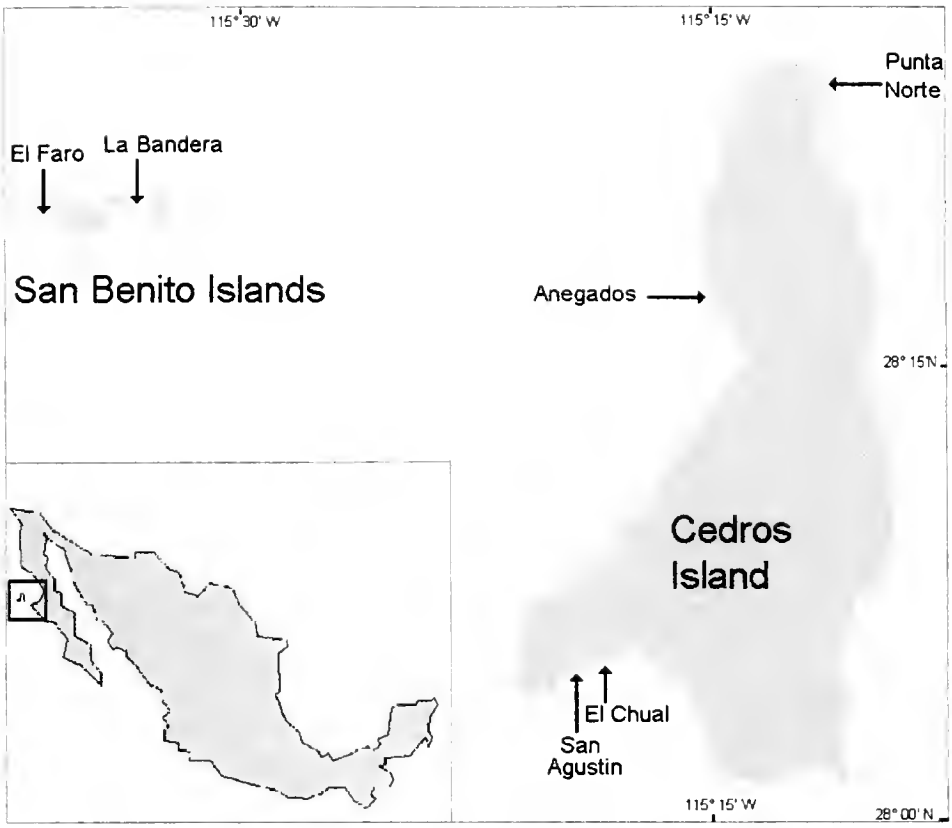

Figure 1. ***Haliotis corrugata*** **sampling localities in Cedros and San Benito Islands.**

was a high number of tests, the level of significance (α) was Bonferroni adjusted using the Dunn-Šidák method [$\alpha'' = (1 - (1 - 0.05)^{1/k})$; where k = number of test] (Sokal & Rohlf 1995).

RESULTS

Yellow abalone mean sizes were between 128 and 157 mm; there were significant differences between localities, but four out of six localities had similar sizes (Table 2).

From the 11 allozyme systems tested, only eight loci gave reliable results (Table 2). PGD, GSR, and MPI did not give positive staining results. Two loci were found at LAP and MDH, but the first locus of each one was not reliable and thus, excluded from further analysis.

The mean sample size was between 15.4 to 31.8 and the number of alleles per locus was from 1.9 to 2.8. The percentage of polymorphism without criterion ranged from 62.5% to 87.5%, while direct count frequency of heterozygosity was from 0.094 to 0.201 and unbiased frequency of heterozygosity was from 0.141 to 0.258. In all cases El Chual had the lowest values (Table 2). Frequencies of the 100 allele were similar between localities except at the *Hk* in Punta Norte and at *Mdh-2* in La Bandera, which both showed substantially reduced frequencies of the most common allele (Table 3).

Agreement with H-W was present in all cases, except in 3 loci from Punta Norte (after Bonferroni adjustment), all of which had a heterozygote deficiency (Table 3). Furthermore, all positive and negative cases of *D* were counted, the total was $D+ = 21$ and $D- = 13$, which was not significant from a 1:1 proportion (sign test, Sokal & Rohlf 1995).

The UPGMA phenogram using Nei's genetic distance grouped localities: first La Bandera with El Chual, then El Faro with Anegados, and then these two groups clustered together, then San Agustin joined and finally Punta Norte (Fig. 2).

Wright's F statistics showed positive and negative values for the loci (Table 4). F_{IT} had three positive values significantly different from zero at the *Lap2*, *Mdh2*, and *Hk* loci (Table 4). Four cases of F_{ST} were significantly different from zero at the *Lap2*, *Me*, *Mdh2*, and *Hk* loci. While the F_{IS} had two negative and significant values at *Me* and *Aat* and only one negative and non-significant value at the *Pgm* locus. All mean F values were significantly

different from zero, indicating heterozygote deficiency and population differentiation. A pairwise comparison among populations was carried out and it did not show differentiation between La Bandera, El Chual and Anegados after Bonferroni adjustment (Table 5). These differences were mainly produced by *Mdh2* and *Hk* loci (Table 5).

DISCUSSION

This is a preliminary survey where the analysis of 8 allozyme loci shows genetic differences between six localities of the yellow abalone *Haliotis corrugata* in Cedros and San Benito Islands, B.C. Mexico. The number of loci sampled is approximately the mean of the numbers of other tested loci in different abalone species (Table 6). Hamm and Burton (2000) found genetic differentiation between localities of the black abalone, *Haliotis cracherodii,* using three allozyme loci (*Aat-1, Pgi* [= *Gpi*], and *Pgm*), although comparisons with partial DNA sequences of the mtDNA encoded cytochrome oxidase subunit I gene failed to differentiate between populations. These loci did not differentiate between three populations of the red abalone, *Haliotis rufescens* (Burton & Tegner 2000). Similarly, 7 loci tested with the blue abalone, *Haliotis fulgens,* failed to separate six localities in the middle of the Peninsula of Baja California (Zúñiga et al. 2000), and 16 loci did not separate four populations between Isla de Cedros and Isla Magdalena (Gutiérrez-González 2000).

Size difference among samples is not considered to have an influence in population differentiation because localities with similar abalone size did not join together (Fig. 2, Table 2). Sample sizes are similar to those from the blue abalone (Zúñiga et al. 2000) and may be considered as small sample size, but the statistical methods used here are considered to be robust enough to avoid the bias produced by small sample size.

The polymorphism, mean allele number per locus, and the observed heterozygosity found in *H. corrugata* are similar to other abalone species, marine invertebrates and invertebrates in general (Table 6).

Only Punta Norte population was not in H-W equilibrium and was genetically more separated from the other populations, which may be due to its location on the East coast of Cedros Island. In this area, an anticyclonic eddy is formed during August and September due to an upwelling event on the coast of the Peninsula of Baja California (Mancilla-Peraza et al. 1993, Palacios-Hernández et al. 1993, Amador-Buenrostro et al. 1995). The main stream east of the Cedros Island goes north around the island and then west towards San Benito Islands, and from these to the San Agustin area (Palacios-Hernández et al. 1993). The spawning peaks in these areas are in August and in November, then, if spawning occurs when currents go north-south to the west of Cedros Island, currents could transport some larvae from one place to another; these larvae could be carried from Anegados and San Benito towards the south of Cedros Island. There are no studies regarding abalone larval dispersal and oceanographic conditions around Cedros and San Benito islands during spawning time. However, it is considered that migration is small among abalone populations (Guzmán del Próo et al. 2000). Although, Guzmán del Próo et al. (2000) consider that abalone larvae usually settle around parental beds, in some cases, larvae may be transported about 3–5 km; because this distance is smaller than the actual distance among islands, it is considered that geographical distance may be one of the most important factors in population differentiation and in H-W equilibrium of *H. corrugata.*

Other factos may influence the agreement with H-W equilibrium (i.e. selection, migration, and inbreeding). Fishing may be considered as a selection pressure, because abalone larger than 140 mm are commercially caught. Environmental factors may have an effect on the population structure. It has been observed that sea surface temperature anomalies have a positive effect on *H. corrugata* population (Shepherd et al. 1998). This may reduce stock density and the possibility of genetic differentiation due to genetic drift increases.

Non-random mating may be considered to be important in population differentiation because of the spawning behavior of abalone and because larvae tend to settle in adult beds (Guzmán del Próo et al. 2000). Another source of non-random mating is the introduction of cultured organisms and may have an influence on

the genetic structure of a population, by reducing the genetic pool (Gaffney et al. 1996).

With the mean value of F_{ST} 0.093, it can be considered that the localities of *H. corrugata* conform to discrete populations with moderate diversification, since this value is between 0.05 and 0.15 (Wright 1951, Wright 1965). This contrasts with the low diversification of *H. fulgens* in Mexico which shows low values of F_{ST}, 0.022 to 0.036 (Table 6), and it has been considered that *H. fulgens* forms a single population from Cedros Island to Isla Magdalena (Gutiérrez-González 2000). *H. corrugata* also shows a

slightly higher F_{ST} value in comparison with other abalone species, showing more diversification (Table 6).

Yellow abalone localities at Cedros and San Benito Islands form different populations, which should be considered in fishery management. More studies on other populations of the yellow abalone need to be performed to test whether population differentiation is also present along the Peninsula of Baja California. Also, studies on larval ecology should be carried out to determine migration among islands.

ACKNOWLEDGEMENTS

We thank all people from the Cooperative "Pescadores Nacionales de Abulón" and Isla de Cedros, including José Mario Espinoza and Rogelio Amaro. We thank Diana Rodríguez for technical assistance. This study was supported with funds of CICESE project No. 6153.

MOVEMENT AND RE-AGGREGATION OF THE BLACKLIP ABALONE, *HALIOTIS RUBRA* LEACH, AFTER FISHING

RICKARD A. OFFICER,[1]* CAMERON D. DIXON,[2] AND HARRY K. GORFINE[2]

[1]*Tasmanian Aquaculture and Fisheries Institute, University of Tasmania, Nubeena Crescent, Taroona, Tasmania 7053, Australia;* [2]*Marine and Freshwater Resources Institute, PO Box 114, Queenscliff, Victoria 3225, Australia*

ABSTRACT Movement and re-aggregation after fishing of a stock may have a major impact on estimates of abundance and stock assessment parameters such as natural mortality. The propensity of blacklip abalone (*Haliotis rubra* Leach) to re-aggregate after fishing was studied using a combination of *in situ* tagging with fine-scale mapping of two distinctly different abalone populations. Controlled fishing of each population was conducted to test the hypothesis that removal of abalone by fishing stimulates movements that result in re-aggregation. Declines in abundance due to fishing were evident but less than those expected had no recovery occurred. Changes in the fine-scale spatial distribution of abalone suggested that re-aggregation occurred through a series of contiguous displacements. Smaller emerging abalone did not appear to be the prime source for this re-aggregation. These results undermine the utility of change-in-ratio and catch-per-unit-effort methods of abundance estimation. They also highlight the need to develop methods of abundance estimation that accommodate the impact of aggregating behavior on blacklip abalone populations.

KEY WORDS: *Haliotis rubra*, abalone, movement, aggregation

INTRODUCTION

Blacklip abalone, *Haliotis rubra*, form the basis of a large and extremely important fishery in southern Australian waters. The year 2000 total allowable catch of 2720 tons was worth about $AUD 80 million at the point of first sale. Despite the economic importance of abalone fisheries, stock assessment of abalone has remained problematic (Breen 1992). These difficulties are partly a product of the biology of abalone and the way they are fished. The tendency of abalone to live in aggregations renders them more vulnerable to overfishing by increasing their catch rates (McShane 1995). Divers are able to maintain high catch rates by moving from aggregation to aggregation and by relocating to a different area once catch rates drop below an acceptable level (Prince 1989, Breen 1992, McShane 1995). If the abalone remaining after fishing then re-aggregate, a diver returning to the area may well fish the area at a similar catch rate to the first excursion. These processes may all contribute to hyper-stability in catch rates and conceal real fluctuations in population size (Breen 1992, Prince & Shepherd 1992, McShane 1994).

Understanding how abalone reform aggregations is therefore central to understanding the resilience of abalone populations to fishing. Furthermore, because stock assessment techniques are based on assumptions about the spatial and temporal distribution of animals, understanding the nature of re-aggregation is crucial to the choice of tools used for stock assessment.

This paper first describes the response of two blacklip abalone populations to experimental fishing. It then focuses on determining where "replacement" abalone come from to reform aggregations and how these processes change with time. Several hypotheses that could explain re-aggregation are examined. These include emergence (from cryptic habitat within the fished area), immigration (from outside the fished area), relocation (from sparsely populated regions within the fished area), and a combination of these processes. A fifth hypothesis of growth (of pre-recruits to recruits) is not examined because growth was negligible during the period of the study.

MATERIALS AND METHODS

Experimental sites were selected off the coast of Victoria, Australia, at Point Cook and at Flinders (Fig. 1). Both sites were subject to little illegal or recreational abalone fishing, and were closed to commercial fishing for six months prior to and throughout the experiment. The sites were chosen to represent extremes of habitat type and abalone distribution.

The Point Cook site (37°55.893′ S, 144°47.104′ E) was 3–4 m in depth and was not subject to strong swell or current. The reef consisted of basalt boulders, rarely over 1 m in height, on a sandy substrate. Conditions appeared anaerobic beneath the boulders and there was very little cryptic habitat that could not be thoroughly searched by a diver. The dominant macro-algae included *Ecklonia radiata*, *Caulerpa* spp., *Enteromorpha linza*, *Cystoseria* spp., and, during summer months, a thick mat of drift red algae (mostly *Jeanerettia pedicellata*). Abalone were abundant at Point Cook and were relatively evenly distributed. At Flinders (38°29.397′ S, 145°01.274′ E) the depth was 7 to 9 m and the site was prone to strong swells and currents. The reef consisted of fractured and stepped basalt platforms, often over 1 m in height, and interspersed by sand gutters. The fractured nature of the reef provided an abundance of unsearchable cryptic habitat. The dominant algae included *Phyllospora* spp., *Ecklonia radiata*, and coralline algae. Abalone were less abundant at Flinders than at Point Cook and were more patchily distributed.

Four square plots were set up in fixed positions at each site. The boundaries of each plot measured 24 m and each plot was separated from the other plots by 10-m corridors (Fig. 2). At each site two plots were fished to assess the impact of fishing and two plots were left unfished to compare the fishing impact with unfished areas. Fished and control plots were chosen randomly, but were constrained to being diagonally opposed. Surveys were conducted prior to fishing, 3–4 wk after fishing (to assess the impact of fishing), and, 10 wk later to assess the recovery from fishing. This design allowed for temporal and spatial comparisons between plots, both fished and control, and between sites.

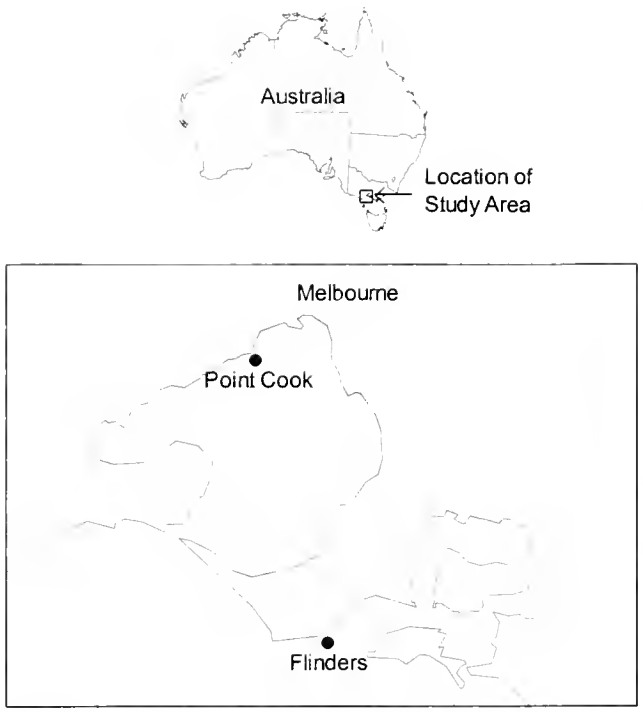

Figure 1. Location of the experimental sites at Point Cook and Flinders.

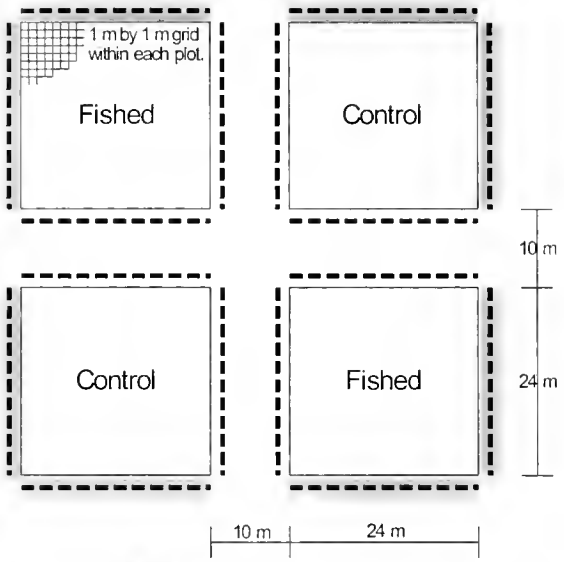

Figure 2. Diagram showing the set-up of experimental areas at each site. Shaded areas outside the plots indicate areas in which abalone were mass marked. Dotted lines indicate the position of fixed transects swum outside the plots.

Changes in abundance were assessed by counting all emergent abalone within the plots using an exhaustive 1 × 1 m grid system. These grid counts were also used to calculate Morisita's index of dispersion (Krebs 1989) (Eq. 1):

$$I_d = n\left[\frac{\sum x^2 - \sum x}{(\sum x)^2 - \sum x}\right]$$

where I_d is Morisita's index of dispersion, n is the sample size, $\sum x$ is the sum of grid counts, and $\sum x^2$ is the sum of grid counts squared.

This index is a useful descriptor of the degree of aggregation in observed spatial patterns. The significance of observed spatial patterns was tested using the standardized Morisita index of dispersion (described in Krebs 1989). This index allows comparisons between plots and sites because it is independent of both population density and sample size.

Differences in the spatial distribution of abalone were also studied by measuring the distance between abalone and their first, second, and third nearest neighbors. The source individuals for these measurements were selected randomly from cells with the greatest and least abundance of abalone within each plot. A chi-square goodness-of-fit test was also used to compare the observed and expected distributions of nearest-neighbor distances (Campbell & Clarke 1971). These tests indicated the significance of any departure from random spacing. The shape of the observed distributions indicated any departure from a random pattern. The distribution of nearest-neighbor distances at each survey was compared to assess temporal changes in the degree of aggregation.

During each survey the abundance of abalone outside each plot was estimated by making counts along fixed transects (Fig. 2). These transects measured 24 m in length by 1 m in width. These counts were made to assess the extent of immigration into the plots.

Lengths were recorded to assess fishing-induced changes in the size composition of the population. The extent of weed growth on shells was also noted. These data were collected under the assumption that abalone emerging from cryptic habitat were smaller and carried less algal cover than the conspicuous population.

To examine immigration and relocation abalone were individually tagged. This was done with a rivet tag through a respiratory pore using a method modified from that of Prince (1991). All abalone were tagged and measured *in situ* to minimize disturbance and displacement. To spread the tagging within the plots across the range of conspicuous abalone sizes and across all habitats, divers attempted to tag every fifth abalone sighted. The positions of tagged abalone were then recorded within the grid to an accuracy of ±0.1 m. The 1322 and 819 abalone tagged within the plots at Point Cook and Flinders represented 19 and 18 percent of the unconcealed populations, respectively.

To assess the extent of immigration into the plots after fishing, abalone on the outer perimeters of the plots were also marked (Fig. 2). Starting closest to each plot boundary and working outwards, all abalone encountered were marked until at least 170 had been either tagged or painted with a uniquely colored paint-stick (50% for each marking method). Abalone between the inner borders of the plots were not marked so that interaction effects along the internal borders between plots were avoided. Approximately 1400 abalone were marked outside the plots at each site.

The relocation of tagged abalone within the plots was examined by using grid-cell abundance as an index of habitat quality. The assumption was that the greater the number of abalone initially resident within a grid cell, the better the habitat quality of that cell. The initial abundance in cells that tagged abalone occupied prior to moving was compared with that of the cells in which they settled. Abalone were determined to have settled when subsequent surveys revealed that they had moved less than one meter from their previous position.

Experimental fishing was done above minimum size limits. The size limits used were less than those normally in use in the Victorian abalone fishery (Point Cook: normally 100 mm, used 93 mm; Flinders: normally 110 mm, used 100 mm). These size limits made a greater proportion of the population available to fishing and hence, allowed a greater fishing impact. About 50% of the population at each site were over the respective size limits. Of those, 20% were tagged and therefore unavailable to fishing. The remaining 40% of the population oversize were fished until a reduction of 35% of the abundance prior to fishing was achieved. To allow comparison between sites the same relative reduction in abundance was applied at both sites.

RESULTS

Changes in Abundance

Changes in the total abundance of abalone counted within the plots were compared as a percentage of the initial abundance counted prior to fishing (Fig. 3). At each site changes in abundance were consistent within each type of plot and were therefore combined for analysis. In all cases the observed change in abundance was different to that expected. If no movement had occurred after fishing, a 35% reduction was expected in fished plots, and no change was expected in control plots. At both sites a decrease in abundance of less than 20% was observed in fished plots. An increase in abundance was observed in all control plots. At Point Cook the apparent recovery of fished areas was sustained but at Flinders the recovery slowed or possibly waned.

Changes in Distribution

At both sites and during all surveys the distribution of abalone was found to be significantly aggregated (standardized Morisita index of dispersion >0.5, therefore >95% confident of aggregated pattern). Changes in the non-standardized Morisita index of dispersion indicated site-specific differences in distribution (Fig. 4). The Flinders plots showed a consistently higher degree of aggregation. This was indicative of there being many areas with no abalone and a few areas with many. The lower degree of aggregation at Point Cook was indicative of a more homogenous spatial distribution. These initial distributions influenced the change in distribution observed after fishing. At Flinders the removal of abalone from aggregations made the size of aggregations less extreme and lowered the degree of aggregation. At Point Cook the even removal of abalone across the entire area created grid cells with no abalone, thereby causing an increase in the degree of aggregation. The longer-term recovery after fishing generally showed a return toward the initial distribution.

The complete enumeration of all abalone within the plots meant that a Chi-square test of goodness-of-fit (Campbell & Clarke 1971) could be used to compare the observed and expected distributions of first, second, and third nearest-neighbor distances. These tests indicated that significantly aggregated patterns existed in all plots at both sites during each survey ($P < 0.01$, df = 5). Prior to fishing the distribution of first, second, and third nearest-neighbor distances was similar in fished and control plots at each site (Fig. 5 and Fig. 6). At both sites approximately 80% of abalone were located within 30 cm of their nearest neighbor. This aggregated pattern was more extreme at Flinders where about 50% of abalone were located within 5 cm of their nearest neighbor (compared with about 40% at Point Cook). Distances to second and third nearest neighbors were also less at Flinders than at Point Cook. About 25% of second and 10% of third nearest neighbors were located within 5 cm of the source abalone at Flinders compared with 10% and <5% respectively, at Point Cook. This pattern prior to fishing is indicative of the more aggregated pattern at Flinders and the more homogenous distribution at Point Cook.

The apparent impact of fishing was most noticeable at Flinders (Fig. 6). In both control and fished plots the proportion of first, second, and third nearest neighbors found close to the source abalone decreased during the first post fishing survey and the proportion located some distance from the source abalone had increased. This change was most noticeable in the fished plots. At Point Cook these changes were only noticeable in the fished plots (Fig. 5) and to a lesser extent than at Flinders. Changes in the distribution of

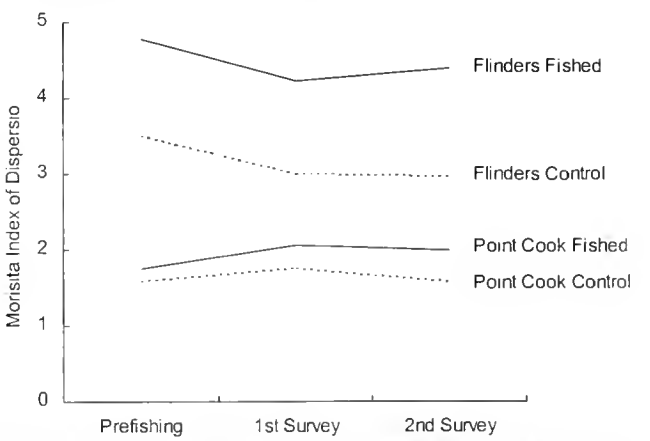

Figure 4. Changes in the non-standardized Morisita Index of Dispersion for abalone within fished and control plots at Point Cook and Flinders over the course of the experiment.

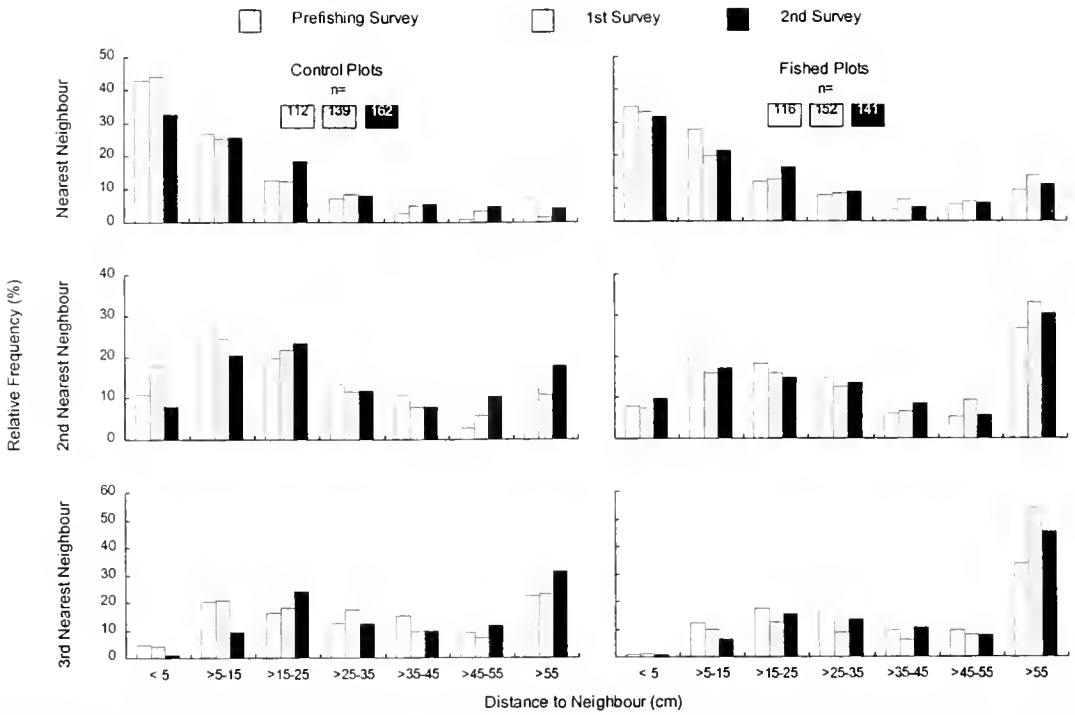

Figure 5. Relative frequency distributions of distances from abalone to their nearest, second nearest, and third nearest neighbors at Point Cook prior to fishing, and at each post-fishing survey.

nearest-neighbor distances in the control plots at Point Cook between the pre-fishing and first post-fishing survey were erratic. Between the first and second post-fishing surveys changes in these distributions in control plots at Point Cook remained erratic.

Conversely, by the second post-fishing survey the distribution of first, second, and third nearest neighbors at Flinders and in the fished plots at Point Cook had shown a general recovery toward the distribution found prior to fishing. At Flinders this recovery was most complete in the control plots. In fished plots the proportion of first, second, and third nearest neighboring abalone found

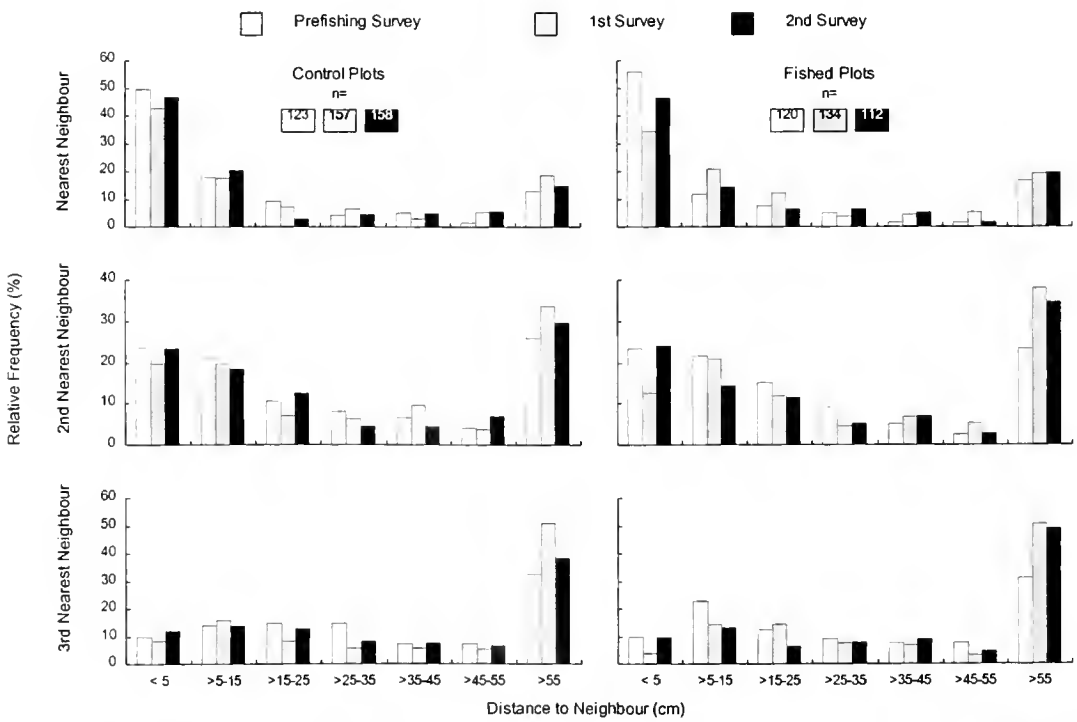

Figure 6. Relative frequency distributions of distances from abalone to their nearest, second nearest, and third nearest neighbors at Flinders prior to fishing, and at each post-fishing survey.

within 5 cm of the source abalone was similar on the second post-fishing survey to that found prior to fishing. In contrast, the increase noted on the first post-fishing survey in the proportion of abalone located some distance from the source abalone decreased only marginally on the second survey.

Emergence

Categorizing the shell cover of abalone proved to be difficult and imprecise. Therefore, these data were not used for analysis. Figure 7 shows the relative length frequency distributions of the abalone in fished areas at each site. Length frequency distributions before and after fishing did not show great change in the proportions of animals above and below the size limit.

Immigration

Figure 8 shows changes in the number of abalone counted on fixed transects around fished and control areas at each of the sites. At Point Cook there was a general and sustained decline in the number of abalone around fished areas after fishing. This result was not as apparent around control plots. At Flinders there was a decline in abundance around both fished and control areas but this decline was not as marked as at Point Cook.

The immigration of abalone tagged outside the plots is illustrated for the Point Cook site in Figure 9. The movement of abalone into control plots was just as significant as the movement into fished areas. While the number of tag movements at Flinders was not as great as at Point Cook, the results were similar.

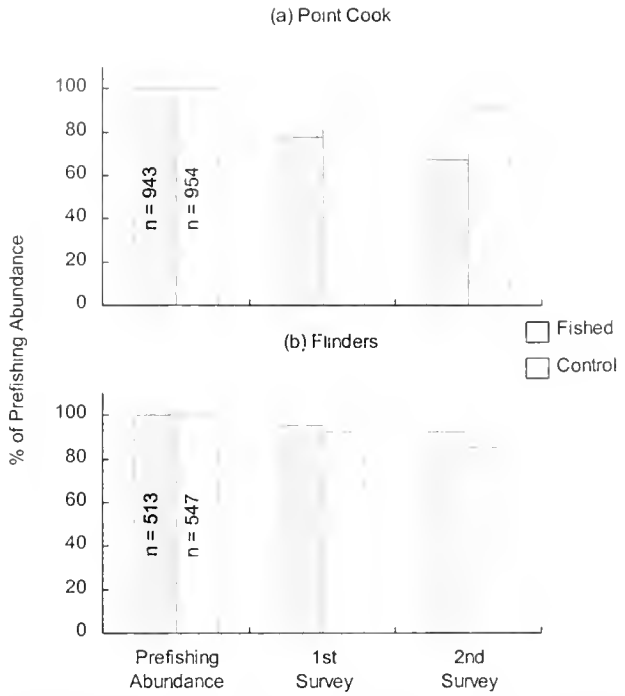

Figure 8. Changes in the abundance of abalone counted on fixed transects outside fished and control plots at (a) Point Cook and (b) Flinders over the course of the experiment.

Relocation

Figure 10 shows the number of abalone that moved and subsequently settled at each site plotted against the initial abundance of the cell in which they were tagged. At both sites abalone settled in cells of lower initial abundance than that of the cells in which they were tagged. This movement occurred in both control and fished plots but was more apparent in fished plots.

DISCUSSION

Many traditional methods of fisheries stock assessment assume that movement-driven changes in spatial distribution have little impact on estimates of abundance or important parameters such as catchability and natural mortality. Such methods have been applied in abalone population surveys despite many anecdotes describing the propensity for abalone to re-aggregate after fishing and during spawning (Shepherd 1986b, McShane 1996, Hart & Gorfine 1997). Although there have been previous studies of abalone movement (Newman 1966, Poore 1972, Shepherd 1986a, Ault & DeMartini 1987, Prince 1992) and the frequency of aggregations (Shepherd 1986b, McShane 1996), a synthesis of these results has remained problematic. This study attempted to redress this deficiency by employing a combination of *in situ* tagging with fine-scale mapping of two distinctly different abalone populations. Controlled fishing of each population was conducted to test the hypothesis that removal of abalone by fishing stimulates movements that result in re-aggregation.

Experimental fishing clearly had an impact on the populations, evident as declines in the abundance of abalone counted in all fished areas. However, these reductions were less than those expected. Without fishing induced movement a 35% reduction in fished areas was expected and no change was expected in control areas. The increase in abundance in control areas, while not as great, may suggest a response to fishing at some distance. The fact that these changes in abundance within the plots were the opposite of those shown outside the plots suggested that recovery of the populations after fishing was occurring.

Substantial movement was observed and both populations showed a trend to return to their original spatial distributions. However, understanding how this redistribution was achieved proved difficult because contradictory results were obtained from two parts of the study. Analysis of the movements of tagged abalone showed an apparent dis-aggregation during the recovery, whereas the analysis of changes in the spatial distribution of abalone during the recovery suggested a re-aggregation. It was anticipated that the movement of tagged abalone would provide data that would best describe the nature of recovery of the abalone populations to fishing. Unfortunately these data were apparently the least reliable as the number of tagged abalone available for this analysis was only a small proportion of the tagged population. Furthermore, the repeated disturbance during the tagging, fishing, and re-surveying could well have caused abalone to disperse, reducing the likelihood of recapture, and resulting in dis-aggregation. Increased movement activity has been noted in other abalone species subject to disturbance (Shepherd & Godoy 1989, Werner et al. 1995). One of the important, but unforeseen, outcomes from this study was the impact that tagging-induced dispersal may have on estimates of natural mortality (Dixon et al. 1998).

Changes in the distribution of nearest-neighbor distances appeared to better describe the recovery of the populations after fishing. These data represented the entire population under study and were therefore less likely to be affected by tagging induced disturbances. These data suggested that restocking of aggregations occurred at both sites but that it was less noticeable at Point Cook where the abalone displayed a more homogenous distribution. The attenuated recovery at Flinders suggests that reformed aggregations contained fewer individuals than they did prior to fishing and that sparsely populated areas surrounding aggregations were not

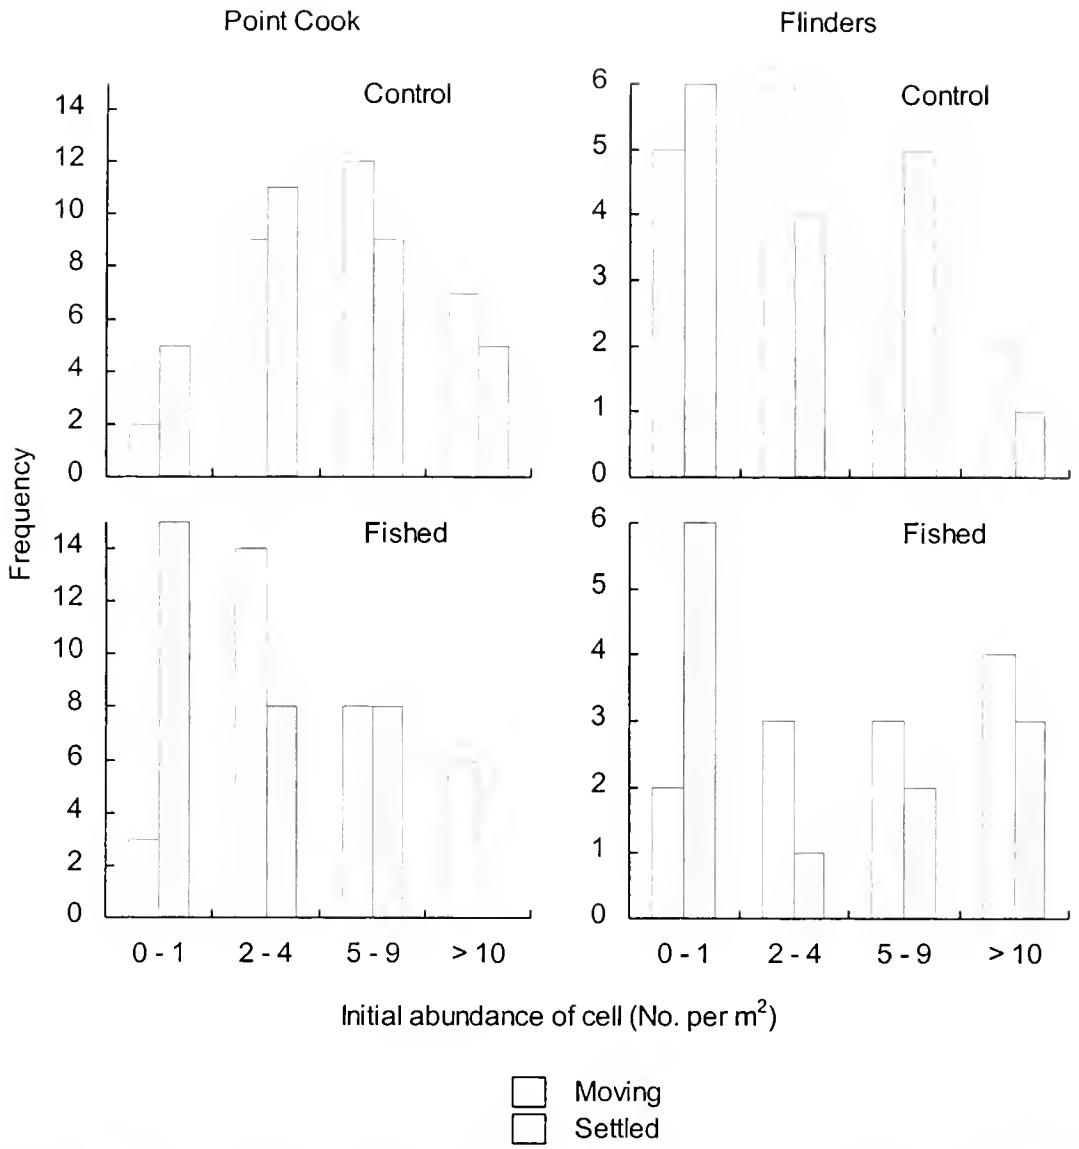

Figure 10. Position of moving and settled abalone relative to the initial abundance of the cell in which they were sighted.

quickly restocked following fishing. The recovery of a population through re-aggregation without complete restoration of pre-fishing population densities has important implications for area-based population surveys because such a re-distribution of abalone will mask depletion caused by fishing. Moreover, the tendency for recruited abalone to re-aggregate ensures that catchability will be maintained despite stock depletion. This means that abalone populations are more vulnerable to over-exploitation than populations of species whose catchability declines as stock numbers decrease. This is not surprising given the global history of abalone stock collapses.

Smaller abalone were not the prime source of re-aggregation particularly where emergence from crevices was a factor. This result is contrary to the conclusions of other studies (McShane & Smith 1989, Hart & Gorfine 1997, Hart et al. 1997). It is, however, consistent with the notion that smaller abalone seek the shelter afforded to them by cryptic habitat until they are large enough that the risks of occupying more exposed locations are outweighed by the benefits of improved food availability and the need to reproduce. Most of the observed movements involved relatively small displacements that, when considered together with post-fishing changes in abundance, suggest re-aggregation resulted from a series of contiguous displacements similar to a "domino effect." This implies that post-fishing spatial dynamics involves size-related competition for preferred home-sites.

Our results cast serious doubt on the validity of change-in-ratio methods that have sometimes been used for estimating abalone abundance (Nash et al. 1994). Our results indicate that violation of the critical assumption of equal catchability of two animal types (pre-recruits and recruits) is inevitable. Fine-scale hyper-stability in catch per unit effort (CPUE) is another consequence of re-aggregation and renders CPUE useless as an index of abundance except under conditions of severe depletion. This is not to suggest that instantaneous catch rate may not be sensitive to localized stock depletion. Immigration of abalone into fished areas, such as that suggested in this study, would further undermine the assumptions of change-in-ratio analyses. This will be even more apparent if immigration is most noticeable in recruits only.

Blacklip abalone populations can be regarded as comprised of

two parts, the aggregations that collectively constitute the stock commercial abalone divers are adept at targeting, and the more sparsely distributed abalone that serve to re-supply and thus maintain the aggregations after fishing. Although estimates of the numbers and sizes of aggregations provides a picture of the size of the stock, it is likely that these estimates tend to be hyper-stable whereas the density of sparsely distributed abalone may be a more sensitive indicator of the impact of fishing. Future research should be directed toward developing methods of abundance estimation that accommodate re-aggregation. Further analysis of our data using techniques developed for terrestrial ecosystems that estimate density using distances between nearest neighbors and distances from randomly selected sampling points offer promise in this regard (Byth & Ripley 1980, Byth 1982, Officer et al. 2000). Here, the distances are considered as radii that define areas occupied by both sparse and clumped individuals. As the degree of aggregation increases, the distances between nearest neighbors decreases while the distances from randomly selected points tends to increase. The geometric mean between the overall density of nearest neighbors and the overall density relative to random points gives an estimate of density with less bias than more conventional estimates from quadrats and transects. Regardless of the survey methodology employed, the results of this study indicate that aggregating behavior must be considered when assessing the impact of harvesting on blacklip abalone populations.

ACKNOWLEDGMENTS

Without the support of the Victorian abalone industry this project would not have been possible. Commercial abalone divers refrained from diving at the two study locations for 6 mo prior to field sampling, during the study, and for the following 6 mo. Miriana Sporcic provided extensive assistance with data analysis. Scientific advice was generously provided by Warwick Nash (Australian Maritime College) and Neil Andrew (NIWA, Wellington). Terry Walker (MAFRI) reviewed initial drafts of this manuscript and provided many valuable suggestions for its improvement. Acknowledgment must be made of the substantial effort made by the project's field staff. Assistance with vessel operations and diving support in the initial establishment of experimental sites was provided from within MAFRI by Mark Ferrier, David Beyer, Dale Thomson, and Ian Duckworth. Andrew Tulloh provided invaluable expertise for the design and fabrication of tagging equipment. External charter vessels were provided at Flinders by Geoff Rodda (Peninsula Diving Instruction), at Point Cook by Graham Leckie (Ultimate Fishing Charters) and Alistair MacDonald (Port Campbell SCUBA and Marine). Diving contractors employed on the project included David Forbes and Bruce Waters of Aquatic Research Support Services, Rod Knights from Professional Diving Services, Geoff Rodda from Peninsula Diving Instruction, and Michael Callan. The research divers collectively accumulated 1000 hours underwater during the surveys. We are extremely grateful to Joanne Merry who generously volunteered her time and expertise to support the field team with the logging of dives and the management of data collection while at sea, and who subsequently entered and processed the data on computer. The project was funded by the Fisheries Research and Development Corporation (Project 95/165) and the Marine and Freshwater Resources Institute.

DISTANCE-BASED ABUNDANCE ESTIMATION FOR ABALONE

RICKARD A. OFFICER,[1]* MALCOLM HADDON,[1] AND HARRY K. GORFINE[2]

[1]Tasmanian Aquaculture and Fisheries Institute, University of Tasmania, Taroona, Tasmania 7053, Australia; [2]Marine and Freshwater Resources Institute, Queenscliff, Victoria 3225, Australia

ABSTRACT Indices of abundance are an important component of stock assessment models. Unfortunately, conventional attempts to estimate the abundance of abalone are hampered by the patchy spatial distribution characteristic of abalone. An alternative distance-based abundance estimator was evaluated by the simulated sampling of a large natural population of abalone whose relative positions had been accurately mapped. Distance-based abundance estimators can better accommodate the aggregated distribution of abalone. The simulated sampling of the real population of blacklip abalone (*Haliotis rubra* Leach) was used to examine the accuracy, bias, and sensitivity to changes in abundance of the distance-based approach. In each sample the distances from a randomly selected point and from a randomly selected abalone to the nearest abalone were used as the basis for a compound estimate of abundance. A Monte Carlo procedure was used to obtain percentile confidence limits about abundance estimates. The distance-based method was found to approximate the true abundance of the population and therefore may be useful as an indicator of absolute abundance. The method was also sensitive to changes in abundance. This sensitivity was examined by simulating the effects of fishing at varying rates of exploitation. Simulated reductions at moderate levels of exploitation (20–25% overall reduction) showed that the method was able to detect changes in abundance with reasonable confidence (90%). The resolution of some technical difficulties may enhance the ability of the distance-based method to detect changes in abundance in a real fishery.

KEY WORDS: *Haliotis rubra*, abalone, blacklip, stock assessment, abundance estimation, nearest neighbor distance, distance

INTRODUCTION

Blacklip abalone, *Haliotis rubra*, form the basis of a large and valuable fishery in southern Australian waters. Despite the economic importance of the fishery, stock assessment of blacklip abalone has remained problematic. Proper estimation of the sustainable yield from the fishery requires assessment of how the size of the stock changes over time. For assessment methods to be useful in routine monitoring they must: provide a reliable relative or absolute index of abundance for the stock, be sensitive to changes in abundance in the population, and be easily applied across a representative proportion of the fishery.

Fishery-dependent methods of stock assessment often fail for abalone fisheries because of the inherent hyper-stability in catch-rate indices (Breen 1992, McShane 1994). The tendency of blacklip abalone to live in aggregations renders them more vulnerable to overfishing by increasing their catchability. Divers are able to maintain high catch rates by moving from aggregation to aggregation and by relocating to a different area once catch rates drop below an acceptable level. If the abalone remaining after fishing then re-aggregate, a diver returning to the area may well fish the area at a similar catch rate to the first excursion. These processes may all contribute to hyper-stability in catch rates and conceal real fluctuations in population size due to local depletion.

Unfortunately, fishery-independent methods of assessment are also difficult to apply to abalone populations. Area-based abundance estimators can provide accurate measurement of abundance and an ability to detect change (Hart & Gorfine 1997, Hart et al. 1997). However, the patchy distribution of abalone unfortunately introduces high variance into such estimates and sample sizes must therefore be extremely high to achieve acceptable levels of precision (Nash 1995). Methods such as mark-recapture and change-in-ratio both may show reasonable precision and sensitivity (Hart and Gorfine 1997). Unfortunately, the sampling intensity needed to achieve this makes these measures useful only for the assessment of small populations. The time required to apply such measures across a large fishery would make them prohibitively expensive as a routine monitoring tool.

Fishery-independent assessment methods that are less time consuming offer scope for the monitoring of large areas but may forsake precision. Estimates provided by techniques such as timed collections suffer from variation in collection efficiency between divers (Shepherd 1985, McShane 1994) and in sea conditions at the time of sampling. Such methods are also prone to hyper-stability due to the tendency of abalone to aggregate and the unintentional attraction of research divers to these aggregations (McShane 1994). Where the research diver spends most time within an aggregation handling abalone, rather than searching, the estimated density tends unrealistically toward infinity (Hart et al. 1997).

The development of assessment methods that better handle the aggregated distribution of abalone would clearly be an advantage. Distance-based methods of abundance estimation offer scope for species such as abalone that are largely sedentary and aggregated. Techniques developed for terrestrial ecosystems that estimate density using distances between nearest neighbors and distances between randomly selected sampling points and the nearest individual of the species of interest offer potentially workable methods (Byth & Ripley 1980, Byth 1982). As the degree of aggregation increases, the distances between nearest neighbors tend to decrease while the distances from randomly selected points to individuals tend to increase. Compound estimates of the overall density using these two measures may therefore accommodate a wider range of spatial distribution types than more conventional abundance estimates (Diggle 1975). While such methods have been in existence for some time (Clark & Evans 1954) they have not been applied to abalone. This is perhaps because the data requirements necessary to test the efficacy of the methods are particularly difficult to achieve—samples are required for a population of known abundance and distribution.

The objective of this study was to evaluate the efficacy of a relatively simple distance-based abundance estimator. This was done using simulated measurements and removals of abalone from a blacklip abalone population of known abundance and spatial

*Corresponding author. Current address: Marine Institute, Marine Fisheries Services Division, 80 Harcourt St., Dublin 2, Ireland. E-mail address: rick.officer@marine.ie

distribution. The evaluation examined the accuracy, precision, and sensitivity to changes in abundance of the estimator.

MATERIALS AND METHODS

Study Site

The mapping of abalone distributions was undertaken at Point Cook, Victoria, Australia (37°55.893′ South, 144°47.104′ East). The site was 3 to 4 m in depth and was not subject to strong swell or current. The reef consisted of basalt boulders, rarely over 1 m in height, on a sandy substrate. There was very little cryptic habitat that could not be thoroughly searched for abalone.

The study site covered an area of 58 × 58 m, subdivided into four plots of 24 × 24 m separated by corridors 10 m wide. Each plot was further divided into 1 m^2 cells using a grid system. The grid was used to record the position of all abalone observed within the plot within an accuracy of ±10 cm. To simplify the application of the computer simulation procedure the 10-m corridors between plots were removed, creating one plot measuring 48 × 48 m.

Simulation Procedure

The position of all abalone observed by divers in the plot was recorded in two dimensions as an X-Y coordinate and saved in a Microsoft Excel spreadsheet (Fig. 1). A total of 8009 abalone was observed by divers in the plot. The length composition of the population was determined for a sample of 1809 abalone measured in the study area. To allow for comparisons between the size structure of abalone occupying densely populated habitat and those in sparsely populated areas, lengths had been recorded separately for abalone in each type of habitat. Each of the 8009 abalone was assigned a length from the known length composition data.

An interactive macro program was written in Visual Basic to calculate a series of distances between source positions (either randomly chosen points or randomly chosen abalone) and the nearest abalone. The method assumes that distances can be measured from source positions within the plot to abalone located outside the plot. Because there was no data for abalone outside the plot, source positions were restricted to lie inside a 2-m border region around the plot (Fig. 1). It was possible to measure from a source position located within the inner plot to an abalone located within the border region but no measurements originated within the border. In all simulations reported here the border region used was 2 m. This reduced the size of the area from which source positions could be chosen to 44 × 44 m. 6596 abalone were observed within the 44 × 44 m inner plot.

Calculation of Randomly Chosen Point to Nearest Abalone Distances

A random number generator was used to generate the required number of randomly chosen points within the inner plot. For every randomly chosen point the distance to the nearest abalone was recorded. The nearest abalone could be located in the 2-m border region outside the inner plot.

Calculation of Randomly Chosen Abalone to Nearest Abalone Distances

Because the number of abalone within the plot was known it was possible to assign each abalone a random number. A table of random numbers was then used to choose abalone located within the inner plot from which distances to the nearest abalone would be calculated. The nearest abalone could be located in the 2-m border region outside the inner plot. The number of randomly chosen abalone from which to calculate distances could be specified. The macro prevented abalone from being chosen more than once in any sample taken from the plot. This avoided the remeasurement of nearest neighbor distances from the same abalone.

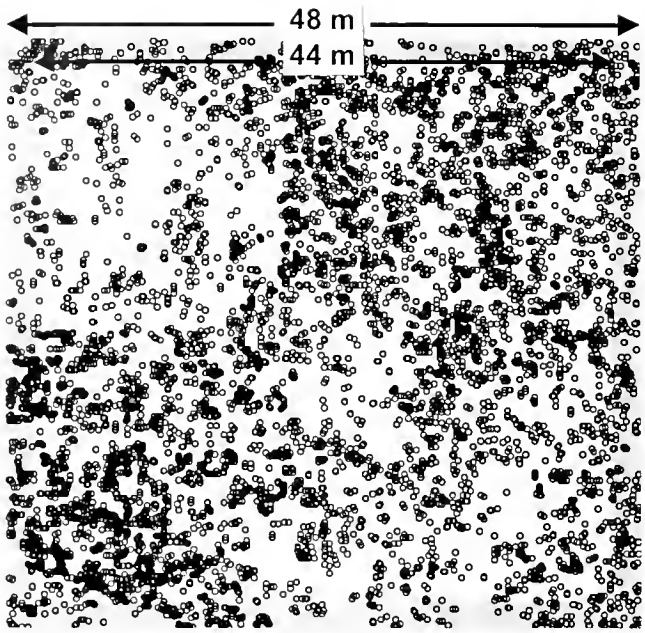

Figure 1. Diagram showing the position of all 8009 abalone within the study area. Abalone are plotted as unfilled circles several times their actual size. Where abalone are densely aggregated the plotted circles overlap creating dark patches. Source positions for either randomly chosen points or randomly chosen abalone were prevented from originating within a 2-m border region (shaded area) to prevent the possibility that the nearest abalone to a source position was outside the mapped region. However, it was possible to measure from abalone located within the inner plot to abalone located within the border region.

For every randomly chosen abalone the distance to the nearest abalone was calculated. The lengths assigned to each abalone were used to compare the calculated nearest neighbor distance with the minimum possible distance between the centers of each abalone. The greater of these two distances was recorded. This was done to avoid assigning nearest neighbor distances smaller than if nearest neighbors were touching.

Calculation of Distance-based Density Estimates

The formula suggested by Byth and Ripley (1980) was used to generate estimates of population density (Eq. 1):

$$\hat{N} = \frac{n}{\pi \sum (r_i^2)}$$

Where

$\hat{N}$ is an estimate of population density,

n is the sample size (number of distances measured), and

r_i is the distance from the ith random source position to the nearest abalone.

Density estimates were calculated separately from the series of randomly chosen point-abalone distances and from the series of randomly chosen abalone-abalone distances. Unfortunately the density estimates derived from each type of calculation are sensitive to the spatial pattern of the organisms under study (Diggle 1975, Krebs 1989). Diggle (1975) found that as the degree of

population aggregation increased, point-organism distances also tended to increase resulting in underestimates of population density. Conversely, organism-organism distances tended to decrease and result in overestimation of population density. He showed that an unbiased estimate of the population density could be obtained by calculating the geometric mean of the point-organism and organism-organism density estimates. In this study Diggle's protocol was followed and a compound and theoretically unbiased estimate of density was calculated as (Eq. 2):

$$\hat{N} = \sqrt{\hat{N}_{RCPt}\,\hat{N}_{RCAb}}$$

Where

$\hat{N}$ is a compound estimate of population density, and

$\hat{N}_{RCPt}$ and $\hat{N}_{RCAb}$ are respectively the randomly chosen point-abalone and randomly chosen abalone-abalone estimates of population density (derived from Equation 1).

Calculation of Expected Densities

The expected density of abalone in the plot was calculated as the total number of abalone within the inner plot divided by the total area of the entire plot (48 × 48 m = 2304 m^2). To more closely reflect the approach taken by the distance-based density estimation, the number of abalone within the inner plot was divided by the total area, rather than the area of the inner plot. The distance-based method estimates density for a larger area than that of the inner plot because it was possible to measure from a source position located within the inner plot to an abalone located within the 2-m border region.

Expected densities were calculated for the initial population and for three levels of population reduction. The levels of reduction simulated were 25%, 50%, and 75% less than the initial population size. Little difference was found between the size composition of abalone located in densely populated habitat with that of abalone located in sparsely populated areas. The simulated removal of abalone from the plot was therefore done randomly to effect each level of population reduction.

Estimation of Optimal Sample Size

By successively increasing the number of distance measurements used in the calculation of the compound distance-based estimate, the simulator was used to determine the sampling intensity required for consistent density estimation. The number of distance measurements of each type was increased from 50 to 800 in steps of 50. Five iterations were run at each step to allow variability to be examined for each number of measurements.

Estimation of the Minimum Detectable Difference

Subsequent distance-based estimates of the initial population density were calculated from 250 distance measurements of each type of density estimate. This number was chosen for two reasons: Further increases in the number of distance measurements did not appear to greatly increase the precision of density estimates, and, 250 was thought to be a practical number of measurements to take if conducting the sampling in the field.

250 randomly chosen abalone represented 3.8% of the initial population of 6596 abalone within the inner plot of the study area. 100 iterations of the simulation procedure were run to generate a distribution of estimated densities for the population within the entire plot. 80%, 90%, and 95% percentile confidence limits were calculated from this distribution.

To estimate the minimum detectable difference the population was reduced in successive steps and the simulation procedure rerun 100 times at each level of reduction. The number of distance measurements of each type was kept at the same percentage (3.8%) of the residual population within the inner plot to maintain the same level of sampling intensity as that used in the estimation of density of the initial population. 80%, 90%, and 95% percentile confidence limits were calculated for each level of reduction.

A comparison was made between the 100 estimated densities calculated at each level of reduction and the corresponding expected densities. The relationship between the two was described using linear regression. Regression lines were also drawn between the various upper and lower percentile confidence limits. These relationships were used to estimate the ability of the method to detect changes in abundance at various levels of confidence and population density.

RESULTS

Estimation of Optimal Sample Size

Successive increases in the number of distance measurements used in each simulation improved the consistency of density estimates calculated for the initial population (Fig. 2). Variability in repeated simulations reduced markedly when 300 or more distances of each type were measured. Density estimates of the initial population approached a central limit of about 2.7 abalone/m^2.

Estimation of the Minimum Detectable Difference

Negligible differences in size structure were found between abalone in densely populated habitat and those in sparsely populated areas (Fig. 3). This justified the random removal of abalone from the plot to affect each level of population reduction.

Estimates of density were less variable at reduced population sizes (Table 1, Fig. 4) despite there being no increase in sampling intensity in simulations run at lower population sizes. Density

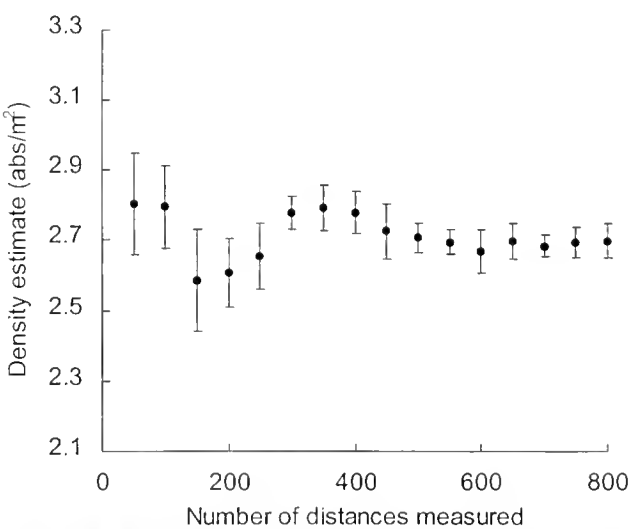

Figure 2. Average density estimates (±SE) calculated by the simulator at various sampling intensities. Five iterations were run at each sampling intensity. The sampling intensity is indicated by the number of distances measured of each type (i.e., 200 indicates that 200 randomly chosen point-abalone and 200 randomly chosen abalone-abalone distances were measured).

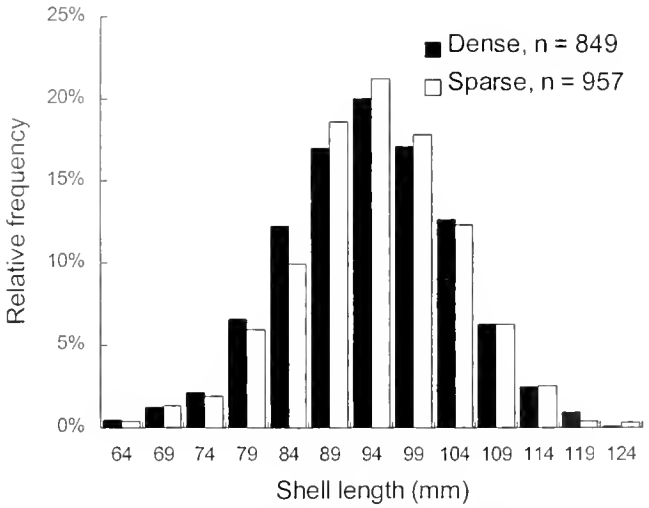

Figure 3. Comparison of the size structure of abalone collected from densely populated habitat and sparsely populated habitat at the Point Cook site. There is little difference in the size structure of abalone collected from each habitat type and above the minimum legal length of 100 mm these differences are negligible.

estimates at each population size were normally distributed and reflected relative reductions in population size (Fig. 4).

The relationships between estimated and expected densities, and between the various upper and lower percentile confidence limits were linear (Fig. 5). Estimated densities closely estimated the true density of the population, and estimated reductions were close to the true levels of reduction (Table 1). Estimated densities appeared to be a good indicator of absolute abundance. This was demonstrated by the strong proportional relationship found between estimated and absolute abundance (Estimated density = 0.92 × Expected density + 0.10, $R^2 = 0.96$). The ability to detect proportional differences in abundance was dependent on the size of the population and declined in proportional terms with reducing population size.

The linear relationship between estimated and expected densities (and the confidence limits about this relationship) allowed an evaluation of the power of the method to detect changes in abundance at a range of initial population densities. At greater initial population densities (i.e., >3 abalone/m^2) the method was able to detect declines in abundance of as little as 22% with 90% confidence (Fig. 6A). Power to detect declines with greater levels of confidence was high at greater initial population densities (e.g., at an initial density estimate of 3 abalone/m^2, declines in abundance of 24% could be detected with 95% confidence) (Fig. 6A). Power to detect proportional declines in abundance reduced markedly with declining initial density estimates less than 1 abalone/m^2 (Fig. 6A). Power to detect increases in abundance followed a similar pattern to that for detection of declines (Fig. 6B). At an initial population density of 3 abalone/m^2 the method was able to detect increases in abundance of about 26% with 90% confidence (Fig. 6B).

DISCUSSION

The distance-based abundance estimator described here was able to detect measurable changes in the absolute abundance of an abalone population. The minimum differences detectable were relatively small even at reasonably high levels of confidence. The method appears to satisfy two primary requirements of abundance estimation methods: it is a good indicator of abundance, and it is able to detect changes in abundance. A third requirement, that the method be easily applied across the fishery, was not examined completely in this study. The technical requirements of the method appear to be minor. The time consuming repeated surveys characteristic of change-in-ratio and mark-recapture methods are not required. The method therefore minimizes reliance on prolonged periods of good diving conditions. The measurements required are relatively simple to achieve and the skill required to take the measurements would probably be acquired quickly by an observer with limited experience. This satisfies the need of long-term monitoring programs to accommodate changes in the survey team and avoids the requirement for a standard dive team when using timed collection methods.

The simulated sampling using real field data presented here suggests that the method has the accuracy of area-based measures but the ease of application of timed collections. The levels of sampling demonstrated here do not represent an insurmountable amount of work. At lower densities the number of measurements that need to be taken could be increased. The method accommodates an uneven amount of randomly chosen point-abalone and randomly chosen abalone-abalone measurements, making it adaptable to field situations. Furthermore, by considering the randomly chosen point-abalone and randomly chosen abalone-abalone density estimates separately, the method provides an opportunity to describe the patchiness and patch density in the population and

TABLE 1.

Results of simulations performed at various population sizes.

Population Size	Number of Distances Measured	Population Reduction		Density (abs/m^2)		Percentiles	
		Actual	Estimated	Actual	Estimated	10th	90th
6596	250	–	–	2.86	$2.73_{0.19}$	2.40	3.06
4943	187	25%	25%	2.15	$2.05_{0.16}$	1.81	2.32
3300	124	50%	48%	1.43	$1.42_{0.15}$	1.16	1.66
1648	62	75%	72%	0.72	$0.75_{0.09}$	0.63	0.90

Population reductions were effected over the entire plot. Therefore the population size of reduced populations represents the average number of abalone remaining within the inner plot. To maintain the same relative sampling intensity the number of distances measured was less for simulations performed on reduced populations. The number of distances measured indicates the number measured of each type (i.e., 62 indicates that 62 randomly chosen point-abalone and 62 randomly chosen abalone-abalone distances were measured). Estimated reductions were calculated by comparing the estimated density of reduced population sizes with that of the initial population. Actual densities were calculated as the population size divided by the area of the entire plot (2304 m^2). The estimated density is the mean of 100 density estimates calculated at each population size. Sub-scripted numbers indicate the standard deviation about the mean.

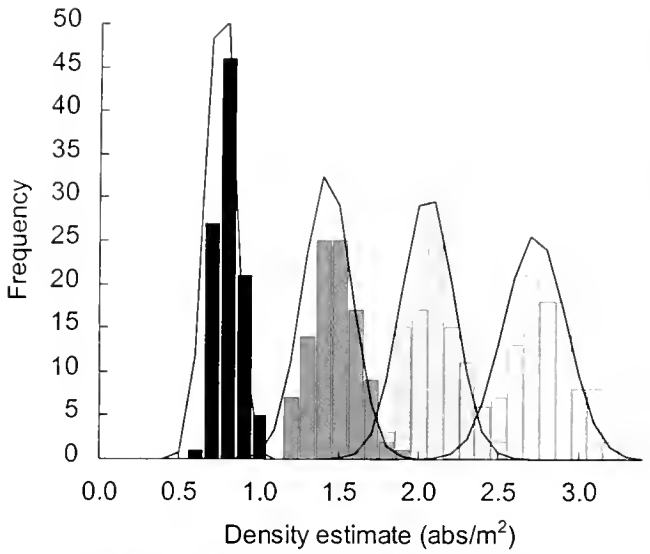

Figure 4. Distributions of density estimates generated from 100 simulations calculated at various population sizes: initial population (white bars), 25% reduction (light-shaded bars), 50% reduction (dark-shaded bars) and 75% reduction (black bars). Overlaid lines indicate normal distributions fitted to the estimated data for each population size. Note that the variance reduces as the mean density estimate decreases.

changes in these measures over time. Information on the patch structure of abalone populations may be an important indicator of productivity (McShane 1995, Taylor et al. 2000), but this information is not collected by most monitoring methods.

If the field requirements of the method could be satisfied then the method could be particularly useful as a routine estimator of abundance. However, the simulations reveal several limitations of the method and indicate some further areas for investigation. Perhaps the most important limitation of the analysis presented here is that the fishing patterns simulated were not real. The removal of abalone was effected by random selection of abalone from the entire plot. True fishing patterns are focused on aggregations of abalone (Hart et al. 1997). Random fishing assumes that all fish in the plot are of legal size and equally likely to be removed. In most abalone fisheries adherence to minimum size limits makes only a proportion of the population available to fishing. If the size structure of abalone occupying sparsely populated habitat differs from that in aggregations, fishing will dramatically affect the spatial structure of the population. In this study no evidence for differing size structure between densely and sparsely populated habitats was found in the Point Cook population. Similar results have been found at another site (Officer et al. 2000).

Even if no differences exist between size structures in densely and sparsely populated habitat, fishing patterns that focus on aggregations are likely to have both immediate and prolonged effects on the population. In the short term, the removal of abalone from aggregations would create a more dispersed and homogenous distribution pattern after fishing. However, there is evidence that abalone are capable of moving considerable distances if disturbed and that this enables re-aggregation into preferred home-sites to occur rapidly (Gorfine et al. 1998, Officer et al. 2000). At the Point Cook site this behavior returned the distribution of abalone to the initial distribution pattern (albeit at a lower density) within weeks of intensive fishing (Gorfine et al. 1998, Officer et al. 2000). The random removal of abalone simulated here is therefore likely to

approximate the distribution of abalone found in the real Point Cook population several weeks after fishing.

Whether or not this relationship would hold generally is uncertain. In a study of the movement and re-aggregation of abalone, Officer et al. (2000) subjected the Point Cook site and a second abalone population (Flinders) to similar levels of experimental fishing. At Flinders the reef had much greater relief and cryptic habitat than at Point Cook and the abalone were less abundant but more patchily distributed. Recovery of the initial distribution pattern took much longer at Flinders (Officer et al. 2000). The Point Cook site was unusual in that it contained little cryptic habitat and low relief. This apparent success of the distance-based method at Point Cook may result from the two-dimensional area assumed by the estimator correlating well with the actual area of the site. Testing the efficacy of the distance-based method in areas of more complex topography and cryptic habitat will require further experimental work. Unfortunately the role of the cryptic component of abalone stocks remains poorly understood despite its importance to stock assessment (Haddon 2000).

Another shortcoming of the method is that it is only sensitive to changes in abundance when the population density is relatively high. In this respect the method differs from other assessment techniques that may become hyper-stable at higher population densities [e.g., the timed collection (Hart & Gorfine 1997, Hart et al. 1997)]. Fortunately, at lower population densities methods such as the timed collection come into their own as measures of relative abundance. A benefit of applying the method at higher population densities is that the area that has to be searched between nearest neighbors by research divers will tend to decrease. This will increase the efficiency of the method in the field. The method may therefore be particularly useful for *H. rubra* populations in Tasmania where the abundance of abalone appears to be relatively high and the amount of coast that needs to be monitored is extremely large.

There are also some technical limitations to the simulations applied here. Designing a field protocol that selects source positions and abalone randomly will not be a trivial task (Ripley 1981). Selecting a randomly chosen point underwater is relatively easy. The main problem may occur when the point falls on inappropriate habitat. This suggests a need to stratify sampling by habitat when applying the distance-based method. Selection of a randomly chosen abalone is far more complicated and may be a source of potential bias in the method (Ripley 1981). For the method to remain effective it will be important to avoid one of the shortcomings of the timed collection procedure: attraction of research divers to aggregations. The apparent utility of the method as a sensitive abundance estimator suggests that attempts to overcome these difficulties warrant serious attention.

ACKNOWLEDGMENTS

The data used in these simulations could not have been collected without the support of the Victorian abalone industry. Commercial abalone divers refrained from diving at the study location during the course of the study. Mapping the position of over 8000 abalone required substantial effort from the project's field staff. Assistance with vessel operations and diving support was provided within MAFRI by Mark Ferrier, David Beyer, Dale Thomson, and Ian Duckworth. Charter vessels were provided by Graham Leckie (Ultimate Fishing Charters) and Alistair MacDonald (Port Campbell SCUBA and Marine). Diving contractors employed on the project included David Forbes and Bruce Waters of Aquatic Research Support Services, Rod Knights from Professional Diving Services, Geoff Rodda from Peninsula Diving Instruction, and Michael Callan. The research divers collectively accumulated 1000 hours underwater during the surveys. We are extremely grateful to Joanne Merry who generously volunteered her time and expertise to support the field team with the logging of dives and the management of data collection while at sea, and who subsequently entered and processed the data on computer. The initial project was funded by the Fisheries Research and Development Corporation (Project 95/165) and the Marine and Freshwater Resources Institute.

DIVER BEHAVIOUR AND ITS INFLUENCE ON ASSESSMENTS OF A QUOTA-MANAGED ABALONE FISHERY

HARRY K. GORFINE* AND CAMERON D. DIXON

Marine & Freshwater Resources Institute, P.O. Box 114, Queenscliff, Victoria, Australia

ABSTRACT During 1998, we initiated an on-board observer program to gain a better understanding of spatial and temporal patterns of catch and effort in the blacklip abalone fishery of Victoria, Australia. Although average catch per unit effort (CPUE) for this fishery has been increasing, there has also been significant spatial contraction of the fishing grounds away from reefs of low productivity as a consequence of quota introduction during 1988 to 1989. It is this shift away from reefs of low productivity rather than an increase in abalone abundance that is responsible for the trend in CPUE. From our on-board observations, divers do not operate in an area if they believe that they will not meet their daily catch expectations; they have a relatively high catch rate threshold for deciding when to shift to another reef. Catch rates per bag of abalone are several times higher than the daily reported CPUE rates, but vary substantially. We conclude that the incentive to maintain high catch rate thresholds for cessation of fishing has led to patterns of rotation of effort at the reef scale that tend to mitigate against high rates of exploitation. This has provided an effective tier of fine-scale self-governance below that controlled by management regulations. However, contemporary changes in the fishery, such as reductions in the number of divers who own access entitlements and their levels of experience, may lead to reduced catch rate thresholds and unfavorable patterns of fishing behavior. There is also a tendency for divers who have recently entered the fishery to concentrate their effort on shallower reefs for reasons of health and safety. Although there is no evidence to date that the over-all status of Victorian abalone stocks has been compromised by these changes, managers need to be aware that regulations affect diver behavior and that it is the divers not the resource that is managed. Our studies reinforce the importance of identifying and promoting behaviors among divers that are desirable in terms of sustainable production within the context of contemporary management strategies.

KEY WORDS: quotas, management, fishing behavior, abalone

INTRODUCTION

Although quota management is ubiquitous among productive abalone fisheries in the Southern Hemisphere, management agencies in the Northern Hemisphere are still considering the merits of quotas as output controls for abalone (CDFG 1997). In an assessment of the efficacy of quota management, it would be imprudent to assume that total allowable catches (TACs) per se have been the reason for the relatively prosperous state of abalone fisheries in the Southern Hemisphere. Quota management regimes are usually implemented over broad scales that provide considerable latitude for abalone divers to choose where and when to expend their fishing effort. For example, the abalone fishery in Victoria, Australia, which provides about 14% of global wild-stock production and spans about 1,500 km of coastline, is divided into three relatively large quota management zones that are not subject to seasonal closure (Fig. 1). Such expansive zones do not facilitate control of catch outputs at the metapopulation scale that delimits population recruitment (Shepherd & Baker 1998).

Not only may quota management regimes not be as effective in controlling outputs as intended, they may also have inadvertent effects on diver behavior. Prince and Shepherd (1992) identified potential for spatial maldistribution of effort arising from the implementation of quotas, with overfishing of the more productive areas of the fishing grounds proximal to port and underutilization of the more remote and less productive reefs. Since the introduction of TACs in the Victorian fishery, the fishing grounds have contracted substantially. There has been a progressive shift in effort away from reefs with lower catch rates toward more highly productive reefs (Gorfine et al. this publication). Although improbable, there are no regulatory constraints to prevent divers within a management zone from intensively harvesting the TAC from only one region in a relatively short time period (currently an aggregate of 50–55 days effort per diver is required to harvest annual quota allocations in Victoria). Quotas have also brought about structural changes in the Victorian abalone fishery. Mean experience levels among those participating in the catching sector has decreased markedly in all zones of the Victorian fishery since quotas were introduced. At the same time, the number of fishery access license owners choosing to engage the services of contract divers to harvest their quota allocations has increased commensurately (Fig. 2). It is reasonable to speculate that some impetus for this transition from owner-operator to contract diver came from increased profitability associated with an escalation in market demand for Australian abalone products that saw the beach price more than double between 1991 and 1992 and 1993 to 1994 (Fisheries Victoria 1998).

Despite the potential for intense fishing pressure to cause serial depletion of the more productive reefs, this has not been manifest in the Victorian abalone resource (McShane 1992), although recent modeling predicts a slow decline in relative biomass (Gorfine & Dixon 2000), and there are some recent instances of localized depletion. Possible explanations for the apparent sustainability of Victorian abalone stocks include:

1. Reductions in real and latent effort through a combination of limited entry, nontransferability, and diver attrition during the two decades preceding quota introduction in 1988 (Sanders & Beinssen 1972, McShane 1992). Further effort reductions when transferability on a "two divers out for each diver in" basis was introduced during 1984.
2. Divers varying their effort at a given reef considerably from year to year. In many instances, effort is rotated among reefs to maintain catch rates and allow substocks on recently fished reefs time to recover (McShane 1992). This is akin to the rotational harvest strategies discussed by Perry et al. (1999). However, although many reefs may recover periodically over short time scales, the extent to which this is sustainable for each reef complex is presently unclear.

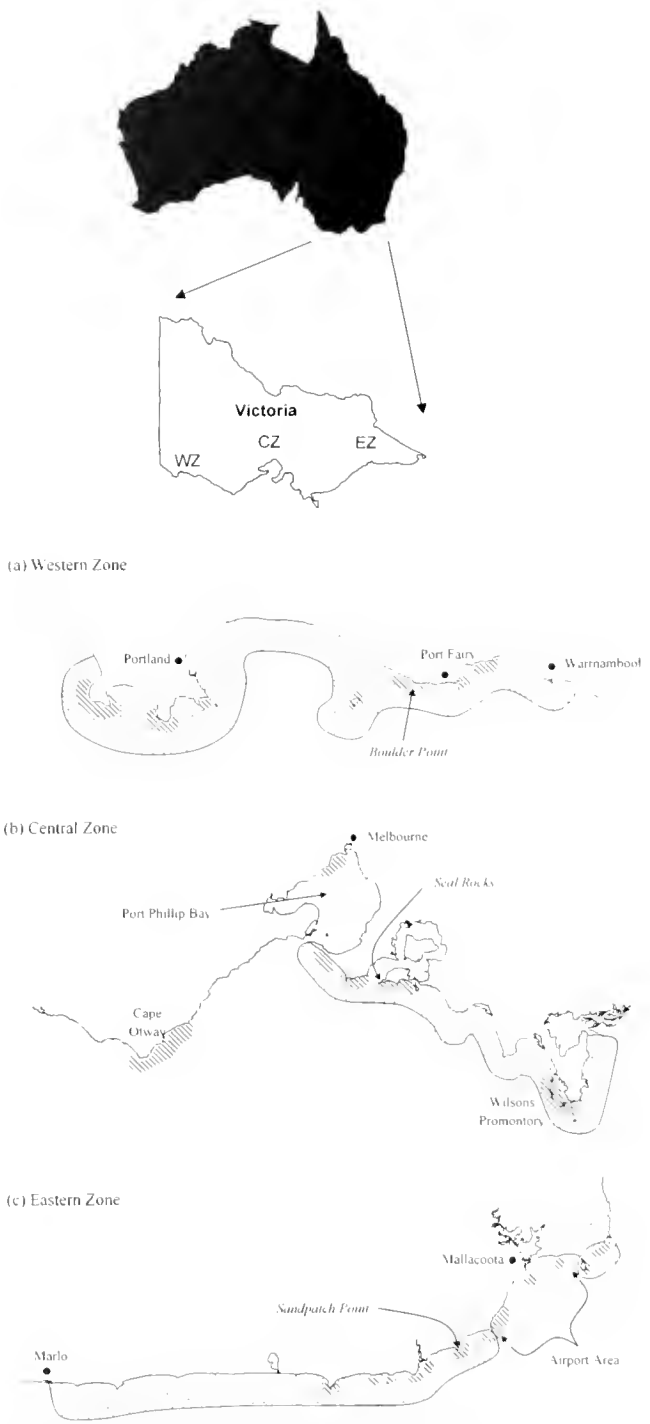

Figure 1. Fishing grounds (stippled) and key reef areas (hatched) in the (a) Western Zone, (b) Central Zone and (c) Eastern Zone, that were included in on-board observations of the Victorian abalone fishery.

3. Self-imposed daily quotas. For example, in the Eastern Zone of the Victorian fishery, the Abalone Fishermen's Cooperative, which includes about 21 out of the 23 fishery access licenses, has a self-imposed daily limit of twelve bins (approximately 480 kg live weight) per diver. Similar forms of self-governance have been evident among Victorian divers generally during the formative first decade of the fishery (Sanders & Beinssen 1972).

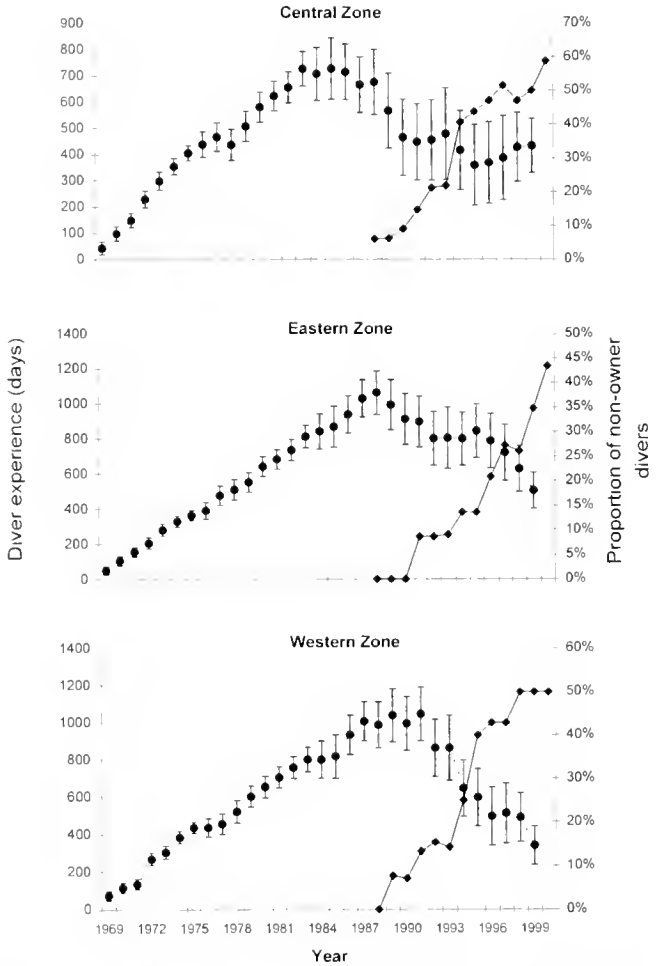

Figure 2. Changes in diver experience (mean ± SE; broken line) and the proportion of fishery access licences where the diver was not the license owner (solid line), in each of the three management zones during 1969–2000.

The latter two points describe an effective second tier of finer-scale self-management below the controls imposed by fisheries regulations. It is our belief that maintenance of this voluntary regime is both critical to the future sustainability of the resource and vulnerable to changes in industry structure that have a propensity to diminish stewardship.

With quotas comes the need to establish data collection programs that will support modeling and assessment of stocks for future TAC adjustment (Ramade-Villanueva et al. 1998). Diver-reported catch and effort statistics will generally be perceived as inadequate for this purpose (McShane 1992, although see Andrew et al. 1997). Like the limitations of quota management, this is partly a consequence of geographic scale that renders catch per unit effort data hyperstable to serial stock depletion (Breen 1992), although the abundance of dense aggregations of abalone also plays a role (Hart et al. 1997, Prince 1992). Inevitably, fishery-independent survey methods will be considered to provide the necessary data (McShane 1994). However, government-led independent surveys can be an expensive approach beset with the problems identified by Prince et al. (1998) about shrinking public sector resources in the face of the need to cover extensive fishing grounds.

In contrast with fishery-independent survey data, opportunities

to sample dependent data are more numerous, and their acquisition is cheaper (Kesteven 1997). This led us to speculate as to whether some of the impediments to using catch–effort data could be overcome if we considered divers as an integral part of the fishing gear. In trawl fisheries, for example, much data is collected about vessels, their fishing power, and fleet dynamics. Fisheries observer programs in southeastern Australia are well established as methods for collecting detailed information about trawl fishing fleets and their catches. Although the fishing power of divers has been studied in Australia (Beinssen 1979, Hart & Gorfine 1997), this has not been extended to monitoring programs involving fisheries observers. During late 1998, we initiated an on-board observer program directed at gaining a detailed understanding of the fleet dynamics, fishing effort, and contemporary fishing grounds of the Victorian abalone fishery (Gorfine et al. this publication). Although the quantity of data acquired to date is relatively small, these data provide information unavailable from catch and effort reporting. In this paper, we examine some descriptive statistics from our observer program and the insights they reveal about diver behavior. We draw comparisons with reported catch and effort statistics and then consider the implications of these behaviors for fishery management and stock assessment.

MATERIALS AND METHODS

Casual fisheries observers were employed at several major abalone-fishing ports along the Victorian coast. Each observer had contact information for licensed abalone divers in their vicinity who had agreed to participate in the program. The observers were instructed to spread their observations among as many divers and fishing locations as possible, because random sampling of the abalone fleet was impractical. Where possible, observers followed the catch through to processing to enable each day's observations to be linked to catch and effort information reported by divers and processors. A more extensive commercial catch-sampling program also operated in parallel with the observer program.

Observations made during each day aboard a particular diver's vessel comprised three levels of information:

1. An overview of the day's fishing, which included intended diving location, reason for its selection, catch expectation, type of abalone sought and reason why, details about the size, power, and hull style of the vessel, and weather and sea conditions;
2. GPS coordinates and divers' observations of the underwater habitat and environmental conditions, qualitative abundance of competitors and predators, and condition of abalone population as compared with previous visits at each dive location; and
3. Quantitative estimates of catch weight, number in the catch, and effort for each catch bag of abalone, qualitative estimates of the amount of shell epibiota and proportions of "tiger" variants and greenlip abalone, and the dive profile of the diver (depth recorded every 3 min by dive computer). Where possible, length frequency samples were taken from the day's catch after landing. However, to date length-frequency data have been collected too sporadically to analyze.

The three levels of information were entered into a relational database (MS Access®), and summary statistics were produced.

RESULTS

Summary

Six observers collected data from eighty-five dives over sixty-seven diver days. Observed catches totaled 32.3 tons live weight harvested by expending 215.6 h diver effort.

Vessels

Vessel length ranged from 5.6 to 8.5 m and engine power from 90–450 horsepower. Catamaran hulls were the most popular in the Western and Eastern Zones at 63 and 87%, respectively; however, Central Zone divers favored monohulls slightly, with only 40% catamarans.

Diving Practices

The maximum depth recorded out of 3,112 observations was 27 m, and the minimum was 1 m, with an average of 9 m and 95% confidence interval of 8.8–9.2 m. Percentiles of the distribution of depths show that 80% of all harvesting occurred shallower than 13 m or 43 ft (Table 1).

Diving practices ranged from lower to higher risk as demonstrated by recorded depth profiles (Fig. 3a). High-risk profiles involving progression to deeper depths later during the day were not necessarily associated with improved catch rates (Fig. 3b). Multiple ascents were a feature of most dive profiles recorded.

Site Selection

Of those occasions where divers gave specific reasons for site selection 50% related to weather, 38% to high catch expectation, 15% to diving safety, 12% to market requirements, and 4% to exploration of unfamiliar territory. Note that there were no constraints on the variety of reasons that could be recorded and that totals exceed 100% because of more than one reason given on some occasions.

Only one or two reefs were visited daily on 91% of the days observed during this study (Table 2). Although movement between reefs during a day's fishing was infrequent, divers often relocated within a reef complex, depending on their personal diving practices.

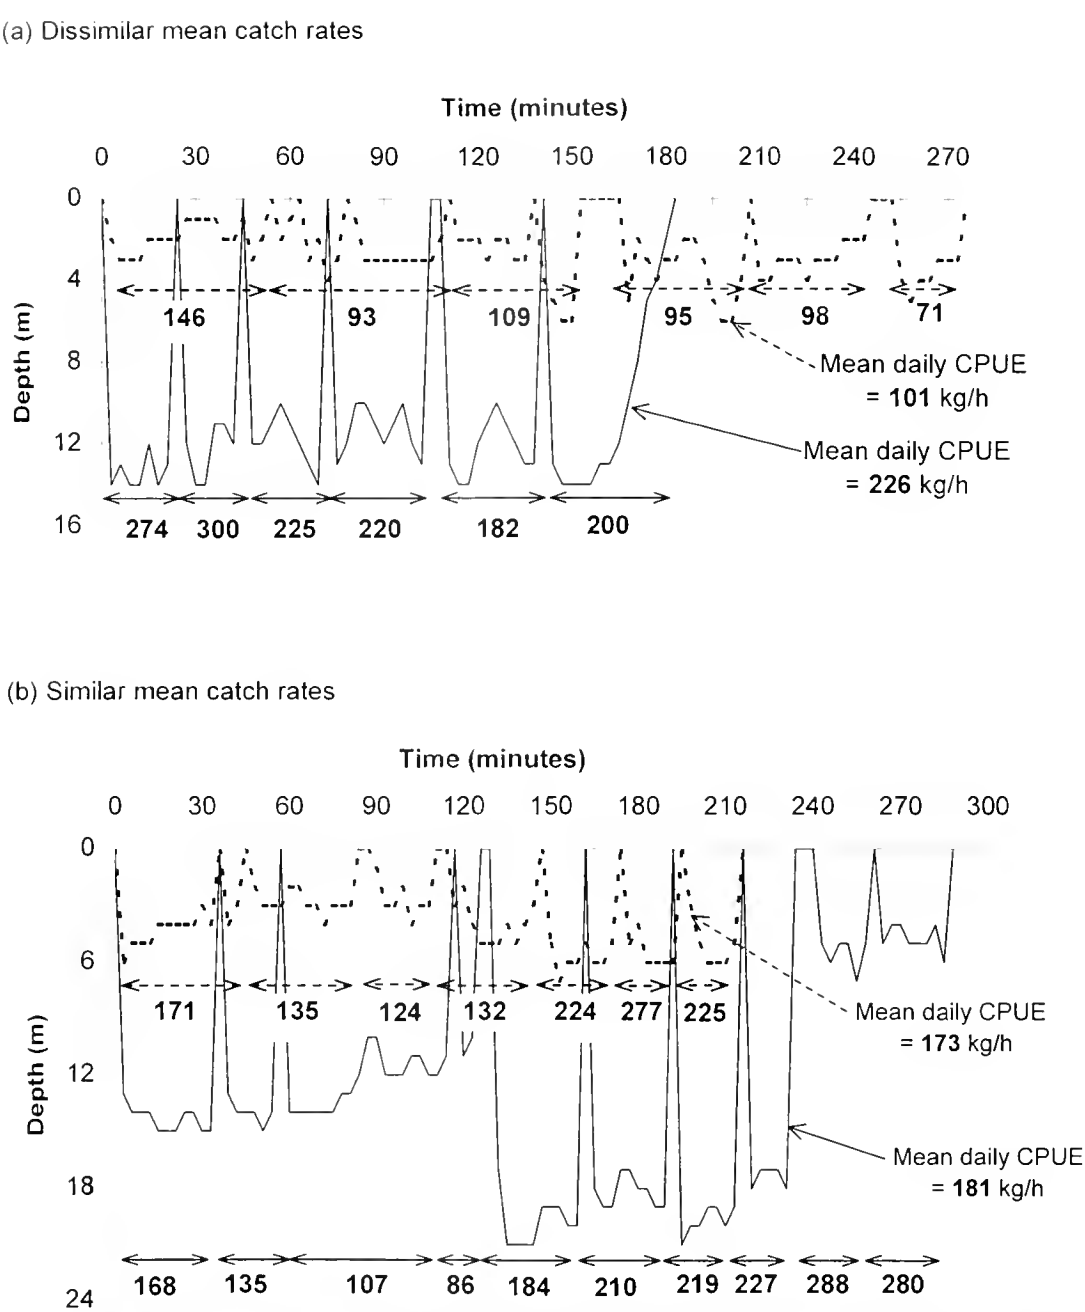

Figure 3. a) Different dive profiles yielding dissimilar mean daily catch rates (CPUE) for two divers in the same management zone of the Victorian abalone fishery. b) Different dive profiles yielding similar daily catch rates (CPUE) for two divers in the same management zone of the Victorian abalone fishery. (Broken line depicts low-risk dive profile and solid line depicts high-risk profile. Catch rates (kg/h) for each interval between surfacing are shown for each profile).

Harvesting Objectives

Divers reported that their principle objective for the day's fishing was large abalone on 28%, small abalone on 4%, and live abalone on 6% of occasions. Tigers; that is, a blacklip variant exhibiting a striped epidodium, were the target on 19% of occasions, usually in conjunction with small- or medium-sized abalone with the usual black epipodium.

Catch Expectation

The 95% confidence interval for daily catch expectation was 430–490 kg. The highest catch expectation was about 900 kg, and the lowest was 60 kg.

TABLE 2.

Frequency of number of reefs visited daily during on-board observations of the Victorian-abalone fishery.

	Number of Reefs Visited				
	1	**2**	**3**	**4**	**5**
Proportion of days (%)	55	36	5	2	2

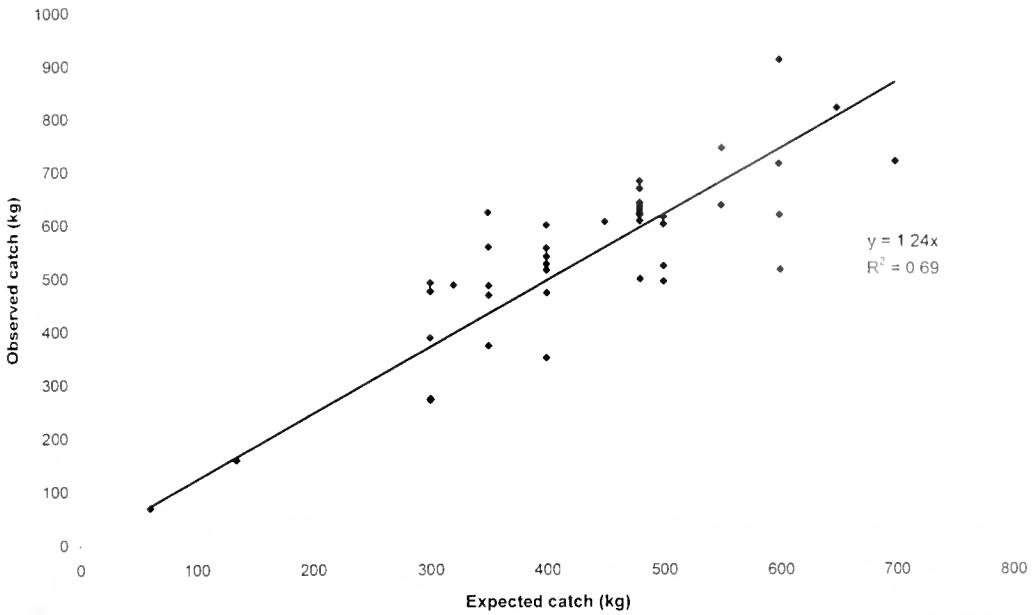

Figure 4. Relationship between expected and observed daily catches from observations on-board commercial divers' vessels in the Victorian abalone fishery.

Regression of observed catches on daily catch expectations showed that catches increased linearly with expectation (Fig. 4) and tended to exceed expected weights by 24% (df = 1, 41, r^2 = 0.69, t = 40.29, $P < 0.0001$). Comparison of expected, observed, and reported catches for a sample of the observations shows that reported catches were 8 ± 4% (mean ± SE) less than observed and expected catches were 15 ± 9% less than observed (Table 3). Only a small sample (n = 7) was available because of difficulties in matching observations with reported catches.

Catch Rates

Reef-specific catch rates ranged from 0–300 kgh^{-1} with 95% of values between 134–156 kgh^{-1}. Net bag catch rates ranged from 0–386 kgh^{-1} with 95% of values between 150–161 kgh^{-1} (Table 4). Reported effort values used to calculate catch per unit effort were 17 ± 9% higher than those we observed for the same catches (Table 3). Calculation of catch per unit effort (CPUE) using the mostly lower reported catch and lower reported effort gave values 12–29% (95% CL) less than the actual rates.

Although it is difficult to identify a threshold catch rate for the fishery explicitly, it is informative to consider that 80% of catch rates were greater than 106 kgh^{-1} (Table 1). The relatively small number of values below 50 kgh^{-1} (five observations) was for efforts of less than 20 min. Generally, there was no relationship between catch rates and duration of effort. However, unfavorable weather and low abundance accounted for the relatively few instances when catch rates were low. The former involved an ex-New South Wales diver new to the fishery, and the latter was associated with efforts of short duration. Maximum catch rates were associated with efforts of about 0.5 to 3.5 h, and longer efforts tended to produce slightly lower catch rates.

DISCUSSION

This modest study reinforces perceptions that commercial divers in the Victorian abalone fishery have developed fishing behaviors that maintain high catch rates enabling them to predict the quantity of abalone they expect to harvest from a specific area on a particular day reliably. To some extent, these patterns in behavior provide a degree of resource protection above that afforded by management regulations, because they tend to ensure that fishing mortality is generally low (McShane & Smith 1989).

TABLE 3.

Sample of divers' expected catches, estimated weights on landing and observed daily catch, effort, and CPUE, matched with reported catch, effort, and CPUE for the same observations.

Catch (kg)				Effort (min)		CPUE (kg/h^{-1})

TABLE 4.

Comparison of catch rate statistics at different scales of sampling during on-board observations of the Victorian abalone fishery.

Statistic	Scale of Sampling		
	Daily (kgh^{-1})	By Reef (kgh^{-1})	By Catch Bag (kgh^{-1})
Mean	144	156	156
Maximum	234	300	386
Minimum	7	0	0
Upper 95% CL	158	156	161
Lower 95% CL	131	134	150

Not surprisingly, the main harvesting objective of divers during this study was to maximize catch rates. However, on some occasions, abalone with striped epidodia (tigers) and smaller abalone were sought as the prime objective because of market preference. Smaller abalone, particularly from Port Phillip Bay, where the legal minimum length (LML) is 100 mm, are preferred for canning, because cans containing four or five whole pieces attract the best prices. The targeting of these specific morphotypes did not compromise divers' abilities to achieve average daily catches. Although daily catch expectations were mostly high, low catch expectations occurred when divers only required small quantities to obtain the balance of their quota allocations. Divers' catches exceeded their expectations in most instances. This is likely to have occurred because the divers base their catch expectations on weights used to decrement quota allocations. Consequently, we suspect that the divers have made allowances for losses attributable to the removal of epibiota and drainage during postharvest transport and storage (Gorfine this publication).

The faster catch rates observed at a within-reef spatial resolution highlight the loss of accuracy in effort associated with aggregating values at the reef scale. These inaccuracies are further amplified when catch rates are reported as total effort for the entire time spent at sea. When combined with post-harvest weight losses caused by removal of epibiota and drainage, it becomes evident why CPUE values extracted from Fisheries Victoria's catch and effort reporting system are often substantially lower than those measured directly during the course of this study.

Inspection of fisheries observers' comments noted on datasheets shows that the highest catch rates were for locations with very large abalone, each about 600–650 g live weight, that had large amounts of such shell epibiota as barnacles and sponges accounting for up to 30% of their weight. Allowing for removal of epibiota, the highest catch rate of 386 kgh^{-1} may have reduced to 270 kgh^{-1}. The amount and composition of epibiota generally reflects the particular habitat occupied by the abalone, with cunjevoi adding the most weight, and divers inform us that they believe abalone with clean shells are usually those that have recently emerged from cryptic habitat. Previous studies we have undertaken at a limited number of sites have not supported this hypothesis (Officer et al. this publication).

Weather played a dominant role in divers' decisions about where to fish. Generally, most Victorian divers do not head to sea if weather conditions are likely to prevent them from satisfying their catch expectations. This is reflected in some of our fisheries observers' experiences of aborted trips despite preplanning and weather forecasting. Examination of the relationship between effort and catch rate showed that a small number of low catch rates for large effort expenditure related to weather, lack of experience, or a combination of both these factors. Indeed, one of the divers had only recently commenced in the Victorian fishery after having fished in NSW where maximum catch rates are typically about 25 kgh^{-1} (Worthington et al. 1999). Although an experienced and competent diver, he may have been prepared to fish at lower catch rates than most Victorian divers would tolerate, because the 70 kgh^{-1} he achieved was more than double the rate he would have experienced in the NSW fishery.

The vessels used by Victorian divers reflect a combination of geography and economics. In some instances, individual divers may own different vessels to access different parts of the coast. Monohulls are preferred where on-road towing distances are long and at-sea distances short and where beach launching across sand is required. This applies more to Central Zone divers than to those from the other zones of the fishery. The lower operating costs of monohulls as compared to catamaran hulls also make them attractive to contract divers. Twin hulls are preferred where bar crossings are made and where long distances on the water are necessary in sometimes fickle weather conditions, such as in the Eastern and Western Zones. As more contract divers participate in the fishery, we may see an increase in the number of monohulls. To some extent, this may limit the intensity of fishing at remote locations and concentrate effort in relatively safer areas closer to ports of access.

Despite the consistency in high catch rates among divers, there is considerable variability in diving practices. A small number of divers spend a large proportion of their time continuously underwater, preferring to send their catch bags of abalone to the surface using inflated parachute-style lift bags. These divers ascend infrequently; whereas, others make frequent multiple ascents, sometimes from relatively deep depths. Some divers use large catch bags with a capacity of about 150 kg; whereas, others use small bags that hold about 50 kg. Time spent transporting the catch across the substrate and to the surface is counted as effort, and the size of the catch bag could reasonably be expected to influence catch rates.

Two divers reported that they only dived to shallow depths. One diver never exceeds 10 m; whereas, the other, who suffered two episodes of decompression illness (DCI) during 1998, does not exceed 12 m, in accordance with medical advice. Although these divers believe their practices are conservative, examination of their profiles shows an ignorance of the effects of multiple ascents in precipitating DCI (Fig. 3a). The trade-off for these "conservative" profiles was reduced catch rates in some instances but not in others, so it does not necessarily follow that diving to deeper depths will yield better catches. In contrast, another diver showed a willingness to defy accepted wisdom by diving deeper on successive dives in an attempt to maximize his catch rates (Fig. 3b). Ironically, it was during a shallow "decompression" dive toward the end of the day that he achieved his best results.

Although diving depth may be unrelated to the ability to satisfy catch expectations, at present it may become a factor if stocks in shallower locations decline because of increased intensity of effort. The relatively shallow depths of most of the diving observed during this study reflect a tendency for younger contract divers to adopt safer practices and concentrate their effort on shallower reefs. In recent instances where localized stock depletion has oc-

curred (Gorfine et al. this publication), divers have relocated effort previously expended on the depleted reefs to other regularly fished reefs in their zone. There is no evidence that divers have shifted their effort offshore to those deeper or more remote reefs that have been infrequently fished since quotas were introduced.

This study has illustrated some aspects of diver behavior that may have substantial influence on the state of Victorian abalone resources and the long-term sustainability of the fishery. One of the key observations was the high, but variable, catch rate thresholds that prompted divers to shift their effort within a reef complex. Net reductions in these thresholds over time will signal overfishing of the most productive reefs. It is likely that such changes will lead to an over-all decrease in the performance of the fishery, because underutilized reefs where effort can be redeployed are mostly those with historically low catch rates.

Departures from established such practices as self-imposed daily quotas and rotational harvesting will threaten abalone stocks regardless of current zonal quotas and regional size limits. This is not merely speculative, given that the fishery is progressively shifting to a new generation of contract divers (Fig. 2) motivated by different values, past experiences, and expectations that will be reflected in their fishing behaviors. Although many contract divers seem to be genuinely interested in the on-going viability of the fishery, they do not necessarily have the same incentive as quota-owning divers to ensure that their fishing practices are compatible with long-term sustainability (Prince & Shepherd 1992, Parliament of Victoria 2000). Victorian abalone divers are understandably proud of their history of resource stewardship and the altruism they displayed in reducing their catches in the shift to quota-based management twelve years ago. In a brief discussion on the evolution of altruism, noted ecologist Simon Levin (1999) points out that altruistic behavior is the manifestation of "enlightened self-interest" and is strongest when there are expectations of rapid payoffs to individuals or coalitions sharing common aspirations. Obviously, the self-interests of divers who are either quota owners or close relatives likely to inherit some proportion of quota entitlement will differ from those without equity in quota. The proportion of the beach price (usually less than 10%) received by contract divers from the owners of fishery access licenses is sufficiently small to ensure that the contract divers are likely to be more concerned with reducing the costs of fishing effort to maximize their incomes. In an assessment of the Tasmanian abalone fishery, where there is clear separation between quota ownership and the licensing of divers, Officer (1999) expressed similar concerns that contract divers reluctant to incur the costs of travel to remote locations may be prepared to endure lower catch rates than owner-divers on more accessible reefs.

Currently, those charged with developing a management plan for the Victorian fishery are proposing changes toward a system similar to the one adopted in Tasmania. These changes will facilitate further separation between quota ownership and fishery access licenses that confer the right to dive or engage a contractor to dive for abalone. Whether additional management arrangements, such as small-scale subzonal quotas, are required to modify potential changes in diver behavior to be within acceptable limits is unclear.

At this stage, there is no evidence that the over-all status of Victorian abalone stocks has been compromised by changes in the licensed catching sector. However, there is clear evidence that the fishing grounds have contracted substantially since quota introduction and that the fishery is now dependent on a limited number of relatively shallow and highly productive reefs (Gorfine et al. this publication). There is no doubt that this makes the Victorian abalone fishery more vulnerable to the impact of serial depletion and threatens its sustainability. We believe it would be preferable for industry to remain self-regulating at finer spatial scales, but this view is contingent on the Victorian abalone industry's ability to maintain the resource stewardship characteristic of the retiring generation of owner-divers. The concept of a Territorial Users' Rights Fishery (TURF) espoused by Prince et al. (1998), with potential benefits of fine-scale monitoring and industry self-governance, could be an effective framework for such stewardship. However, the public acceptance of this kind of scheme would be improbable for a resource that is the common property of the whole community of Victoria.

As fisheries management agencies in the Northern Hemisphere look toward quota management as a means of improving the sustainability of their abalone fisheries they should be cognizant of the limitations of this approach, particularly for a fishery in need of restoration. Although quotas may prove to be the best option, how they are applied as part of a suite of management arrangements will be critical for their effectiveness. Abalone fisheries managers must be mindful that regulations affect diver behavior and that principally it is the divers, not the resource, that is managed. We believe that this study highlights the importance of identifying and promoting diver behaviors that are compatible with resource sustainability within the context of contemporary management strategies. Such fisheries observer programs as ours can provide valuable information to managers for achieving this objective.

ACKNOWLEDGMENTS

This study would not have been possible without the willingness of commercial abalone divers to have fisheries observers aboard their vessels. This level of cooperation between abalone divers and fisheries biologists has been a hallmark of the Victorian fishery for many years, for which we owe a debt of gratitude to both industry and our predecessors. We thank our fisheries observers who are required to go to sea at short notice, sometimes in adverse weather that makes conditions aboard small vessels unpleasant for most people. Sonia Talman is thanked for efficiently entering the data into the relational database expertly erected by Masaaki Machida. The manuscript was greatly improved as a result of the constructive criticisms of an erudite anonymous reviewer.

POST-HARVEST WEIGHT LOSS HAS IMPORTANT IMPLICATIONS FOR ABALONE QUOTA MANAGEMENT

HARRY K. GORFINE*
Marine and Freshwater Resources Institute, Queenscliff, Victoria, Australia

ABSTRACT Regulations forming part of the abalone quota management system in Victoria, Australia require that abalone processors notify fisheries authorities of quantities of abalone consigned from commercial divers within 25 h of landing. The regulations also require that the abalone are to be landed whole in the shell, and transported and stored in sealed bins until confirmation of official notification. Although the bins cannot be opened before notification, the 25-h limit for notification provides a window of opportunity to make potential gains through weight loss in those abalone destined for canning. This arises because notified weights, rather than weights estimated upon landing, are used to decrement the quota allocations of individual divers. I investigated the potential for post-harvest weight loss by subjecting abalone to three experimental treatments selected to simulate a range of possible transport and storage regimes. My results demonstrate that substantial weight loss can occur in whole abalone during both ambient and refrigerated storage. Loss of weight in abalone during storage results from the release of water and body fluid associated with physiological responses to hypoxic stress caused by exposure to air. In Victoria, about 60% of the landed catch is used to produce canned product. Because of the observed weight losses during storage, divers supplying abalone for canning have to harvest more abalone to achieve their quotas than those supplying abalone for live export. Losses in weight of 10–20% observed during this study equate to a harvest of 6–12% (350,000–700,000 abalone) more than the total allowable catches. Harvesting these additional quantities of abalone may exceed desired fishing mortalities for long-term population sustainability. If beach weights were deducted from quotas, then this problem could be resolved.

KEY WORDS: quotas, management, weight loss, air exposure, abalone

INTRODUCTION

The Victorian fishery for blacklip abalone (*Haliotis rubra* Leach) has operated under quota management since 1988. Total allowable catches (TACs) were initially based on average annual catches during the preceding 5 y. A quota docketing system was implemented concurrently to track divers' progress in attaining their annual TACs. It became apparent during the early 1990s that some processors were taking advantage of regulations that permitted a transportation period of up to 1 day post-harvest before the consignment of catches and completion of quota dockets. Potential fluid loss during this period enabled some processors to pay less for the same number of abalone. Correspondence from this period shows that some of the larger processors and diver associations sought to have this loophole in the regulations removed.

During 1994 additional regulations were proposed to ensure that, immediately upon landing, abalone would be placed in bins sealed with nonreusable identification tags and weighed at the beach. The principal objective was to eliminate the potential for overquota harvesting through understatement of estimated catches on quota dockets. Sealed bins prevent the removal of abalone between the point of landing and delivery to registered abalone processing or storage premises. Beach weighing ensures that processor weights can be reconciled with landed weights. New regulations requiring the sealing of bins and establishing a comprehensive audit trail were introduced during 1996. However, attempts to introduce beach weighing for decrementing quota allocations were unsuccessful. This was largely because processors close to points of landing argued that it was an unnecessary imposition when their factories were only about 10 min away. Ironically, processors distant from points of landing, and the divers supplying these processors, lobbied for sufficient time before notification to allow abalone harvested at one end of the state to be transported to a processor at the other end (a distance of almost 900 km). Such arguments by the abalone industry tend to be successful because of the Australian federal government's National Competition Policy legislation, which, in seeking to remove barriers to business and trade, requires any commercially restrictive regulations to be justified on resource protection grounds.

The 1996 regulations, forming part of the Abalone Quota Management System, require abalone processors to notify Fisheries Victoria of quantities of abalone (as weights to the nearest 0.1 kg) consigned from commercial divers within 25 h of landing. This is done via electronic facsimile to an automated notification service that then provides confirmation by return transmission within 15 min of receipt. Processors must not break the seals on the bins until this confirmation is received. The particular diver's quota is then decremented accordingly. The current practice among many abalone processors is to take possession of abalone during the afternoon or evening on the day of landing, store them in a cool room overnight, and not effect consignment and notification until early the following morning before processing. This means the abalone may be emersed for 12–25 h before weighing.

Despite the paucity of literature on the effects of emersion on haliotids, there is a substantial body of work on intertidal gastropods, including prosobranchs. Many intertidal prosobranchs have adapted to survive extensive periods of hypoxic stress and desiccation associated with exposure to air, as well as temperatures beyond the range experienced during immersion. Physical adaptive strategies include a relatively large water storage capacity within the mantle cavity (Hyman 1967), a shell morphology that provides a large volume to surface area ratio (Newell 1979), capacity to key the irregularities of the shell margin to fit the perimeter of the homesite occupied closely (Hyman 1967), closure of the shell aperture with opercula (Newell 1979), and vertical orientation (Hyman 1967). Physiological strategies include enhanced osmoregulatory ability (Gardiner 1972), excretion of uric acid rather than ammonia compounds to conserve water (Hickman 1973), uptake of seawater into the gland cavities of the foot, remaining motionless while exposed, and acclimation by lowering the meta-

*E-mail address: Harry.Gorfine@nre.vic.gov.au

bolic rate to reduce oxygen consumption (Hyman 1967). Among all these strategies, water-holding capacity is the most important, because it prevents desiccation of the gill tissues, provides limited oxygen for metabolic activity, reduces thermal stress through evaporative heat loss, and dilutes otherwise lethal concentrations of solutes in body fluids (Newell 1979).

Although they are mostly subtidal, air-exposed blacklip abalone have been observed under vertical overhangs immediately above the low-water mark and may possess some of the adaptations of predominantly intertidal species from the same order. Other species of abalone are more frequently exposed to air in the lower intertidal. For example, the tropical species *Haliotis asinina* (Linné) forages atop coral heads exposed at low tide (Donovan et al. 1999), and some populations of *Haliotis rufescens* (Swainson) may be exposed to air for up to 1 h during normal tidal cycles (Tjeerdema et al. 1991). This may explain why blacklip abalone are able to retain water after removal from the sea; furthermore, it may explain the pattern of progressive water loss while these abalone attempt to survive extended periods of air exposure. Survival time is likely to affect the rate of water and body fluid loss, and abalone biochemistry shows some adaptation in glycolytic pathways that promotes survival of hypoxia during air exposure (Donovan et al. 1999, Wells & Baldwin 1995).

The present study aims to measure the weight loss associated with up to 25 h emersion by simulating conditions typically encountered at abalone processing facilities. I was originally requested to investigate this potential for weight loss during storage in 1994, because some sectors of industry had indicated they would seek compensation if beach weighing was introduced. My initial research demonstrated that industry claims regarding post-harvest weight loss could be substantiated. However, recent development of a fishery model, aimed at establishing the risks to sustainability of different TACs, created the need for additional research to confirm the initial results and enable more accurate catches to be input to the model.

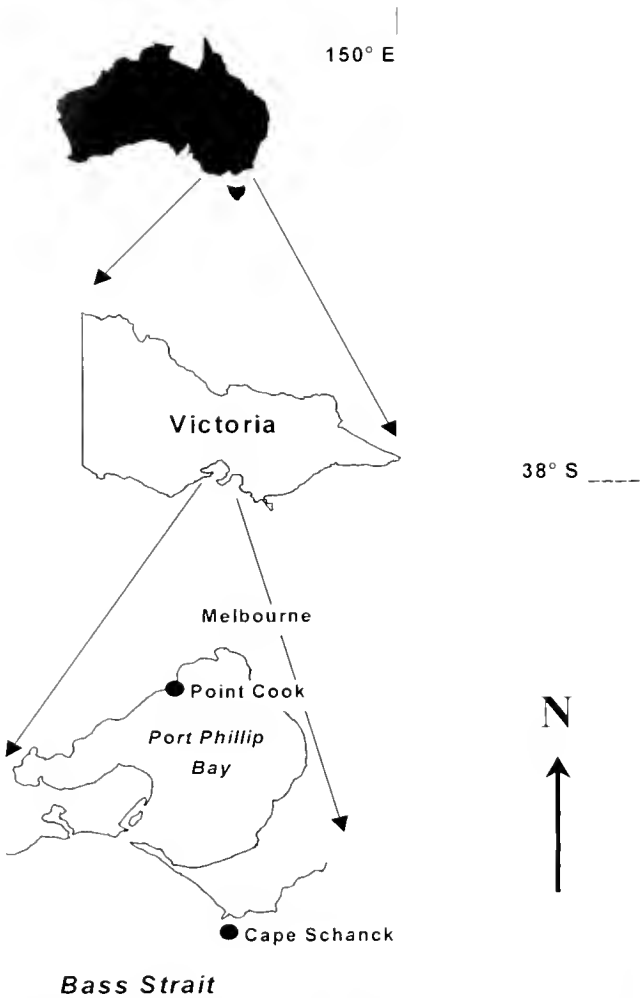

Figure 1. Locations of blacklip abalone (*H. rubra* Leach) collection sites along the coast of Victoria, Australia.

MATERIALS AND METHODS

Two experiments were conducted to investigate post-harvest weight loss in air-exposed blacklip abalone (*H. rubra*) during storage. The first experiment measured losses through drainage from commercially used bins of abalone, and the second experiment measured fluid loss from individually contained abalone.

Experiment 1: Weight Loss from Commercial Bins of Abalone

In warm to hot weather between 0930 h and 1330 h during December 1994, research divers harvested 300 kg whole weight of abalone from Bushranger's Bay near Cape Schanck, Victoria (Fig. 1). The majority of these abalone were marginally larger than the legal minimum length of 110 mm and did not seem to have recently spawned. The abalone were packed into prelabeled Nallys® No.12 fish bins in a primary layer consisting of three longitudinal rows of abalone oriented vertically and a secondary layer placed in a horizontal plane. The total weight for each bin was about 20 kg. The bases of the bins were perforated to allow for the drainage of water and abalone body fluids. Abalone harvested at different times were equally distributed among experimental treatments, and all abalone were landed at 1445 h when initial weights were measured to the nearest 0.05 kg. Each bin was reweighed every half-hour for a period of 5 h, and final weights were determined after an additional 12 h.

Three experimental treatments were applied to sets of five replicate bins of abalone:

1. *cool*—involved refrigeration at 6°C immediately post landing;
2. *ambient*—required the abalone to remain uncovered at ambient temperature (24.5°C @ 1445 h to 22°C @ 2000 h) for 5 h before refrigeration at 6°C for a further 12 h; and
3. *moist*—the abalone were covered with moist cloth towels at ambient temperature (24.5°C @ 1445 h to 22°C @ 2000 h) for 5 h before refrigeration at 6°C for a further 12 h.

Treatments 2 and 3 were conducted under covered walkways, so the bins of abalone were not exposed to direct sunlight. The air temperature at 1200 h in direct sunlight was close to 30°C. Relative humidity was not measured.

Experiment 2: Weight Loss from Individual Abalone

This experiment was conducted on a warm day (26°C at 1200 h in direct sunlight) during November 1999. Two storage environments were used, an air-conditioned laboratory in which temperature was maintained in the low 20s (°C) and a cool room with the thermostat set at 3°C. Abalone ranging in shell length from 83–120 mm were collected from Point Cook in Port Phillip Bay (Fig. 1) and held in one ton capacity, flow-through aquaria for several

months before this experiment. Abalone were removed from the aquaria, blotted on absorbent towels to remove excess external seawater, individually placed in preweighed 1.0-L plastic containers, and weighed to the nearest 0.1 g. Orientation of abalone in the containers was, where possible, in a vertical plane with the leading shell margin facing downward. Each container was fitted with a plastic grill to allow water to drain away from the abalone. Forty-five abalone were randomly assigned to each of the following three storage treatments:

1. *cool*—involved refrigeration at 3°C immediately after weighing;
2. *amcool*—required the abalone to remain at ambient temperature (24°C @ 1400 h) for 4 h before refrigeration (3°C @ 2000 h) for a further 20 h; and
3. *ambient*—the abalone remained at ambient temperature (24°C @ 1400 h to 20°C @ 2000 h) for 24 h.

Abalone were reweighed in their containers after 1, 2, 4, 6, 8, 10, and 24 h. At each weighing, the combined weight of the container, abalone, and drained abalone fluid was measured. Then the weight of the container and fluid with the abalone lifted above, but not out of, the container was measured. As the abalone were weighed, observations were made regarding the degree of pedal adhesion and responsiveness to stimulation.

Although relative humidity was not measured directly, evaporative loss of water was used as a *de facto* alternative. To test for evaporative loss of water 10 1.0-L plastic containers filled with about 350-mL tapwater were placed in each of the two storage environments and reweighed at the same time intervals as the abalone, and additionally at 5 h.

Potential for fluid loss was investigated by measuring the volume and weight of fluid that could be drained by gentle squeezing of the soft tissues of fifty abalone selected at random from the same aquarium.

Statistical Analysis

Weight loss in the first experiment was determined from the difference between the combined weight of the bin and abalone at t_i and the initial weight at t_0. In the second experiment, weight loss caused by evaporation and handling was calculated as the difference between the weight of each abalone in its container at time t_i and at the commencement of the experiment at t_0. The differences between the weight of an abalone in its container at t_i, the weight of the container with the abalone suspended above it at t_i and the weight of the empty container at t_0 were used to determine the weight of fluid lost directly through physiological processes.

For both experiments, the weight of fluid lost was then subject to analysis of variance using the ANOVA procedure in the SAS® statistical software package (SAS Institute 1990). Data from Experiment 2 were log (x + 1) transformed to reduced heterogeneity of variances among treatment combinations, eliminate a positive linear relationship between treatment means and their variances, and reduce non-normality in their distribution.

The ANOVA tested weight loss as a response to the predictor variables of storage exposure (Treatment) and duration of exposure (Time). A two-factor ANOVA model with repeated measures on Time was specified. Because, in all instances, the interaction between storage treatment and time was highly significant ($P < 0.01$) simple investigations of levels of main effects were conducted. One-way ANOVA was performed on storage treatments for each level of time and then repeated measures one-way ANOVA on time was applied to each storage treatment. The Scheffé test for multiple comparison of means was used to detect significant differences among levels of each predictor variable. Volume of fluid lost by squeezing was regressed against the weight of this fluid for 50 additional abalone.

RESULTS

Experiment 1: Weight Loss from Bins of Abalone

Significant weight loss (df = 10,120, F = 3.04, $P = 0.0001$), ranging from 8–14%, occurred through drainage from bins of abalone over 17 h. Although there were no significant differences among treatments (df = 2,12, F = 0.07, $P = 0.5168$), probably because of low statistical power (Table 1), continuous storage in the cool room produced the largest loss; whereas, covering with a moist cloth at ambient temperatures produced the least (Fig. 2). Further analysis showed that weight loss increased significantly over time for all three treatments (df = 10,40, $F_{Cool} = 41.33$, $F_{Ambient} = 24.46$, $F_{Moist} = 5.89$, $P = 0.0001$). Multiple comparison of means (Table 2) showed that weight loss of abalone stored under cool conditions was not significant over the first 5 h but was significantly greater between 5 and 17 h. Weight loss under ambient conditions differed significantly over time intervals greater than 3 h throughout the experiment. There were significant differences between the weight loss during the first 1.5 h and losses over the subsequent 15.5 h. The lack of significant contrast in the means is almost certainly a result of the low power of the analysis. Minimum significant differences (MSDs) over time were greater than 50% of the grand mean for all treatments (Table 1). The low power was a consequence of the use of only five replicates per treatment under circumstances where differential drainage through holes in the bases of the plastic bins caused substantial within-treatment variation.

Experiment 2: Weight Loss from Individual Abalone

Fluid loss from individual abalone varied significantly between cool (3°C) and ambient (21°C) storage (df = 2,132, F = 6.16, $P = 0.0028$) and over time (df = 6,292, F = 905.17, $P = 0.0001$). After 24 h, fluid loss from ambient (15% loss) and cool (14% loss) did not differ significantly, but fluid loss from those abalone transferred from ambient to cool conditions (20% loss) was significantly greater than in the other two treatments (Table 3). The

4.5	5.02	4.32	86
5.0	5.30	4.29	81
17.0	10.83	8.15	75

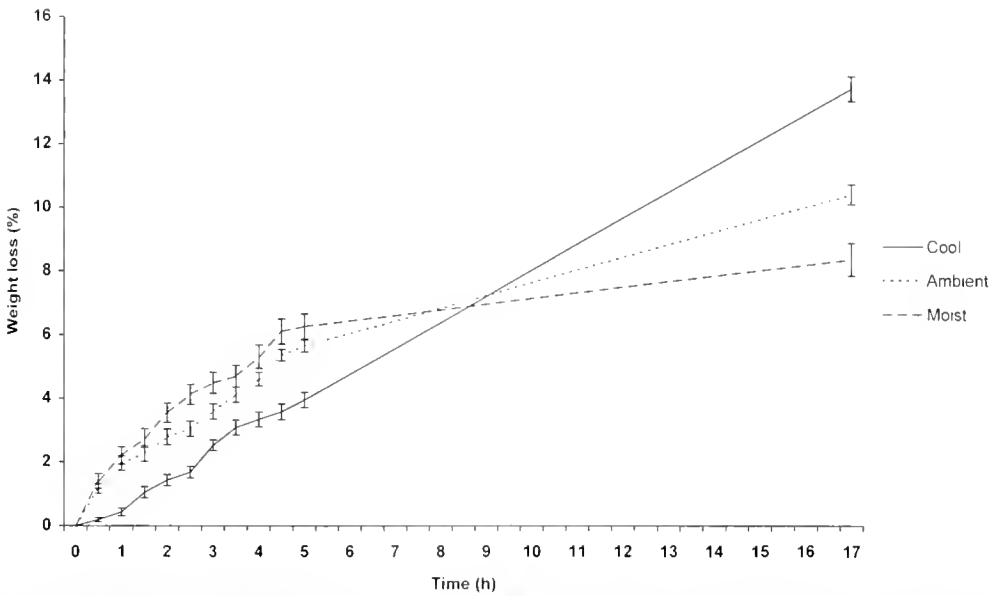

Figure 2. Mean cumulative weight loss (%) over time for commercial sized bins of blacklip abalone (*H. rubra*) subjected to three different conditions of storage (error bars are standard errors).

largest difference between cool and ambient treatments occurred after 4–6 h, and the greatest difference among all three treatments occurred at 8 h (Fig. 3). Most fluid loss occurred during the first 6–8 h of exposure (Table 4). Abalone with the most weight loss at each time of measurement tended to have the poorest pedal adhesion, consequently strong pedal adhesion was least apparent among abalone undergoing cool storage.

Differences in evaporative loss of tapwater between cool and ambient temperatures (df = 1,18, F = 8.61, $P = 0.0089$) and over time (df = 7,126, F = 137.95, $P = 0.0001$) were significant but small (<2% of treatment means). For each treatment, the losses were relatively small, ranging from 1.4–1.5% (95% confidence) in the cool room and 1.5–1.7% (95% confidence) in the ambient room after 24 h. Evaporation under ambient conditions was initially less than in the cool room during the first 4 h (Table 5). After 4 h had elapsed, the two curves converged when the ambient temperature rose to a maximum for the experiment of 24°C (Fig. 4). From 4–10 h, there was no significant difference between treatments and after 24 h, ambient evaporation was slightly greater than in cool room (Table 5a). Evaporative loss occurred significantly throughout the time period, although the difference in loss between 5 and 6 h under ambient conditions was nonsignificant (Table 5b).

Evaporative losses of the more viscous abalone fluid from the containers in which the abalone were housed over the same period were somewhat greater than the tapwater evaporation. The 95% confidence ranges for the evaporation of abalone fluid were 2.2–2.4% for cool, 4.2–4.4% for ambient and 3.0–3.3% for abalone transferred from ambient to cool.

Potential for loss by squeezing abalone showed fluid contents ranging from less than 1–15%, with 95% of individuals containing between 5–7% of fluid. Regression of volume versus weight of fluid showed close correspondence ($n = 50$, $R^2 = 0.92$) sufficient to assume 1.0 g ≡ 1.0 mL fluid.

DISCUSSION

Exposure of prosobranch gastropods to air occurs naturally for those living in the intertidal zone. The greater the height of exis-

tence above the low-water mark, the greater the adaptation to prolonged air exposure. Resistance to desiccation is of prime importance to these intertidal marine snails, and, in the extreme, some species can survive in their natural habitat for months without seawater contact. Loss of body water is the direct cause of death from desiccation and losses within the range of 10–30% water content have resulted in mortality in several species (Hyman 1967). Abalone are predominantly subtidal and are, therefore, less adapted to survive desiccation, hypoxia, and thermal stress from prolonged air exposure. Although the abalone mantle cavity has a moderate water storage capacity, the ability to retain that water during emersion is limited by having a large shell aperture. My results show substantial loss of water and body fluid through drainage from the mantle cavity within 24 h of air exposure. Newell (1979) provides an example where water loss over time at 21°C for the lower shore limpet *Patella cochlear* ranged between 25–35% at 5 h and 35–40% after 50 h. These ranges of water loss are about twice that of the second experiment in my study.

Losses of 5–20% were sufficient to cause substantial morbidity and mortality within the first 10 h and almost 100% mortality after 24 h with some notable exceptions. A couple of large abalone held at ambient temperature seemed exceptionally healthy at the conclusion of the second experiment. Newell (1979) cites a study of six species of intertidal prosobranchs from the Cape Peninsula, South Africa, that showed median mortality ranged from 16–33% among species, depending on the period of emersion and duration of exposure to low relative humidity. Time to 50% mortality ranged from 1–12 days at temperatures between 3.5–20 C with generally shorter survival at the higher temperatures. As stored water is lost from the mantle cavity and body tissues, thermal tolerance will diminish and osmotic concentration of body fluid may tend toward lethal levels (Newell 1979).

The larger percentage of losses in the second experiment as compared with the first possibly arose because of drainage losses from bins occurring aboard the research vessel while at sea during the first experiment. These losses were not measured; whereas, all losses during the second experiment were accounted for in the estimates. Another plausible reason for the difference between the two experiments may have been retention of lost fluid in the first experiment that failed to drain through the bases of the bins during the postlanding period. The retained fluid would have been included in the weights of the bins of abalone. The high initial MSDs relative to the mean weights during the first experiment possibly reflect within-treatment variability in the amount of water retained in each bin. This variability is likely to have reduced over time, because movement of bins during repeated weighing caused pro-

gressive loss of retained water. In other words, the statistical power to detect significant weight loss increased during the course of the experiment. Although the use of bins accurately portrays industry practice, the use of individual containers more accurately reflects the potential for weight loss.

There is some evidence that contraction of the pedal muscle is associated with water loss. Hyman (1967) cites a study by Morris showing that when the pedal muscle of *Nactica* species is stimulated to contract, fluid is emitted from the mantle cavity in a volume similar to the capacity of the shell. The initial rapid increase in weight loss when abalone were transferred to the cool room may have arisen from pedal muscle activity that caused more rapid water loss than occurred in those abalone stored under ambient conditions. Poor pedal adhesion, particularly among those abalone subjected to cool storage conditions, may have been related to water loss from the pedal muscle, or reduced activity levels to conserve energy. Alternatively, it may have been a consequence of a hypoxia-induced reduction in muscle tone. Failure to maintain strong adhesion to the substrate is a clear sign of stress or morbidity in abalone. Under normal conditions, large abalone have been observed to resist a force of one-half ton (Hyman 1967).

The shell morphology of abalone is also less suited to thermal stress during air exposure than the shells of more globose-shaped prosobranchs, such as the turbinids and trochids, that have the additional advantage of an operculum. Temperature is the single most important factor in controlling the quality and shelf life of fresh seafood. Consequently, it is usual for most seafood to be stored at low temperatures before processing. Both bacterial growth and biochemical reactions will be increased when harvested abalone are stored at elevated temperatures. Although cold storage will suppress increases in hosted bacterial populations, paradoxically, it may depress biochemical processes that otherwise defray the negative effects of hypoxic stress due to air exposure. Abalone of several species subjected to hypoxic stress caused by air exposure have been shown to produce increased quantities of the glycolytic metabolites D-lactate and tauropine rapidly, and to use arginine phosphate as an additional source of anaerobic energy (Donovan et al. 1999, Tjeerdema et al. 1991, Watanabe et al. 1992, Wells & Baldwin 1995). Wells and Baldwin (1995) refer to speculation that the accumulation of tauropine as an additional pyruvate reductase end-product may be an adaptation in haliotids to protect their tissues during hypoxic episodes. Their studies indicate that lactate is the preferred product during such environmental hypoxia as air exposure and tauropine during functional hypoxia arising from exercise. They suggest that abalone may be adapted to continue metabolizing during air exposure associated with commercial handling, processing, and shipping, despite an inability to irrigate their gills. Unlike my results, most of the abalone (*H. iris* Martyn and *H. australis* Gmelin) exposed to air during their study maintained good pedal adhesion and muscle tone for 24 h. The capacity to use anaerobic glycolysis during hypoxia is likely to vary among abalone species (Donovan et al. 1999). It is possible that *H. rubra* is more dependent on aerobic metabolism than species studied to date, but this demands further investigation. The greater weight loss and apparently higher morbidity in abalone initially exposed to ambient air for several hours before refrigerated storage may be related to disruption of these biochemical processes caused by substantial reductions in temperature.

This may partly explain why abalone held at ambient temperature lost less fluid than those placed directly in cold storage (<5°C). However, the poorer performance of those transferred to cold storage after 4 h seems likely to have resulted from the additional stress imposed by multiple temperature changes. The variability in differences among treatments over time may reflect the effects of thermal stress interfering with biochemical responses to hypoxic stress.

Although I initially suspected that fluid loss may involve active physiological processes directed at preventing gill desiccation, this does not seem to have extended to active excretion of water to irrigate the gills, as has been reported for limpets (G. Parry pers.

comm.). What probably occurred in this study was initial excretion of body fluids into the mantle cavity where necessary to maintain the gill tissues in a liquid environment, followed by a loss of body fluid and water retained within the mantle cavity once morbidity progressed to the extent that muscle tone was reduced and active water retention ceased. This would explain why lost fluid had a bluish hue consistent with the oxyhemocyanin respiratory pigment in abalone blood (Barnes 1986) and why I observed episodic losses from some abalone into their containers during weighing.

Evaporative losses simulated using tapwater were small throughout the experimental period and between treatments. In contrast, losses of abalone fluid were greater than the tapwater losses and varied with each treatment temperature regime. Losses of around 4% or more of the fluid from abalone subjected to ambient temperatures warrant further consideration. I would have expected evaporation of this apparently higher viscosity fluid comprising seawater, blood, and mucous secretions to be less than for water. Nonetheless, evaporative loss was accounted for in the estimates and does not affect the conclusions from this study.

Results from this study have important implications for assessment and management of the Victorian abalone fishery. Post-harvest weight losses of 10–20% equate to the removal of 6–12% (about 350,000 to 700,000 average sized abalone) more than expected from the current TACs. Catches used to model the fishery will need to be adjusted to account for these quantities. Because exploitation of weight loss before notification is a recent phenomenon in the history of the fishery, inclusion of the additional quantities in catch inputs will produce model outputs showing a higher risk of decline in population projections. If these risks are deemed to be unacceptable, then management decisions to reduce the TACs may follow that will cost the Victorian abalone catching sector several million dollars in income.

Greatest losses occurred under conditions similar to those most commercially harvested abalone are exposed to during fishing, transportation, and storage before processing. Although losses are inevitable aboard diver vessels while at sea (typically for periods of 4–6 h), these can be offset by careful packing of bins, shielding from the weather, and periodically irrigating or deluging the bins with seawater. Losses estimated during the first experiment were determined after the abalone had been similarly exposed aboard a research boat. Clearly, there is an incentive for abalone processors to become adept at maximizing weight losses before notification for decrementing quota allocations. From a management perspective, it is important to consider whether these practices are desirable and equitable.

Processors exporting live abalone are unable to take advantage of the regulations and must pay more per abalone. This may be offset by higher than normal wholesale prices for live product. Commercial abalone divers harvesting abalone destined for canning are at a financial disadvantage from the additional effort expended to attain quotas, unless they are compensated by higher than normal beach prices. However, the high rate of vertical integration within the industry, where those in the catching sector are also involved in the processing sector, ensures this practice is at least tolerated by most divers. It seems that industry concerns expressed a decade ago have given way to acceptance of overnight

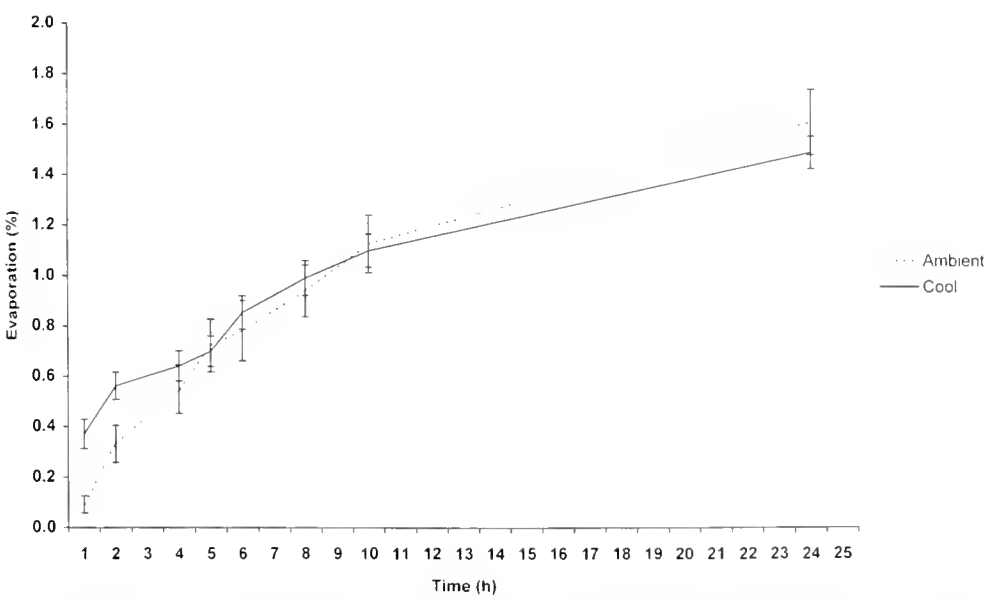

Figure 4. Mean cumulative evaporation of tapwater over time in ambient and cool storage environments (error bars are standard deviations).

drainage as standard industry practice. That most of the weight loss in the second experiment occurred during the first 8–10 h may partly explain why processors do not exploit the full 24-h post-landing period available, preferring, instead, only to allow catches to drain overnight. Alternative explanations include greater risk of spoilage if abalone remain unshucked for too long and cost efficiencies associated with the engagement of casual factory workers.

Evidently, the practice of maximizing weight loss through drainage does not seem to have a negative impact on the quality of canned or frozen abalone products produced in Victoria. Anecdotal information from persons with experience in the processing sector indicates that partial dehydration before canning may enhance the uptake of water into the meat. Some claim that increases of 20–30% are achievable, but this remains to be verified. However, Wells and Baldwin (1995) suggest the possibility that changes in metabolites produced during prolonged air exposure may affect the organoleptic qualities of abalone and cite several studies linking taste and meat quality to biochemical processes. This may be temperature dependent and less likely during refrigerated storage; however, it deserves attention.

In the future, it is probable we will see the introduction of official electronic beach weighing stations that will automatically decrement abalone quotas as catches are landed at major Victorian ports. The impetus for this will come as much from the need to reduce fishery management costs as to ensure compliance. Such practices are already part of the federally managed Southeastern Trawl Fishery in Australia and discussions have commenced regarding trial applications of electronic weighing for quota-managed fisheries under state jurisdiction. Until changes in the determination of official catch weights are implemented, post-harvest weight loss will need to be taken into account when setting annual catch quotas for the Victorian abalone fishery.

ACKNOWLEDGMENTS

This work was funded by the Abalone Assessment Subprogram conducted by the Marine and Freshwater Resources Institute on behalf of Fisheries Victoria. Cameron Dixon, David Forbes, Mark Ferrier, and Bruce Waters are thanked for diving assistance in collecting the abalone, and Cameron and David are also thanked for their assistance with weighing and recording. Sonia Talman provided considerable assistance with weighing and recording throughout the second experiment and made constructive comments on an early draft of the manuscript, for which I am grateful. In addition, Noel Coleman deserves thanks for his helpful suggestions on an earlier draft. Comments from an anonymous reviewer also improved the manuscript.

TRIGGERS AND TARGETS: WHAT ARE WE AIMING FOR WITH ABALONE FISHERIES MODELS IN AUSTRALIA?

HARRY K. GORFINE,* BRUCE L. TAYLOR, AND TERRY I. WALKER
Marine & Freshwater Resources Institute, PO Box 114, Queenscliff, Victoria, Australia

ABSTRACT A variety of quantitative measures have been applied as reference points in the management of Australian abalone fisheries. In New South Wales changes in legal-sized and mature biomass will trigger management responses, in South Australia catch rates, size composition, and abundance indices provide target reference points, and in Tasmania, catch rates and catches have been used to provide triggers for management decisions. However, Victoria and Western Australia have yet to determine their reference points for abalone stock assessment. Victoria has been developing length-based fisheries models similar to those applied in New South Wales and is now confronted with the necessity of converting model outputs into decision-making criteria. A Victorian fishery management plan is also under development in which reference points will be specified within a risk-based matrix of catch control rules for quota adjustment. Recent biodiversity conservation legislation, compelling fisheries management agencies in Australia to demonstrate that export fisheries managed under their jurisdictions are ecologically sustainable, has increased the urgency to establish these reference points. The application of this legislation draws upon the "Principles and Criteria for Sustainable Fishing" of the Marine Stewardship Council in London. We considered a range of alternative measures for reference points that may be useful as triggers and targets applied in a stochastic framework for management decisions. Although not a modeling output, one of the more consistent nonbiological signals of localized depletion in the Victorian fishery relates to spatial allocation of effort at the scale of reef complexes. Reductions in annual effort applied to a particular reef system invariably precede significant decreases in abundance indices with typically large coefficients of variation and in catch rates characterized by hyperstability. Victorian abalone divers have high daily catch expectations and allocate their effort accordingly. Empirical reference points, such as effort allocations, provide utility for fishery management and can be readily assimilated and adopted by industry. Consequently, we conclude that in addition to modeling outputs, maintenance of reef-scale effort allocation and daily catch expectations should form part of a suite of fishery performance indicators and target criteria for the Victorian blacklip abalone fishery.

KEY WORDS: biodiversity, sustainability, reference points, abalone

INTRODUCTION

The Australian Commonwealth *Environment Protection and Biodiversity Act 1999*, effective July 2000, and proposed revisions to the *Wildlife Protection (Regulation of Exports and Imports) Act 1982*, mandate that Australian fisheries resources be fished in ways that can be demonstrated as ecologically sustainable. To provide guidance for assessing sustainability, the lead agency for these Acts, Environment Australia, has recently released "Guidelines for Assessing the Ecological Sustainability of Fisheries Management Regimes" (see www.erin.gov.au/marine/fisheries/assessment/guidelines.html). These guidelines are similar to the Marine Stewardship Council's "Principles and Criteria for Sustainable Fishing." There are two principles underpinned by a series of objectives and assessment criteria that will seriously challenge many conventional approaches to fisheries management, particularly with respect to ecosystem impacts. To satisfy Commonwealth Government requirements, each fishery must operate under a management regime that satisfies both principles.

The first principle relates to avoidance of overfishing and promotion of stock recovery of targeted fish populations. The second principle is concerned with protecting the supporting ecosystem by managing fishing operations so that impacts are minimized.

Of particular interest to abalone stock assessment biologists, are criteria under the first principle that there should be sound estimates of potential long-term productivity, target reference points for levels of fishing and limit reference points beyond which stocks should not be targeted. These are criteria that stock assessment groups should be able to address with existing data and assessment techniques. Criteria under the second principle relating to ecosystem sustainability and biodiversity are more esoteric. It will be difficult to demonstrate satisfaction of these criteria, given our relatively poor understanding of ecosystem processes in abalone-dominated communities and, more importantly, the lack of comprehensive and spatially representative data for these communities.

Although other abalone-producing Australian states have management plans, Victoria has only recently embarked upon the development of a plan that will meet the future needs of its abalone fishery. In a response to the new legislation, Fisheries Victoria has nominated abalone as the first fisheries resource for which they will pursue assessment by Environment Australia. Highest priority in this regard has been given to the determination of reference points for the fishery. Unlike many fin fisheries across the globe where target and limit reference points have become well-established in fisheries management (Caddy 1998), abalone fisheries have yet to embrace a standard suite of reference points. We have already modified and applied a length-based stock-reduction model with an assumed Beverton and Holt stock–recruitment relationship to assess the Victorian fishery, in a fashion similar to an approach used for the NSW fishery. There is an expectation that outputs from the model will form the basis for reference points in the management plan, as is the case in NSW. However, other states use different reference points, and an examination of the efficacy of a range of alternatives is warranted. We describe, and where possible, evaluate some of the biological and fishery reference points currently applied in Australia in an attempt to stimulate debate about the selection of attributes to trigger management decisions and target fishery performance.

MEASURING PERFORMANCE, SETTING TARGETS, AND RESPONDING TO TRIGGERS

Terminology describing reference points can seem somewhat confusing, given everyday usage and varying definitions of tech-

nical terms. Caddy (1998) uses the terms target reference point (TRP) and limit reference point (LRP), respectively, to refer to target values that mostly relate to recovery of overexploited stocks and trigger values that represent thresholds for avoidance of overfishing. For the purpose of our discussion, we consider reference points to be values of biological and fishery attributes that can be used to gauge performance of the fishery. In this context, target reference points are desired values of selected performance indicators against which we can make assessments about the current status of an abalone stock; whereas, trigger points are threshold values below which there is an unacceptable risk of adverse consequences for the fishery. Invoking these triggers should initiate management intervention before the fishery enters an undesirable state. Beyond the trigger points, are limit points or values that when attained indicate collapse of the stock is imminent. The larger the margin between trigger and limit reference points, the more likely that the trigger will be activated before critically low levels of stock occur (Caddy 1998). In a stochastic framework, performance indicators should specify a reference point value, the relationship between an observed value and the reference point, and the confidence probability for acceptance that the relationship is true over a specific time period. Applying reference points in a risk analysis is preferable to relying on individual deterministic values, because it has the advantage of incorporating uncertainty in the decision-making process.

Catch Rate

Although much has been written about the lack of utility in catch per unit effort (CPUE) as it is currently reported by abalone divers in most parts of the world, some studies support a contrary view (Worthington et al. 1998). It is also generally acknowledged that catch rates play some role at a fine scale in determining whether a commercial abalone diver will persist in fishing a specific population. Stock assessment teams inevitably resort to commercial catch and effort statistics and trends in CPUE when alternative data about the fishery are scant or inconsistently collected. This is a reflection of the power that comes from having large amounts of data over a time scale consistent with the history of the fishery and generally at a high temporal resolution. CPUE is used as a reference point in the South Australian abalone management plan (Zacharin 1997) and, until recently, was also part of the Tasmanian plan (Anonymous 1997). The South Australian plan specified that for blacklip abalone, the reference point would be triggered if a change in catch rate within major fishing blocks of greater than 15% between years or greater than a 25% change over a period of 5 consecutive y was observed. In Tasmania, two catch rate trigger points were applied (Officer 1999). The Tasmanian coast is divided into eight regions further subdivided into 51 statistical abalone catch and effort reporting blocks. One of the reference points would be triggered if annual CPUE at the state level from diver returns fell below 95% of the CPUE for the reference year (1993, 1994, or 1995) with the lowest catch rate. The other reference point would be triggered if annual CPUE from diver returns for any region or block fell below 75% of the CPUE for the reference year (1993, 1994, or 1995) with the lowest catch rate for that region or block. Officer (1999) concluded that these reference points were inadequate to indicate whether or not recent catches were sustainable. The 1997 to 1998 fishery assessment showed that, at the higher spatial resolution, only one statistical block was close to being triggered and that, on a statewide scale, average catch rates had increased every year since 1990. However, catches in some blocks had increased to unprecendented levels (in some instances, doubling) so that past performance could not be used to gauge sustainability. Concerns were held that CPUE may not reflect changing abundance and that a better indicator of biomass change was required.

In Victoria, the abalone fishery is subdivided into three relatively large management zones, each spanning several hundred kilometers of coastline (Fig. 1). However, catch and effort data are reported for area codes of tens of kilometers and reef codes that generally represent headlands or reef complexes. Average catch rates for each zone have mostly increased during the past 20 y for which detailed records are available. Before we can interpret this as increased abundance, we need to eliminate the possibilities that such trends are consequences of increased diver efficiency, changes in commercial divers' interpretations of effort, or access to new fishing grounds.

During the history of the fishery, there have been a number of changes in the composition of the Victorian commercial abalone diver population and divers' incentives to fish. License transferability was introduced during 1984 on a two for one basis followed by quotas during 1988. Between 1984 and 1988, beach prices increased threefold, from about $AUD 5–15 per kg, pushing up the price of licences. Divers who bought into the fishery frequently took out large mortgages to pay for consolidated licenses, adding increased incentive to maximize the return for each unit of effort. Further changes occurred as access license owners "leased" their licenses to contract divers, now formally recognized under the Victorian Fisheries Act (1995) as nominated divers. These divers are generally younger and fitter than the "retiring" access license owners and are paid about 10% of the abalone beach price. Discussions with experienced divers suggest that there has been an increase in catching efficiency during recent years. In addition, we have repeatedly implored divers to record only bottom time as effort rather than time spent on the water. Compliance with this request would tend to decrease the effort reported for each unit of catch, although the extent to which this has affected CPUE is unclear. More revealing is the spatial disaggregation of effort into groups of reefs arbitrarily categorized by their long-term average CPUE. This clearly shows a trend toward effort being concentrated on those reefs that provide the highest catch rates (Fig. 2).

Discussions with divers confirm that before quota introduction, divers would often fish low-catch-rate reefs. Once quotas were introduced, there was no longer an incentive to fish the low-catch rate reefs, because quotas could be readily obtained from a smaller number of reefs where abalone were large and abundant. Indeed, we have clear evidence of the hyperstability of CPUE on a reef that recently collapsed in the Eastern Zone of the Victorian fishery (Fig. 3). The Skerries is a seal colony in a relatively remote and ostensibly pristine location. However, difficult but nonetheless available access via 70 kilometers of rough road allows abalone thieves to fish this location. Whether illegal fishing is to blame is unknown; however, what is clear is that declines in prerecruit abundance were followed by declines in the abundance of legal-size abalone at our fixed monitoring site (Fig. 4) and a concomitant decrease in effort (Fig. 3). In contrast, CPUE increased during many of the final days of effort before licensed divers decided harvesting abalone from this location was no longer worthwhile (Fig. 3). Big Rame Head, another important reef approximately 3.5

km to the west of The Skerries, has contributed up to 8% of the Eastern Zone catch in previous years but is showing similar catch and effort trends to The Skerries (Fig. 5). However, declines in abundance were only recorded at the three of our five fixed monitoring sites closest to shore access and were not as substantial as declines at The Skerries.

Relative Abundance

Largely as a consequence of problems in applying conventional models to abalone fisheries (Breen 1992) and the failure of CPUE as an estimate of abundance (McShane 1992), the last decade has seen the introduction of independent dive surveys to estimate abundance of Australian abalone. It was anticipated at the outset that these surveys would provide a time series of relative abundance that would reflect changes in commercially fished abalone populations that could not be detected using catch and effort statistics (McShane 1994). The assumption was made that catch quotas would be adjusted in response to trends in abundance; however, until recently there was no explicit adoption of such adaptive management arrangements by any of the State fisheries authorities

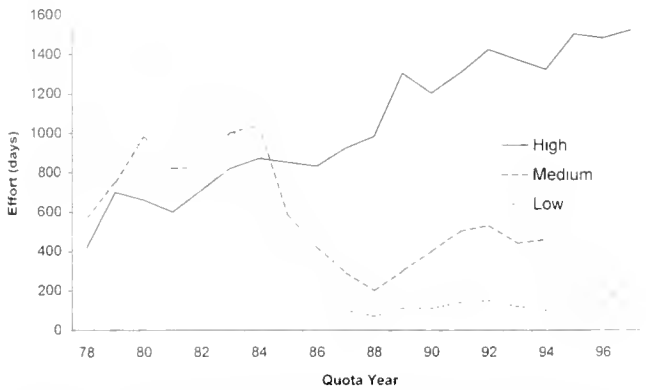

Figure 2. Annual effort (days) from 1978–1998 for reefs from the Central Zone of the Victorian abalone fishery with high (>61 kg/h), medium (55–61 kg/h) and low (< 55 kg/h) average catch per unit effort (CPUE).

responsible for abalone management. Indeed, abundance estimates on their own show sufficient spatial variability that the power to detect change is often low at the levels of replication allowed by available resources (Gorfine et al. 1998). Furthermore, lack of temporal resolution and infancy of these programs has made the detection of statistical trends in these data problematic. That these programs were initiated late in the development of the fishery, well after the initially rapid reduction in prefished biomass (Gorfine & Walker 1996), has meant that there is often little contrast in the temporal effect once residual variation has been partitioned from the data. Nonetheless, South Australia includes indices of abundance from independent dive surveys as one of the reference points in its abalone fishery management plan (Zacharin 1997). This reference point is triggered if a greater than 15% change is detected in the abundance of abalone above the legal minimum size, and abundance of prerecruits between consecutive years.

Our research on independent survey methods and experience in their application for large-scale monitoring during the past decade clearly demonstrates that effect sizes of 15% are unlikely to be detected given the large coefficients of variation (CV) for abundance estimates (Hart et al. 1997). CVs from unstandardized abundance data differ substantially among size classes. Our survey data show those abalone within 10 mm above and below the legal minimum length (LML) generally have CVs less than 30%, whereas the more cryptic smaller size-classes and sparsely distributed larger classes have CVs that make the detection of changes in abundance unlikely (Table 1). Although we have had sufficient statistical power with our methods to detect significant changes as small as 10% on some occasions (Gorfine et al. 1998), patterns in interannual variability fluctuate to the extent that a substantial increase between a pair of consecutive years may often reverse during the subsequent year. Management decisions, particularly about catch quotas, made in response to unstable patterns such as these will almost certainly create more problems than they solve.

In Victoria, we no longer use trends in fishery-independent abundance separately from catch data to assess stock status. Instead, we use the abundance estimates to fit fisheries models that incorporate commercial catch data to describe and forecast trends in relative biomass.

Egg Production

Shepherd and Baker (1998) suggest that egg production may be an acceptable substitute for biomass to predict risks of overfishing. Their eggs-per-recruit (EPR) analyses together with their review of EPR estimates from other studies indicates that the range 40–50% of virgin egg production is associated with sustained yields from medium to large abalone stocks and could be used as an appropriate threshold reference point. However, these values seem to have been derived from deterministic EPR models that take no account of the stochasticity in abalone growth described by Troynikov and Gorfine (1998). In addition, although it is reasonable to surmise that empirical evidence of sustained yield over a long period indicates a stable stock, it does not necessarily follow that the EPRs for a series of populations classified as either stable or collapsed can be collectively used to establish thresholds for EPR. In a review of EPR models, McShane (1995) describes their limitations in failing to account for variability in growth and natural mortality over small spatial scales and in assuming that fishing mortality and recruitment apply uniformly to the exploitable stock.

Differences of opinion exist as to the nature of stock-recruitment relations in abalone and whether or not conserving a particular level of egg production will ensure sustainability of an abalone fishery. Even if stochastic versions of EPR models were applied, the outputs would only allow selection of size limits, because these models provide no information about the effects of varying catch quotas.

Relative Biomass

The New South Wales stock assessment team use relative biomass outputs from their length-based fishery model as performance indicators linked to two trigger points that relate to the biological objectives of the Management Plan for the NSW Abalone Share Management Fishery (Worthington et al. 1999). These reference points are specified in a manner that accommodates the uncertainty associated with model outputs. The first reference point is a performance trigger that is invoked if there is more than a 50% chance that median estimates of legal and mature relative biomass for any region, or for the entire fishery, are less than 85% of the value for 1994. The second reference point is a forecast trigger invoked if model projections over the ensuing 5 y show a greater than 50% chance of the legal and mature relative biomass being less than 85% of estimates for 1994. During 1998, neither trigger was invoked, although at the regional scale, some B/B_0 values averaged only 2% greater than the 85% trigger point with likelihoods only 5–10% less than the 50% reference probability (Worthington et al. 1999). In the absence of target reference points implying the contrary, the premise underpinning this approach is that the state of stocks during the reference year (1994) was at an acceptable level.

In Victoria, we have recently applied our version of a length-based model (unpublished). Our model differs somewhat from the NSW model, because it incorporates a framework for dealing with variability in the distribution of growth within populations, and in its current form, it does not use effort. Like the NSW model, ours fits the model to several time series of abundances of different length classes obtained from fishery-independent dive surveys of commercially important populations (Fig. 1). Outputs from the Victorian model are essentially the same as those of the NSW model; however, in the absence of a management plan, there are no agreed reference points against which model outputs can be assessed.

What we have been able to do for the Victorian fishery is incorporate the model outputs into a risk analysis where future

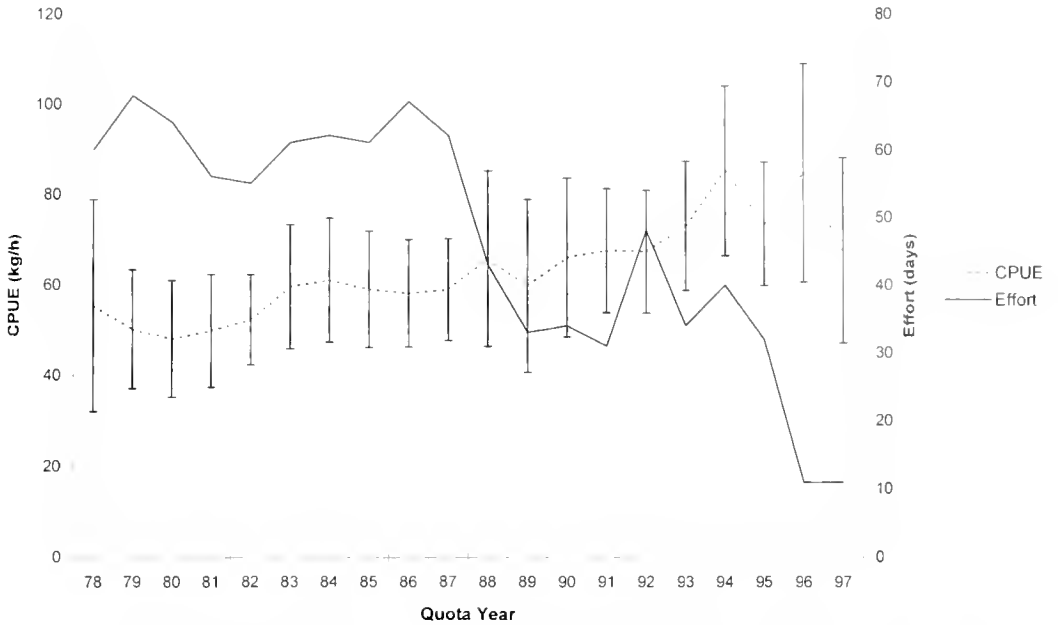

Figure 3. Catch per unit effort (mean kgh^{-1} ± SD) and annual effort (days) from 1978–1998 at The Skerries in the Eastern Zone of the Victorian abalone fishery.

biomass trajectories are predicted for a given harvest strategy (proportion of current TAC) at a selected level of risk. Figure 6 shows relative biomass projections up to 25 y for different proportions of the current TAC at three levels of risk (10, 20, and 30%) of being below the values of B_t/B_0 for each curve. Sensitivity of these projections to three combinations of natural mortality and unaccounted catch is shown. As would be anticipated, increasing the current TAC is likely to produce a decrease in biomass. In contrast, as the level of risk selected increases, the prognosis for sustaining current biomass improves. However, the projections are sensitive to levels of natural mortality and unaccounted catch. Because the model estimates its recruitment parameters internally, high mortalities throughout the life of the fishery will tend to make it more productive; whereas, increased mortalities in its more recent his-

Ranges of coefficients of variation (SE/mean), during 1992–1998, for relative abundance estimates of five size-classes of blacklip abalone surveyed in the three management zones of the Victorian fishery.

Size-Class	Central Zone[a]	Eastern Zone	Western Zone
70–89 mm	1.10–2.09	—	—
80–99 mm	0.43–0.71	1.09–2.28	1.55–4.69
100–109 mm	0.14–0.23	0.50–0.74	0.48–0.80
110–119 mm	0.18–0.22	0.31–0.52	0.17–0.34
120–129 mm	0.82–0.89	0.18–0.27	0.09–0.12
130+ mm	—	0.31–0.58	0.46–0.84

[a] LML = 110 mm in most of this zone, as compared with 120 mm elsewhere.

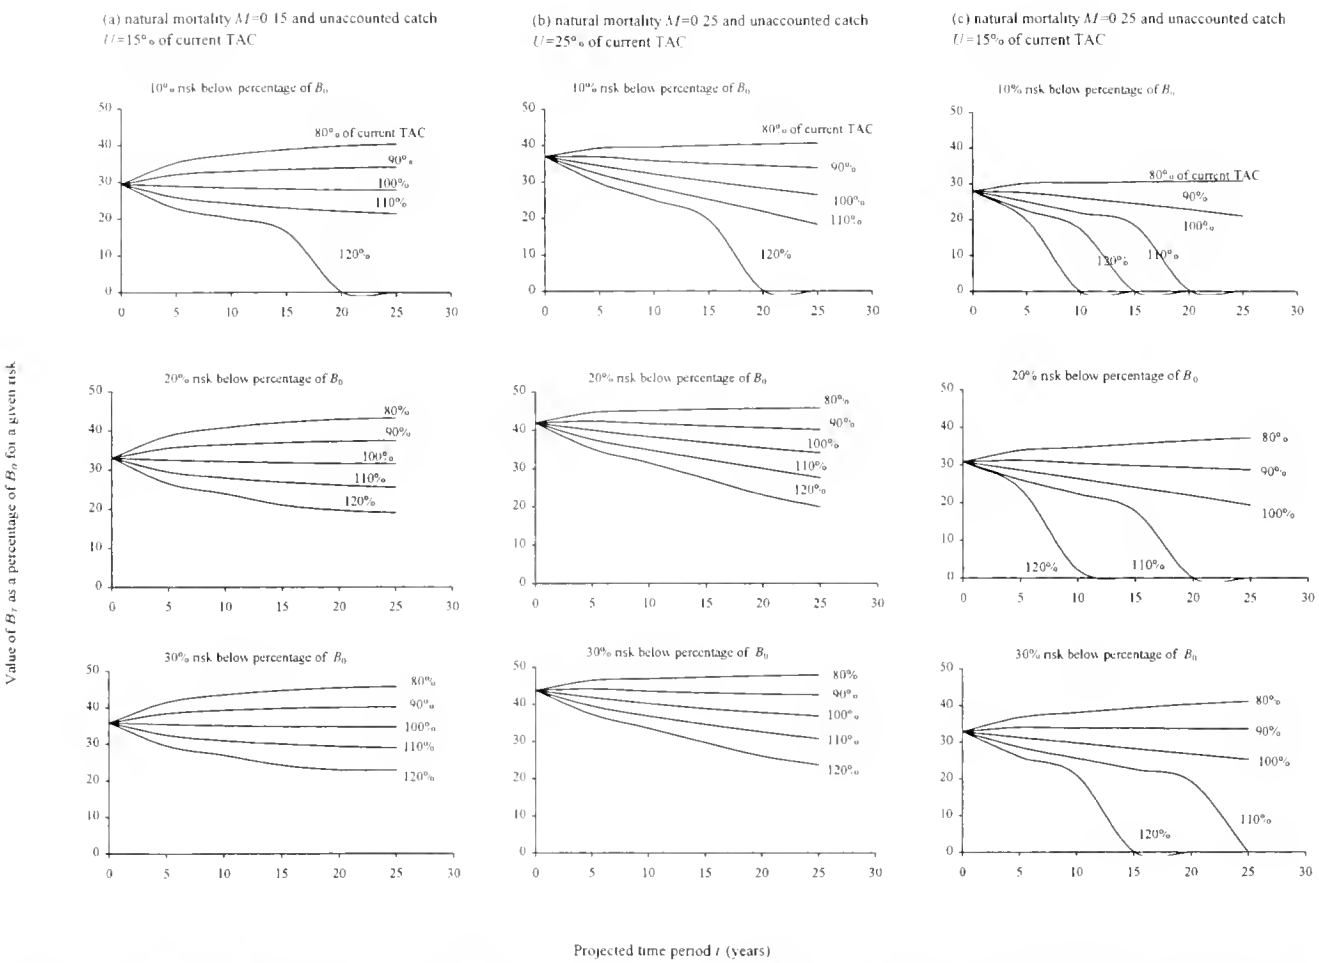

Figure 6. Relative biomass projections for the Eastern Zone for different harvest strategies at three risk levels showing sensitivity to three combinations of natural mortality and unaccounted catch.[B_t is biomass at projected time period t (years), B_0 is initial prefishing biomass, B_t/B_0 is expressed as proportion (0.1, 0.2, 0.3, 0.4, 0.5 and 0.6), constant harvest strategy is expressed as a percentage of the current TAC (80, 90, 100, 110, and 120%), risk is expressed as a percentage probability (10, 20, and 30%) that the true value is below the estimated values for B_t/B_0, and the projected time period is t years beyond 1998 (t = 0, 5, 15, and 25 years). U is the unaccounted catch as percentage of current TAC and, M is the rate of natural mortality].

tory will tend to have the opposite effect. Such issues as when illegal fishing became a problem and whether much catch went unreported in the early years of the fishery can have profound effects on outputs from the model.

Notwithstanding the preliminary nature of these results, depletion curves from model outputs show that current biomass in the Victorian fishery is about 30% or more of the prefished biomass and 97% of the 1988 biomass (Fig. 7). Although stocks generally seem to remain in slow decline since 1988, and for future projections, most of the depletion of prefished biomass occurred during the first 5 y of the fishery, well before quota introduction.

Commercial Effort

Victorian abalone divers have high daily catch expectations and allocate their effort accordingly. Detailed observations aboard commercial abalone vessels show that these expectations are typically about 500 kg for 5 h spent at sea, but may be as high as 1,000 kg (Gorfine & Dixon, this publication). Where divers anticipate lower catches, this almost invariably reflects the balance of unharvested quota on their last day of fishing for the year. These high catches cannot be obtained unless divers select reefs where experience has demonstrated that aggregations of abalone are numerous and dense. Divers will generally also have some perception of how well these populations recover after fishing and when they were last visited. Experienced divers will occasionally have to perform several test dives to locate good patches of abalone if recent intensive fishing has occurred, and inexperienced divers may make many such dives if their local knowledge is limited.

Insights from on-board observations may lead us to develop alternative reference points based on temporal and spatial allocation of effort. The basis for this assertion is that divers respond to change in stock availability that is below the detection limits of analyses of reported catch-effort and fishery-independent abundance indices. However, we must first account for variables that tend to confound this interpretation of effort, such as weather, diver experience, and market requirements. One possible empirical reference point could include reef-scale effort allocation, with a trigger point set at numbers of days per reef falling below some margin of the average number of days per annum since quota introduction. Another reference point could be related to daily catch expectation with a trigger that is activated if average daily catches fall below a specified margin of an historical average.

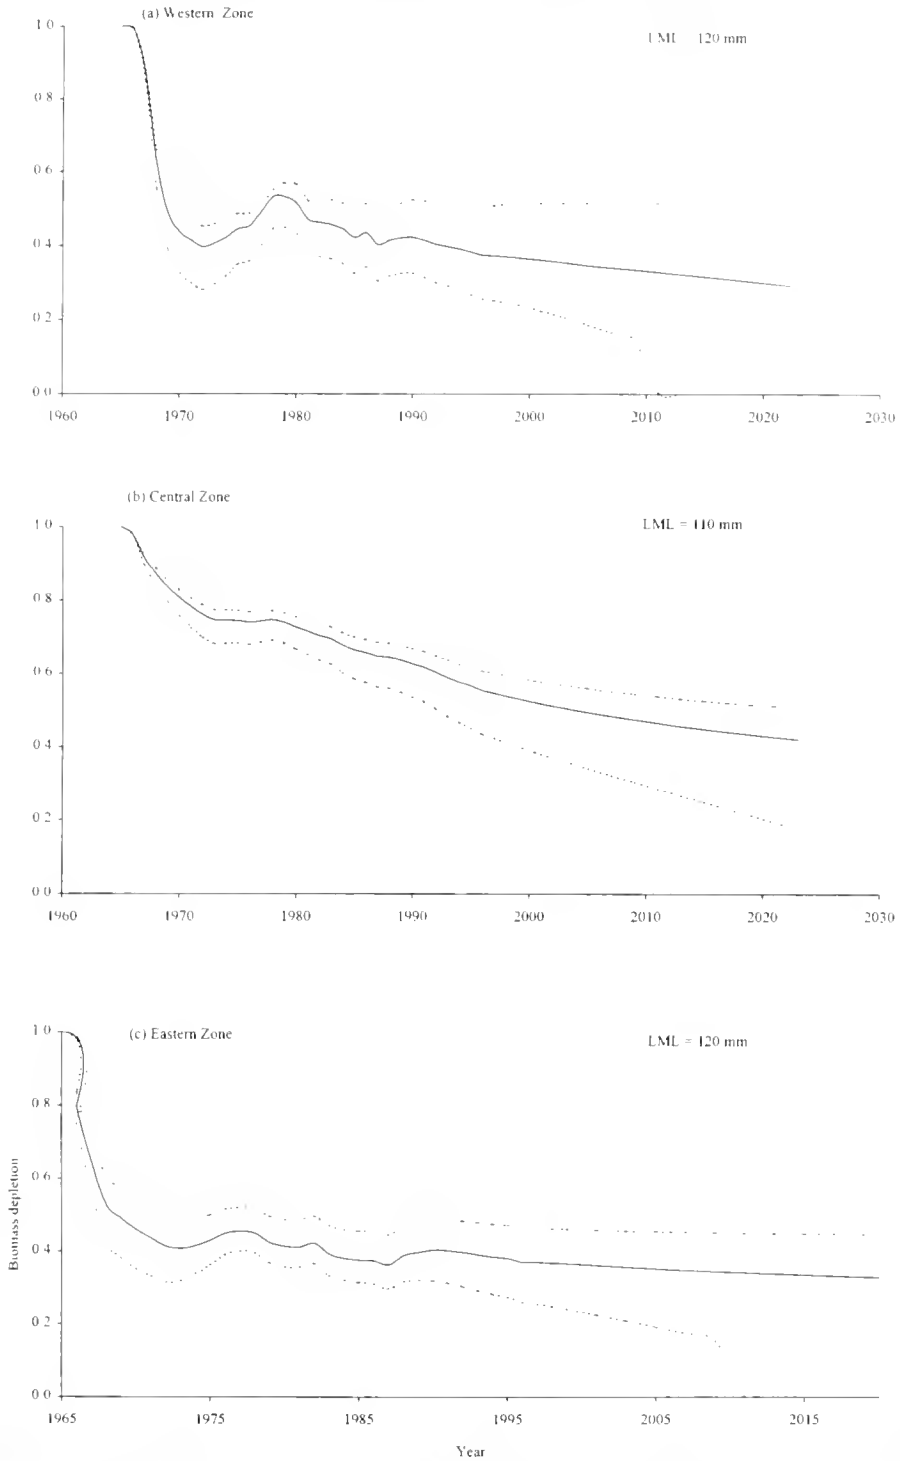

Figure 7. Biomass depletion (with 95% probability interval) for legal-size abalone (projections with current TAC and assumed values of unaccounted catch) in the (a) Western Zone, (b) Central Zone, and (c) Eastern Zone of the Victorian abalone fishery.

As well as changes in CPUE, the Tasmanian management plan specified percentage changes in catch for reporting regions relative to 1995 as trigger points. However, Officer (1999) reports that spurious activation of these triggers occurred in instances where regional catches were exceptionally high during 1995. He also points out that activation of these nonbiological triggers provides no indication that increased catches are unsustainable.

DISCUSSION

Catch per unit effort seems to have little to offer as a reference point for abalone fisheries. Its insensitivity to changing abundance and its sensitivity to changes in the composition and behavior of the diver population ensure that it reflects the state of the predator rather than its prey.

Shepherd and Baker's (1998) %EPR as a reference point provides no information about sustainable catch quotas. However, their conclusion that sustainability for small abalone populations may require the conservation of reproductive capacity at levels nearing 100% of the prefished stocks is consistent with Prince and Guzmán del Próo's (1993) stock reduction analysis of several zones in the Mexican fishery. This Mexican fishery analysis showed the zones to have poor productivity with little surplus yield to support sustained fishing. In another study of the Mexican fishery, Ramade-Villanueva et al. (1998) found that catch quotas based on conserving 75% of the current fishable biomass were too high to prevent recruitment overfishing.

The direct application of current measures of relative abundance as biological reference points is unlikely to be effective for managing abalone fisheries. Incorporation of independent observations of relative abundance into the model fitting process provides more information about trends in a stock than can be gained by the use of abundance indices on their own. However, we must continue to refine our survey methods to reduce the inherent variability in abundance data, because catches must cause large changes in relative abundance for depletion models to function effectively (Walters 1998).

Relative biomass seems to be the most efficacious among performance indicators linked to abalone fisheries models. However, choice of reference year for the denominator of the biomass ratio will depend on some independent information about the fishery during the year selected. For the NSW fishery, 1994 was chosen, because it was the year during which independent surveys of abalone abundance commenced (Worthington et al. 1999). In Victoria, a similar approach could be used by selecting 1992, when we commenced our current series of relative abundance surveys; however, it may also be informative to specify 1988, the year of quota introduction, as the reference year. This is because quotas were introduced at a time when yields from the fishery had stabilized, and managers and industry aspired to maintain stocks at current levels rather than to allow catches to increase and risk overfishing the resource.

In many fisheries, biomass reference points are set at specific values relative to an estimated prefishing or virgin biomass value B_0. For example, $B_t/B_0 = 30\%$ has often been used as a reference point for scale fisheries, particularly in the northern hemisphere (Quinn & Deriso 1999). However, there is no evidence that this or similar values have any relevance to such invertebrate fisheries as abalone. One of the main reasons for selecting a proportion of B_0 as a threshold is the assumption that decreases in biomass are reversible (Perry et al. 1999) and that stocks can be restored to former abundance (Beverton 1990). Although this may be true to some extent for abalone within a metapopulation, it is possible that at low abundances, depensatory effects may lead to irreversible recruitment failure for high levels of exploitation at this scale (Shepherd & Partington 1995). Under these circumstances, it is likely that serial depletion of metapopulations will mitigate against the rebuilding of stocks at the fishery scale.

An important consideration in the selection of biomass reference points is the level of uncertainty in the biomass estimates. Estimates for those years where data exist to fit the model (in our case, the 1990s) will provide less uncertainty than for past years, when reliable fitting data were unavailable. Similarly, the further into the future that biomass estimates are projected, the greater the uncertainty. Although the examples in this study show projected biomass estimates over 25 y for illustration, in actual application, a projection period of, say, 5 y would be more reasonable.

Although intuitively appealing, relative biomass projections can be problematic. As with all models, sensitivity to parameter values and the capacity to estimate these values empirically are issues that must be resolved. It is almost trivially obvious that a model dependent on catch loses its reliability when a large proportion of the catch remains unaccounted. However, this is one of the major problems facing all Australian abalone fisheries. Factoring notional unaccounted catches into a model can be counterintuitive, because, as described above, historically large catches tend to provide less conservative projections. Consequently, we are planning to direct future research efforts to developing robust methods for estimating illegal catches.

Our model outputs highlight the important drawback with constant harvest strategies that, when biomass is declining, the TAC represents an ever-increasing proportion of the available stock (Perry et al. 1999). In the absence of timely management intervention, it is reasonable to expect declines in biomass to accelerate under quota management until some threshold is passed, and the stock suddenly collapses. The modeling also shows that the introduction of quotas was not responsible for arresting declining biomass. The slowing of biomass depletion resulted from diver attrition during the 1960s and 1970s when, due to low beach prices and the introduction of fees, many Victorian divers decided there were insufficient incentives to continue fishing. A constant rate of fishing mortality may seem a better option than quotas, and this is commonly used in scale fisheries. McAllister and Kirkwoood (1998) found that effort control management options outperformed catch control options in simulations by providing 40% more catch for the same risk of stock depletion. However, this approach increases the complexity and intensity of management decisions (Perry et al. 1999)

Although relative biomass seems to offer the most promise for developing abalone reference points, in the short term there must be alternative pathways when the quantity and quality of available data inputs and parameter estimates are poor or model assumptions are substantially violated (Walters 1998). Reference points must embrace not only model outputs but also other factors that are not modeled. For example, until we have sufficient data to disaggregate our model spatially, we require reference points suitable for addressing fine-scale changes in stocks at the scale of bays and headlands. Reference points also must be sufficiently diverse to provide empirical alternatives as reality checks on models.

The use of effort as an indicator of stock status may be of benefit under such circumstances; however, spatial and temporal shifts in effort must be treated cautiously so that reasons unrelated to the state of the resource can be eliminated. The Tasmanian observations on the application of such nonbiological indicators as patterns in catch underscore the importance of careful selection of temporal baselines and the need for analysis on the finest spatial scale practicable. It may be possible, however, to use average values of daily catch expectation and aggregate days of effort per reef as performance triggers that initiate management action when some predetermined threshold is passed. Indeed, Walters (1998) makes the point that there is potential for novel indicators of overexploitation to be developed based on the detailed information available in catch statistics. We believe the spatial resolution in catch and effort data has yet to be used to its full potential in managing abalone fisheries.

The adoption of multispecies approaches, focusing on so-called

keystone species in addition to the target species is a noble and possibly essential goal. However, our current survey techniques are already costly and, consequently, can only accommodate abundance estimates of relatively few organisms. It is unclear how we can attempt to model abalone ecosystems until we have a better understanding of density dependence, interspecific competition, and trophic interactions.

Whatever reference points are adopted for the Victorian fishery and incorporated into its management plan, involvement of stakeholders will be a critical part of the reference point selection process to ensure that triggers and targets are meaningful and of practical value. An inclusive process of involving stakeholders in the prenegotiation of reference points is also required to ensure consensus about management prescriptions (Caddy 1998). Without ownership of the management process by stakeholders, compliance and reporting problems will prevail under adverse circumstances. Access license owners will be wary of providing any information that they perceive may decrease the value of their entitlement, both in direct monetary terms and as a mortgageable asset. Contract divers (and processors) make their money on the quantity of quota they can negotiate to catch on behalf of license owners. Understandably, their focus is on the short- rather than the long-term situation; hence, a rush on declining stocks to get the most out while still able would be inevitable.

The establishment of a suite of empirical and model-based reference points within an agreed decision-making framework in a management plan underpinned by comprehensive catch and effort reporting and broad-scale fishery and habitat monitoring should ensure that the Victorian abalone fishery satisfies the ecological sustainability requirements of Commonwealth legislation. As a secondary benefit, this may provide the Victorian abalone industry with a competitive edge in marketing its products as "environmentally friendly."

ACKNOWLEDGMENTS

This work was funded by the Abalone Assessment Subprogram, conducted by the Marine and Freshwater Resources Institute on behalf of Fisheries Victoria. Discussions with Australian colleagues were invaluable in helping to form the opinions expressed in the manuscript (for which we are solely responsible) and for this, they deserve generous thanks. Cameron Dixon is thanked for assistance in the processing and analysis of catch and effort data and the production of tables and figures. An anonymous reviewer provided helpful suggestions to improve the manuscript.

TOWARD ASSESSING THE SOUTH AFRICAN ABALONE *HALIOTIS MIDAE* STOCK USING AN AGE-STRUCTURED PRODUCTION MODEL

ÉVA E. PLAGÁNYI,* DOUGLAS S. BUTTERWORTH, AND ANABELA BRANDÃO

MARAM (Marine Resource Assessment and Management Group), Department of Mathematics and Applied Mathematics, University of Cape Town, Rondebosch 7701, South Africa

ABSTRACT A deterministic age-structured model is developed for use in estimating resource dynamics parameters and projecting biomass trends for the South African abalone *Haliotis midae*. This constitutes the first quantitative approach applied to the management of this commercially valuable resource. The model focuses on one of seven commercial fishing zones, zone C, because particular concerns have been expressed about the status of the resource in this region, *inter alia* because of the considerable catches taken by the illegal fishing sector. The modeling approach is summarized, and some preliminary results from a single application of the model are given. Model parameters including the pre-exploitation spawning biomass B_0^y, the present annual poaching take CP_{max} and the natural mortality M, are estimated by fitting the model to CPUE data for the period 1980 to 1998, Fishery-Independent Abalone Survey (FIAS) abundance data as well as several years of catch-at-age data for each of various components of the fishery. The CPUE data are standardized using a general linear model, and zone C is split into two "linked" areas, a "poached" and "nonpoached" subarea with common resource dynamics parameters but separate fishing histories. This was necessary because of substantial differences in both the relative abundance trends and catch-at-age information for these two areas. Model results suggest that the resource in the "poached" and "nonpoached" areas of zone C is presently at ca. 1% and 85%, respectively of its pre-exploitation level (B_0^y = 3,360 and 1,580 tons, respectively). The model-estimated annual poaching catch for zone C from 1995 to 1998 (240 tons) exceeds the annual commercial catch in zone C over this period. The model indicates that the maximum sustainable yield (MSY) is reduced by more than one-third if catches include the proportion of animals substantially smaller than the minimum legal-size limit thought to be taken by poachers. Model predictions should be interpreted with caution, because more work needs to be done to improve and evaluate the confidence that can be attached to model predictions and to refine the structure and assumptions of the model. A number of associated suggestions are presented.

KEY WORDS: *Haliotis midae*, abalone stock assessment, age-structured production model

INTRODUCTION

The South African abalone fishery is one of the oldest commercial abalone fisheries in the world, with commercial catch data having been recorded since 1953. The fishery is reliant on a single species, *Haliotis midae*, which is restricted to shallow habitats in beds of kelp, *Ecklonia maxima* (Tarr 1993). Aspects of the biology, including growth, reproduction, and movement, have been well studied and Tarr (1993) summarizes a broad overview of the biology of *H. midae*. A description of the fishery is presented in Tarr (1992) and Tarr (in press). Briefly, the commercially fished area has been divided into seven fishing zones, with total allowable catches (TACs) set separately for each zone over the last 13 y. The main fishing areas are zones A–D (Fig. 1). Uncertainty and concern have been expressed regarding the status of the abalone resource, which is subject to particularly high levels of illegal fishing and an ever-increasing number of recreational divers (Tarr in press). The magnitude of the catch taken by the illegal sector is unknown, and it is difficult to estimate in the field because of the evasive behavior of the illegal fishers (poachers). Spokespersons for the illegal sector have claimed that their catch is approximately half that of the legal commercial fishery in the area. This study represents a first attempt to estimate the illegal catch in zone C by using an age-structured model that simulates plausible abalone resource dynamics. This model provides a basis used at present to develop management advice for this resource by projecting abundance trends under alternative future catch levels. The model is applied in the first instance to zone C because of the severe stock depletion thought to have occurred in this zone and, hence, the urgent need for a more rigorous quantitative stock assessment. Furthermore, the data for zone C exhibit more contrast than the data for the other zones, so that it seems sensible to apply the model first to this area, because the contrast suggests better potential for precise parameter estimation. Such estimated parameter values might be input to applications of the model to other zones where data contrast is insufficient to allow their independent estimation.

Several different stock assessment approaches have been used in abalone fishery management and a review of these is given in Breen (1992). One of the greatest impediments in the application of stock assessment models to abalone fisheries has been that such models usually rely on catch per unit effort (CPUE) data as an index of abundance. Several authors have stressed that CPUE is not a reliable index in situations where the stock is highly aggregated, as occurs for example off southeastern Australia (Breen 1992, Keesing & Baker 1998). We argue that CPUE data have utility in the South African context, especially when used in conjunction with a fishery-independent index. A second impediment to applying standard stock assessment models to abalone populations has been the lack of adequate data on aging. Tarr (1995) used a tagging study to estimate growth rates of *Haliotis midae*. This, in turn, allowed the age structure of catches to be estimated, and consequently, we were able to construct the first fully age-structured population model to assess the status and productivity of the South African resource. This approach could be adapted for use in other areas of the world once aging techniques are refined. The other major requirement would be the availability of a reliable index of abundance for the stock in question. Moreover, the population dynamics model would have to take account of spatial variability in regions characterized by great spatial variation in demography.

DATA

Several historic changes in the commencement and closure dates for the commercial fishing season (Moloney 1999) necessitated all available data being reworked in terms of a standard fishing year y that is taken to run from October of year y-1 to September of year y. Furthermore, previous analyses (e.g. Plagányi & Butterworth 1999) showed that it was difficult to interpret the abalone dynamics in zone C without consideration that the western and eastern areas of this zone differed with respect to both density and size composition (Figs. 2, a,b). For assessment purposes, zone C has, therefore, been split into a "poached" subarea (CP) to the west (Hawston/Mudge Point areas) and a "nonpoached" subarea (CNP) to the east (Hermanus vicinity) (Fig. 1). Although some poaching is still thought to occur in the "nonpoached" subarea, this is thought to be considerably less than that in the "poached" subarea. The two areas are approximately equivalent in terms of available habitat for abalone, because the kelp bed area estimates for areas CP and CNP are 1.38 and 1.59 million square meters, respectively (Tarr 1993). In terms of the length of coastline, CP is approximately half of CNP's length.

Total allowable catches for the commercial fishery were set individually for each of seven fishing zones A to G from the 1986–1987 season onward (Tarr 1992). Moreover, data on the commercial catch of abalone in zone C are available for the period 1977 to 1985. However, before 1972 catch data are available only for all zones (A–G) combined, and, hence, zone C catch estimates for the period 1953 to 1976 are assumed to be a fixed proportion p_c (27%) of this total annual catch, where p_c is the average of zone C's proportional contribution to total catch over the period 1977 to 1981. The same approach is used to apportion the zone C catch estimates for the period 1953 to 1976 between the two subareas CP and CNP. The resultant time series of total commercial catches for zone C as a whole are listed in Table 1.

Table 1 also shows recreational catches. These are estimated from telephonic surveys, conducted since 1992, of selected recreational permit-holders. Recreational catches before the 1990s are thought (Tarr, pers. comm.) to have been negligible relative to the commercial catch, so that a low fixed amount of 2 MT/y was assumed in the model. In contrast to the commercial fishery, where

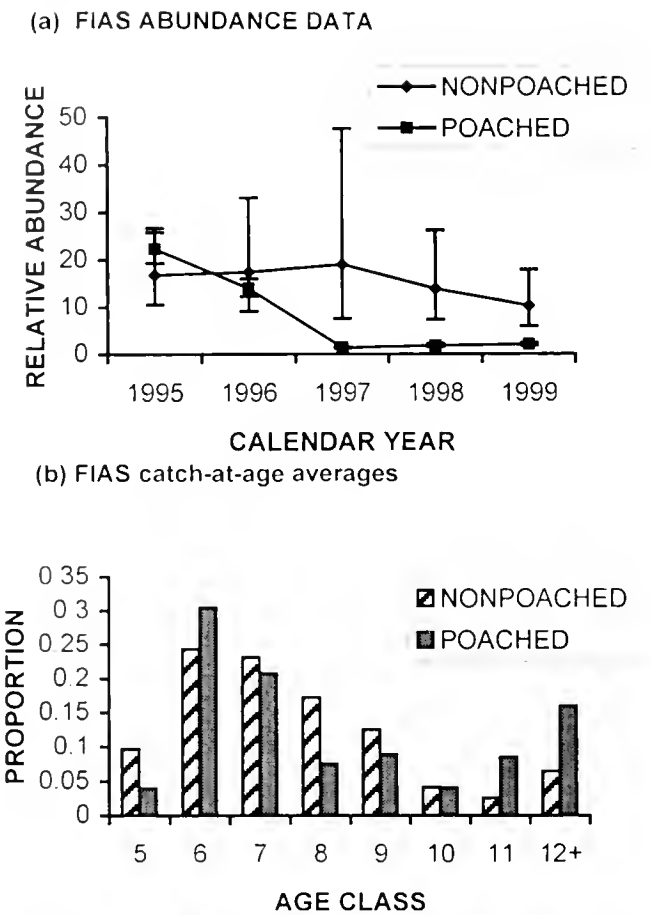

Figure 2. Comparisons between FIAS data obtained for the "poached" and "nonpoached" subareas of zone C. (a) shows the trend in the relative abundance index (average number $\bar{x}$ per 60 m^2) in each subarea. The error bars indicate the 95% confidence intervals calculated as $\bar{x} * e^{\pm 1.96 \cdot CV}$; i.e., assuming a log-normal error distribution. (b) compares the catch-at-age data averaged over the period 1995–1999. The catch-at-age data are derived from length distribution data (from A. McKenzie, MCM, RSA) that is cohort-sliced using a von Bertalanffy growth curve (Tarr 1995).

a law in force since 1966 prohibits commercial abalone fishing operations within 185 m of the high-water mark (Dichmont et al. 2000), the recreational fishery is essentially a shallow-water fishery with divers accessing the resource mostly from the shore. The relative proportions of the zone C recreational catch taken from the two subareas CP and CNP was, therefore, assumed to be proportional to the relative lengths of the coastline (CP:CNP = 1:2).

Total annual catch in each of the zone C subareas is calculated in the model as the sum of the commercial, recreational, and model-estimated poached catches. Analysis of the proportion of the total commercial catch caught during a season indicates that the majority of commercial catches are landed during the first two quarters of the fishing year (i.e., October to March) (Table 2). The fishery is, therefore, modeled as a pulse catch after the first quarter of the fishing year; i.e., at the start of the calendar year. Before 1985, an overall catch limit was allocated for abalone and recorded by calendar year (Dichmont et al. 2000) so that the proportion of the total catch taken in the last quarter of a calendar year was relatively minor (Table 2). Therefore, it may safely be assumed that no adjustment is necessary to equate catches recorded for a

Fishing years are taken to run from October to September, so that 1998 (for example) refers to the period October 1997 to September 1998. The last column shows the estimated catch (MT) by recreational permit holders in Zone C (data from Moloney 1999), where catch biomass was calculated by multiplying numbers by 0.7 kg, the average mass of an abalone of the minimum legal size. Strictly this average mass is somewhat larger, and could be evaluated using the estimated recreational fishing selectivity function (see Table 7), but this complication has been ignored for this initial analysis.

calendar year before 1980 with the catch corresponding to a fishing year running from October to September.

The recreational fishing season during the early 1990s ran from November to July, but as a result of large increases in the recreational catch, the recreational fishing season was reduced from 9 to 6 mo (1 November–30 April) in 1996–1997 and then reduced further to 4 mo (12 December–13 April) as from 1997–1998 and restricted to weekend and public holidays only from the 1998–1999 season (A. MacKenzie pers. comm.). From a modeling perspective, the implications of the recreational fishing seasons are that no adjustments are necessary to equate recreational catch estimates with the catch corresponding to a fishing year as defined above. Moreover, because most recreational fishing is likely to take place during the austral summer months, it seems reasonable to model the recreational catch also as a pulse catch after the first quarter of the fishing year. The same approach is used to model the poaching catch, supported by the observation (A. MacKenzie, pers. comm.) of a slight decrease in poaching confiscations during the winter months.

An important additional data source for the abalone resource is the Fishery-Independent Abalone Surveys (FIAS) conducted since 1995 (Table 3). These surveys were designed to provide an index of relative abundance with a CV of some 25% (which is substantially more precise than that achieved in earlier surveys) (Dichmont et al. 2000). The surveys involve twenty equidistant transects of 30-m length that run perpendicular to the shore in each of zones A–D, F, and Dyer Island. Two divers count and measure abalone encountered within a 1-m swath on either side of the transect. Only animals larger than 100 mm shell length are recorded so as to reduce uncertainty in the estimates attributable to the nonemergent/cryptic behavior of juveniles. This corresponds to a minimum sampling age of approximately 5 y. Because the "poached" subarea CP includes only approximately one-third of zone C's coastline, 6 of the 20 FIAS transects are located within subarea CP versus the 14 transects located within subarea CNP. This obviously has some implications on the CVs attached to the "split" estimates, with CVs in subarea CP ranging between 38–67% versus 24–47% for CNP (Table 3).

Data Used in the Model-Fitting Process

The population model is fitted to standardized CPUE data available for the period 1980–1998 for each of the two subareas constituting zone C (Table 4) as well as to the available FIAS data for each of the two subareas (Table 3). The catch-at-age data used in the model-fitting process are given in Tables 5a–e and include all available data from the commercial, recreational, poaching, and fishery-independent sectors. The catch-at-age data are derived from length distribution data (from A. McKenzie, MCM, RSA) personal communication that are cohort-sliced using a von Bertalanffy growth curve (from Tarr 1995) that was fitted to tagging data. In several instances, age classes have been lumped together to reduce the number of categories containing a proportional abundance of less than 2% in any one year.

METHODS

Standardizing the CPUE Data

A general linear model (GLM) was used to standardize the commercial abalone CPUE time series of abalone for the influence of other factors on the CPUE apart from resource abundance. The

Fishing years y are taken to run from October of year y-1 to September of year y.

explanatory variables included in the GLM were those selected by Moloney (1999). The same is true for the interaction terms in the model. The purpose of refitting a GLM to the abalone data was to update Moloney's results to allow for splitting zone C into two subareas (CP and CNP), and for the fact the "fishing year" has been changed from a calendar year to a year running from October through to September.

The GLM model applied is given by:

$$\ln(CPUE) = \mu + \alpha_{year} + \beta_{season} + \varphi_{holder} + \gamma_{zone} + \eta_{year \cdot season} + \delta_{year \times zone} + \varepsilon_1$$

where μ is the intercept; *year* is a categorical variable associated with a year (i.e., abundance) effect (1980–1998); *season* is a cat-

Fishing years are taken to run from October to September. Note that the reason the standard values are rather lower in absolute terms than the nominal values is that the former have been standardised in terms of entitlement holder no. 1, who happens to be one of the less efficient operators.

Proportions in each age class calculated using age-slicing matrix from Moloney (1999). Note: data lacking for years 1983 and 1984.

The Age-Structured Production Model

The age-structured production model (ASPM) applied is detailed in the Appendix. Because different sectors of the fishery exhibit different selectivity patterns with age, the following four sectors are explicitly differentiated in the model: the commercial fishery sector (mostly offshore); the recreational sector (mostly inshore); the poaching/illegal sector (mostly inshore) and the fishery-independent survey (inshore).

The two subareas constituting zone C are assumed to have identical values for resource dynamics parameters, such as the natural mortality rate M, but to have different catch histories. Two separate pre-exploitation spawning biomasses ($B_0^{yr}[CP]$ and $B_0^{yr}[CNP]$) are estimated in the model. Abalone are broadcast spawners (Tarr 1993), and although it is presently not known to what extent larval mixing occurs throughout the main fishing area, larval and postlarval stages are most likely retained in areas close to the parental population with some larval interchange between adjacent areas. McShane (1992) presented evidence for localized dispersal of larval *Haliotis rubra*. In this initial formulation of the model, the recruitment levels for each of the two zone C subareas are calculated separately. This aspect is explored further in future work.

The annual zone C catch by the illegal sector C_y^{poach} is modeled by assuming that C_y^{poach} increases linearly from a value of zero in 1991 to a maximum value of $CP_{\max}$ tons in 1995, whereafter C_y^{poach} stays constant at this value. The assumptions implicit in this representation are based on both admissions by spokespersons for the poaching sector and well as data from police and fisheries enforcement officers on confiscations of abalone (A. Mackenzie pers. comm.). A separate (year-independent) model parameter p_{poach} defines the relative proportions of the poached catch taken from each of the two subareas. The base-case model assumes that a fixed low proportion ($p_{poach} = 0.1$) of the poaching catch originates from the "nonpoached" subarea. The sensitivity of the model to this assumption is tested.

The minimum legal size limit of abalone is a shell width of 114 mm, which corresponds to an age of 8 y (Tarr 1995). Analysis of confiscated abalone samples recovered from the illegal sector (Table 5d) suggests that the minimum age of individuals caught by this sector is approximately 4–5 y. A particular advantage of using an age-structured (or length-structured) model to assess the dynamics of the resource is that proper account is taken of the fact that the illegal catch component includes animals of sublegal size, which can have important consequences for resource trends. The base-case selectivity functions applied in the model, and the procedure applied to estimate the values of their parameters, are described in the Appendix.

RESULTS

GLM Model Implementation

Commercial data obtained from divers between the years 1980 and 1998 were used to perform the GLM analysis. Following the removal of outliers (1% of total) based upon observations with large residuals in an initial GLM fit, a total of 34–189 data points remained for the analysis. The residuals for the subsequent GLM

Note "year" is calendar year not fishing year, but as explained in the text these are assumed equivalent for present purposes. The proportions in age classes 12 to 15+ have been lumped together to reduce the number of categories containing a proportional abundance less than 2% in any one year.

were further examined to check, in particular, for evidence of heteroscedasticity. Figure 3 shows evidence for larger residuals associated with lower effort. To account for this heteroscedasticity, the iterative procedure used by Glazer (1999) was used to develop a weighted GLM, where the weights are the inverse of the variance, $1/\sigma_i^2$, where the assumption is made that $\sigma_i^2 = a + b/E_i$, with E_i the effort (dive time) for observation i. The resultant maximum likelihood estimates for a and b are 0.8 and 20.5 min, respectively. Full results of the GLM analysis are presented in Plagányi and Butterworth (2000). A summary of the increases in r^2 achieved as the explanatory variables were added to and removed from models in turn is presented in Table 6. Approximately 43% of the total variation is explained by the model. The nominal and standardized CPUE indices are shown in Table 4, and Figure 4 shows a comparison between the standardized CPUE trends computed for the two subareas CP and CNP.

The ASPM

Model parameter estimates as well as log-likelihood contributions are summarized in Table 7, for the base-case scenario and for each of four preliminary sensitivity tests. Sensitivity scenario I tests the effect of reducing the value of the parameter h, which determines the "steepness" of the stock–recruit relationship, from 0.7 to 0.6. This direction of change was specifically chosen, because it effectively reduces the fraction of pristine recruitment that results when spawning biomass drops; i.e., increases the possibility of recruitment overfishing. Sensitivity scenario II is a single test of changing the assumption that only a small proportion ($p_{poach} = 0.1$) of the total zone C poaching takes place in subarea CNP. Sensitivity scenario III provides an example of model results under the assumption that natural mortality M is age dependent (versus age independent, as in the base-case). The age-specific natural mortality M_a in this scenario was estimated using the following simplified functional form:

$$M_a = c_1 + \frac{c_2}{a+1} \qquad (1)$$

where constant c_1 is estimated in the model-fitting process, and constant c_2 set equal to 0.3 for present purposes. Finally, sensitivity scenario IV shows the base-case results obtained before down-weighting the catch-at-age $-\ln L$ contributions as detailed in the Appendix.

The base-case scenario presented in this paper is intended purely for illustrative purposes, and the fits obtained for each subarea to both the CPUE data and the FIAS data are shown in Figures 5a and b. Model results suggest a pristine spawning biomass, B_0^y, of 1,580 and 3,360 tons, respectively, for subareas CNP and CP. The base-case estimate of M is 0.15 yr^{-1}.

The base-case selectivity estimates are illustrated in Figure 6. The estimated commercial and recreational selectivity functions reflect the fact that the minimum legal size corresponds to an age of approximately 8 y; whereas, the estimated poaching selectivity function reflects the fact that sublegal animals are caught. Because the FIAS transects are situated inshore, the estimated FIAS selectivity function (Fig. 6) concurs with the observation of Tarr (1993) that the mean size of *H. midae* increases with depth.

The model estimated an initial steep decline in the spawning biomass of abalone, particularly in subarea CP (Fig. 7), as a result

Note that the "year" indicated refers to a fishing year as defined in the model.

of the high historic exploitation levels in the 1960s (Fig. 8). A slight recovery of the stock level is estimated to have occurred during the 1980s, followed by a relatively stable trend in subarea CNP and a marked downward trend in subarea CP in recent years. The estimate of $CP_{\max}$ furnished by the base-case model was 240 tons, which is greater than the commercial take during the 1990s. Based on the results of the base-case model scenario, the current spawning biomasses of abalone in the "nonpoached" and "poached" areas of zone C are estimated at *ca.* 85% and 17%, respectively, of their pre-exploitation levels, expressed in terms of the spawning biomass B_0^y.

Assuming commercial selectivity, the estimated maximum sustainable yields MSY for abalone are 136 and 289 tons per annum, respectively, for subareas CNP and CP (Table 7; Fig. 8), with a combined zone C estimate of 425 tons per annum and $F_{MSY} = 0.28$. However, if sublegal animals are caught, sustainable yields will be less than this. The estimated MSY assuming poaching selectivity for abalone in zone C is 272 tons per annum (Fig. 8). Assuming poaching selectivity, comparison of the best estimate of MSY with total catch estimates (Fig. 8), suggests that catches probably exceeded replacement yields from about 1993, resulting in a decrease in stock biomass.

Comparisons between observed and model-predicted catch-at-age estimates are illustrated graphically in Figure 9. For ease of viewing, the observations and estimates have been averaged over all years for which data exist.

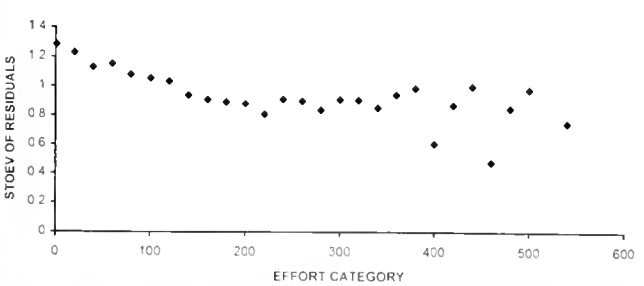

Figure 3. Plot of the standard deviation of the residuals (corresponding to an initial GLM fit of the data) versus effort (min). To take account of this heteroscedasticity, a weighted GLM was developed as described in the text.

DISCUSSION

The same general pattern of an increase in standardized catch rates during the 1980s, followed by a decrease during the 1990s is evident in both subareas (Fig. 4). The observed decline in both catch rates and the fishery independent abundance index (Fig. 2) in subarea CP is particularly steep, and it has been recognized for some time that continued depletion of the resource in zone C is inevitable, unless catches by all sectors continue to be drastically reduced (e.g., Plagányi & Butterworth 1999). Considering that total catches in zone C in the 1960s were substantially greater than those taken in the 1970s and 1980s (Fig. 8) (this hardly seems likely not to have been the case, although the details of the zonal-partitioning of catches assumed above could be in error to some extent), it is not too surprising that the CPUE trend shows an increase toward the end of the 1980s (Fig. 4). This is the obvious explanation for the observed increase in CPUE estimates during the 1980s, despite perceived increases in over-all catch levels over

TABLE 6.

Summary of the results of the GLM analysis showing r^2 as a function of sequentially including the variables shown below in the model.

Model variables	r^2
s	0.075
z	0.102
h	0.162
y	0.144
y, z	0.225
y, s	0.168
y, h	0.286
y, h, s	0.307
y, h, z	0.352
y, h, z, s	0.369
y, h, z, s, $y^* z$	0.411
y, h, z, s, $y^* s$	0.398
y, h, z, s, $y^* z$, $y^* s$	0.426

The variables are abbreviated as follows: y = year (1980–1998), s = season (1–4), z = zone/subarea (A, B, CNP, CP, D), h = entitlement holder (1–84).

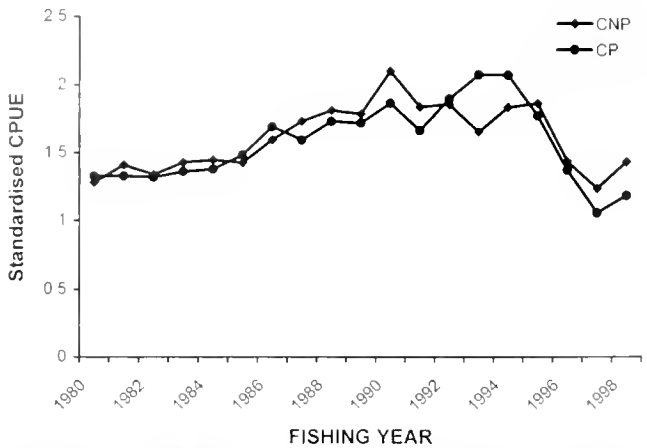

Figure 4. Comparison between the standardized catch-per-unit-effort (CPUE) trends for the "poached" (CP) and "nonpoached" (CNP) subareas of zone C. Values are derived from an iterative effort weighted GLM (see text).

this period (Tarr 1993). It is to be expected from a relatively slow-growing long-lived resource afforded a respite as high and unsustainable historic catch levels are reduced substantially to below the then current sustainable yields. If we assume that the CPUE trend in zone C is a reasonable index of stock abundance, this suggests that; whereas, the zone C commercial take during at least some of the 1970s and 1980s was below sustainable yield (SY) levels, total catches during the 1990s have again exceeded such yields, resulting in a concomitant decline in CPUE values over this most recent period. This recent decline in CPUE is fully consistent with catch data only if the latter are considered to include the considerable poaching component of the over-all catches over recent years as estimated by the model.

The similarities in the catchability coefficient estimates $\hat{q}^{CPUE}[CP]$ and $\hat{q}^{CPUE}[CNP]$ (Table 7) for the two subareas are as expected, given the approximately equal habitat areas and the similarities in the standardized catch rates over much of the 1980s (Fig. 4). The difference in the pristine spawning biomass estimates $B_0^{yp}[CNP]$ and $B_0^{yp}[CP]$ (Table 7) are, in the main, attributable to the partitioning of the historic zone C catch data between the two subareas.

The estimated poaching catches are substantial in all of the scenarios investigated in this analysis (Table 7), despite the fact that the recent steep decreases in the FIAS data are not adequately reproduced by any of the model scenarios. It is important to note that the inability of the model to simulate the trends in the FIAS data successfully, particularly the steep decline in subarea CP, suggests that pending further analyses, model estimates are likely to be positively biased.

The inadequate fit of the model to the FIAS data (Fig. 5) may, in part, be explained by the fact that since 1994, there has been a dramatic decrease in young abalone (5–40 mm) found during diving surveys in zones C and D (Tarr et al. 1996). This has been ascribed to a decrease in the abundance of sea urchins (in turn caused by an increase in the abundance of the rock lobster—an important predator on urchins). Young abalone shelter and feed under sea urchins; hence, it has been proposed that these multispecies interactions are resulting in substantially reduced abalone recruitment (Tarr et al. 1996). This factor is ignored in the current model, but needs to be investigated further (see Future Work). It should be noted, however, that only animals older than approximately 5 y are sampled on the FIAS transects; thus, there is at least a 5-y time lag before the effects of a recruitment failure are manifest in the data.

Comparisons of the log-likelihood contributions for the base-case and scenarios I–IV (Table 7) suggest that the main conflict in the model fits is between the fit to the CPUE data for the poached subarea and the catch-at-age data for the recreational sector. FIAS (poached subarea in particular, see, e.g., Fig. 9) and poaching sector to a lesser extent. In these instances, an improved fit to the CPUE data (i.e., a decrease in the log-likelihood and $\hat{\sigma}$ values) results in a sacrifice to the fit to the catch-at-age data. The fact that the CPUE (CP) and age data are pushing in different directions requires further consideration.

The base-case estimates of the ratios $B_0^{yp}(98)/B_0^{yp}(53)$ are 0.85 and 0.17 for subareas CP and CNP, respectively, but these estimates varied substantially across the various model scenarios. This stresses the importance of refining the estimate of h, for example, as well as investigating further the model's sensitivity to the assumption that natural mortality is age independent. The use of an age-dependent mortality function versus an age-independent mortality value is particularly important because of, among other things, the sensitivity of the estimated MSY values to this assumption (Table 7).

The results discussed above follow only given the CPUE data, but the appropriateness or otherwise of using CPUE data as an index of abalone stock abundance has in the past been questioned both in the South African context and elsewhere in the world. There are a number of reasons why CPUE may be a reasonable index of abalone stock abundance in the South African context but not necessarily elsewhere in the world. The major South African abalone fishery is located in shallow kelp bed areas, relatively close inshore, along a stretch of coastline measuring less than a hundred kilometers and with relatively easy access to most of the areas (R. Tarr pers. comm.). Furthermore, the 10 or so launching sites currently in use along this coastline are exactly the same sites that were in use during the 1950s when the fishery began; hence, fishers have fished fairly evenly throughout the area. Even if very large aggregations existed in the past, the resource was so heavily fished during the 1960s that these would since have been reduced substantially; hence, the effect of spatial patchiness dampened to a large extent. Moreover, fishing effort is spread over most of the major fishing zones so that the general pattern of diver behavior is not one in which new aggregations are sought out and then sequentially depleted so that catch rates remain fairly stable, despite the resource abundance declining, as has been demonstrated for fisheries off Australia (Shepherd & Baker 1998), California (Tegner et al. 1989), and Mexico (Prince & Guamán del Próo 1993). It is now well established that in such areas as South Australia and Tasmania, the spatial variation in density is such that, coupled with the added complexities of diver behavior, CPUE cannot be considered a reliable indicator of stock abundance (Breen 1986, Prince 1992, Shepherd et al. 1992, Keesing & Baker 1998, Worthington & Andrew 1998). As proposed by Dichmont et al. (2000) one option available to resource managers with some confidence in CPUE as an index of abundance for their fishery, is to use a dynamic model tuned to both CPUE data and also a survey index.

The FIAS data series not only provide a valuable independent index of abundance but are also useful, because they include information on abalone from age 5 upward compared with the CPUE data, which captures information on animals aged approximately 8 y or more. This means that the FIAS abundance index is

TABLE 7.

Best fit estimates of the pre-exploitation spawning biomass B_0^{sp} for the "poached" CP and "nonpoached" CNP areas of zone C, the estimated natural mortality estimate M and the poaching maximum CP_{max}, where the proportion of CP_{max} from area CNP is fixed at 0.1 in the base-case.

Minimum values of the negative of the log-likelihood function and estimated current depletion are also shown. The estimated selectivity parameters are shown for the commercial sector (CS), recreational sector (RS), poaching sector (PS) and FIAS (F). Values of σ are given in square brackets alongside the corresponding log-likelihood values.

more sensitive than the CPUE index (cf. Figs. 2 and 4) to changes in the younger age classes. This is particularly important in zone C, where extensive poaching of sublegal abalone individuals as well as a hypothesized multispecies effect (Tarr et al. 1996) have caused a rapid decline in the numbers of small individuals. Consequently, the FIAS data have indicated a more negative scenario than have the CPUE data and are, thereby, providing valuable clues as to the factors to consider in modeling the resource.

Finally, we reiterate that the inferences above are based on preliminary model results only. Coefficients of variation and confidence intervals remain to be calculated for the model estimates, and the sensitivity of the model to its assumptions and parameters must be examined. This paper is not, and does not pretend to be a thorough and complete analysis. Rather it is intended as a description of the stock assessment approach being applied in South Africa, motivated by the fact that it currently differs from approaches in practice elsewhere in the world for abalone resources.

Planned Future Work

Some of the issues to be addressed in future work are outlined below.

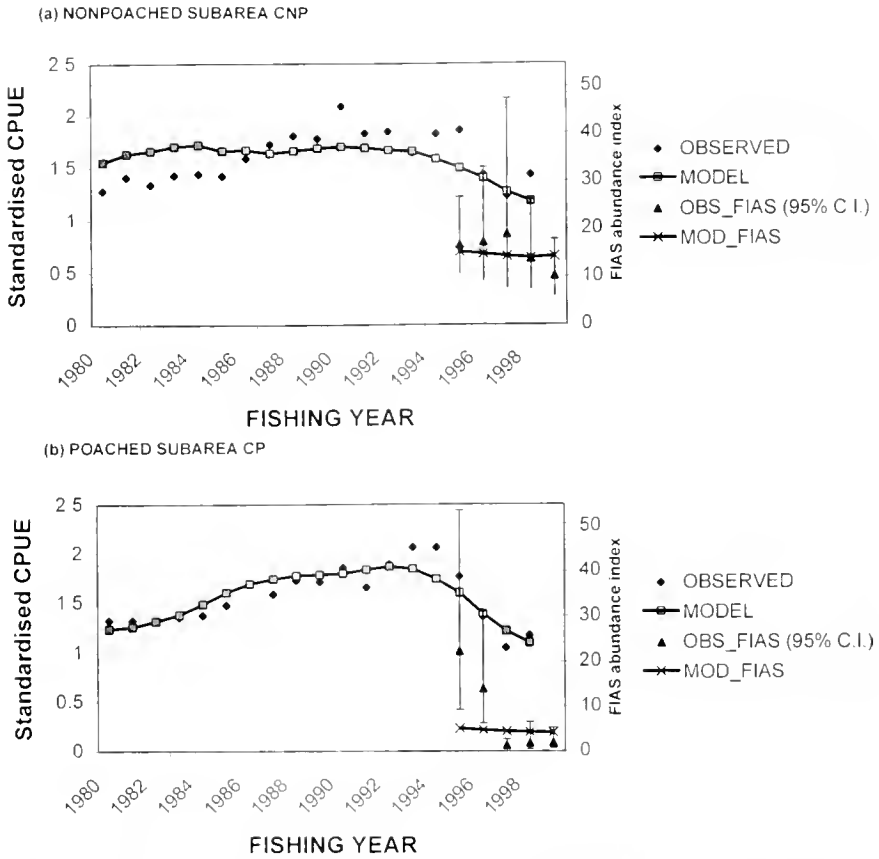

Figure 5. Comparisons between the standardized CPUE and model-predicted CPUE values (from the base-case scenario) for each of subareas CNP (a) and CP (b). The base-case model fit to the FIAS data is also shown. The 95% confidence intervals shown for the observed FIAS data were calculated as $\bar{x} * e^{\pm 1.96 \cdot CV}$.

Sensitivity to variability/changes in the following assumptions must be investigated:

1. the proportions of the all-zone annual commercial catches before 1977 allocated to zone C (currently a fixed proportion of 27% for all such years) as well as the subsequent reallocation of these catches between subareas CNP and CP (24%: 76%, respectively, in the base-case model);
2. the years in which substantial poaching catches commenced (currently 1991), and reached their maximum (currently 1995);
3. the age at 100% sexual maturity (currently $a_m = 7$ yrs);
4. stock-recruitment function parameters (currently $h = 0.7$);
5. alternative choices of growth parameters (current values given in the Appendix);
6. trends in catchability (q) over time that could have resulted from improved efficiency; this could be effected by adjusting the input CPUE values by a multiplicative factor $e^{-\lambda y}$, where y is the year, and λ is a constant, with results being contrasted for different choices of λ; and
7. the assumed linear relationship between CPUE and biomass;

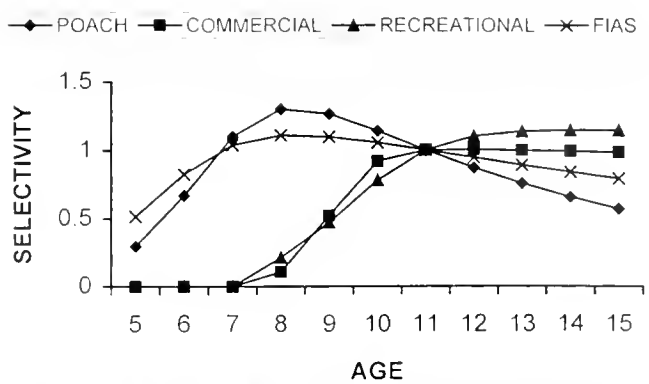

Figure 6. Plots of the base-case selectivity functions estimated for the commercial, recreational, and poaching fishery sectors, and for FIAS. A description of the general functional form used is given in the Appendix and the fitted parameter values listed in Table 7.

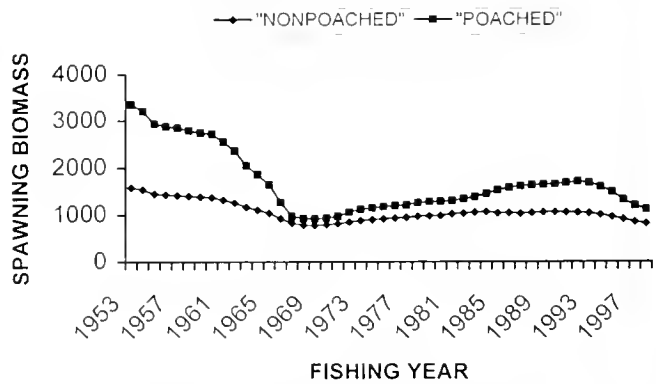

Figure 7. The base-case trend in the spawning biomass (tons) of abalone in the "nonpoached" (CNP) and "poached" (CP) subareas of zone C. The spawning biomass includes all animals older than a_m, the age corresponding to 100% sexual maturity (see Appendix).

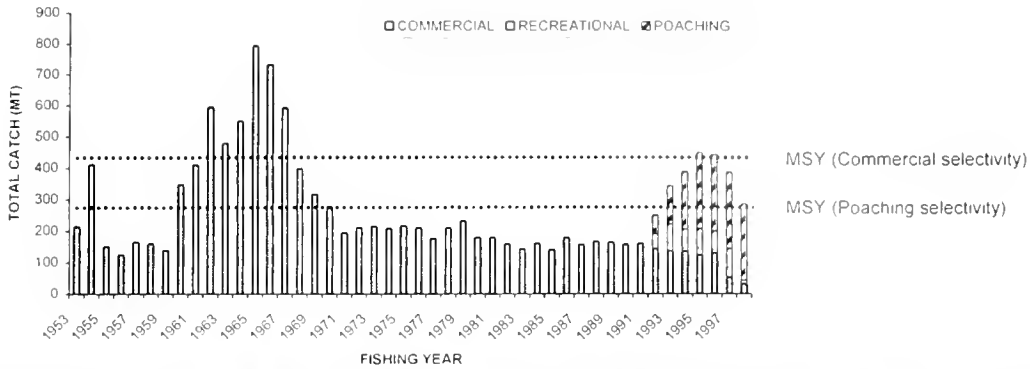

Figure 8. Comparison between the base-case zone C maximum sustainable yield (MSY) (tons) estimates [assuming either a commercial or a poaching selectivity function (see Fig. 6)] and total annual abalone catches (tons) over the period 1953 to 1998. The total catches shown include both the commercial and recreational catches from subareas CP and CNP combined, as well as the total poaching catch estimated in the base-case model.

this could be examined by, for example, exploring the consequences of an assumption such as CPUE proportional to square root (biomass), which implicitly incorporates the saturation effect possibilities raised by several authors.

In addition, likelihood-profile-based estimates of confidence intervals for model-estimated parameters must be calculated.

The model has been substantially revised from that applied in an earlier assessment to the abalone resource in the other main fishing zones (e.g., Plagányi & Butterworth 1999) and the revised version, therefore, must be applied to the other zones. This is not necessarily straightforward, because previous experience has shown that the data concerned do not necessarily support the es-

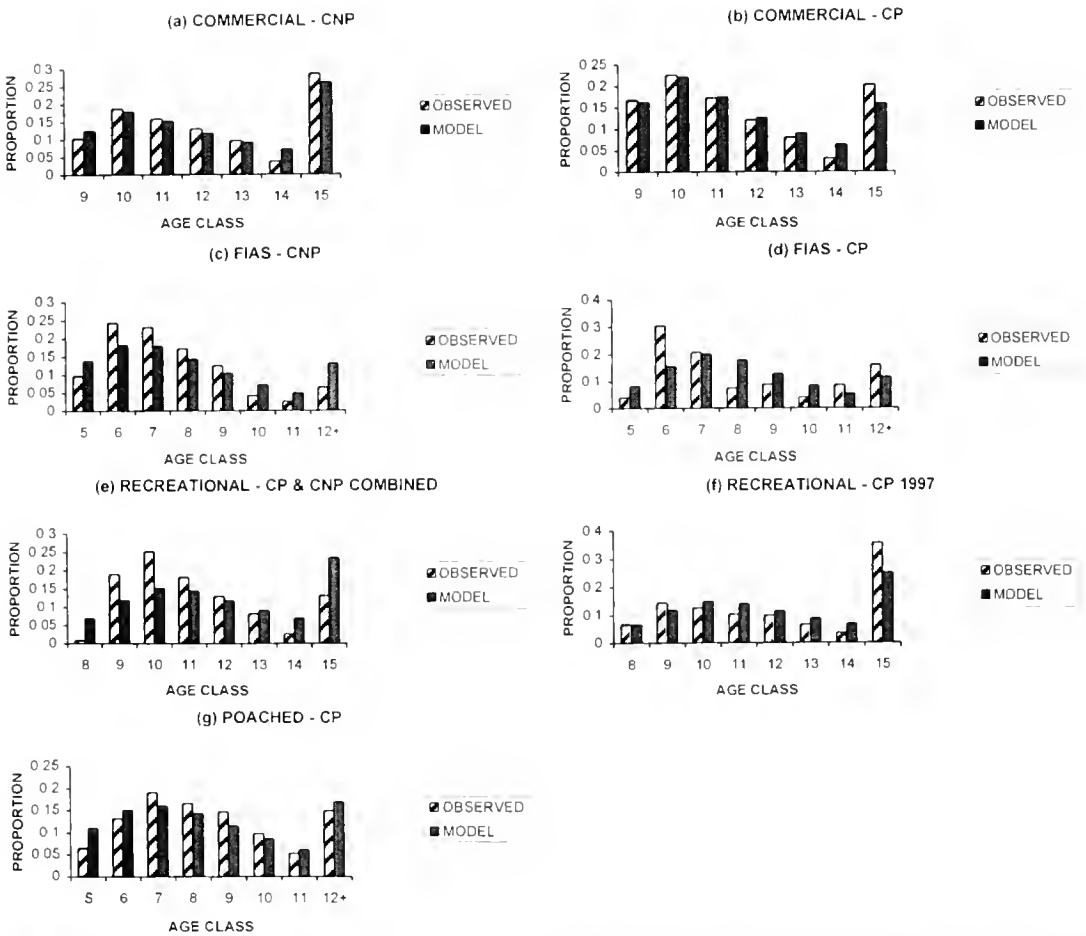

Figure 9. Plots showing the observed versus model-predicted catch-at-age estimates from FIAS and from the commercial, recreational, and poaching sectors. In all instances (except the 1997 recreational data, which is a single year's worth of data), the observations and estimates have been averaged over all years for which data exist (see Tables 5 a–e). The observed catch-at-age proportions were derived from length distribution data that was cohort-sliced using a von Bertalanffy growth curve (Tarr 1995).

timation of as many parameters, so that M (for example) might have to be fixed externally by using the estimate for zone C.

Matters to be pursued in the longer term include the following:

1. computing probability distributions for biomass projections under different future catch scenarios, taking uncertainty in the estimates of the model parameters B_0^{yr}, CP_{max}, and M into account;
2. investigating alternative functional forms for the stock recruitment relationship assumed as well as testing sensitivity to possible depensation effects at low biomass levels;
3. investigating various hypotheses as to the extent of mixing of the larval products throughout the commercial fishery zones;
4. consideration of the possibility (indeed, probability) that natural mortality M is not independent of age—the data are unlikely to support direct estimation of this age dependence, so this investigation will likely need to consider different external specifications; and
5. allowance for multispecies effects, such as a postulated recruitment decrease as a consequence of urchin reductions (Tarr et al. 1996), might be investigated. However, thorough prior discussion is first needed about whether there is a sound basis in the available data to distinguish the alternative hypotheses of a systematic trend in urchin numbers over the near 50-year history of the fishery, and of serially correlated fluctuations of an over-all stationary (i.e., trendless) process. If the latter is the case, the existing model may already make adequate implicit allowance for this, because the effects of such recruitment fluctuations could be integrated out given the large number of year classes in the population, although this should be checked by further quantitative evaluations.

ACKNOWLEDGMENTS

We are greatful to Rob Tarr, Angus Mackenzie, Paul Williams, and other staff of Marine and Coastal Management, South Africa for supplying much of the data upon which this paper was based. We are also indebted to Coleen Moloney for laying the groundwork for the GLM analyses.

APPENDIX

THE POPULATION MODEL USED FOR ESTIMATING RESOURCE DYNAMICS PARAMETERS AND PROJECTING BIOMASS TRENDS

The model applied is a deterministic age-structured production model.

Dynamics

$$N_{y+1,0} = R(B^{sp}_{y+1}) \tag{A1}$$

$$N_{y+1,a+1} = (N_{y,a}e^{-\frac{M}{4}} - C_{y,a})e^{-\frac{3M}{4}} \qquad 0 \le a \le z-2 \tag{A2}$$

$$N_{y+1,z} = (N_{y,z}e^{-\frac{M}{4}} - C_{y,z})e^{-\frac{3M}{4}} + (N_{y,z-1}e^{-\frac{M}{4}} - C_{y,z-1})e^{-\frac{3M}{4}} \tag{A3}$$

where

- $N_{y,a}$ is the number of abalone of age a at the start of fishing year y,
- $C_{y,a}$ is the total number of abalone of age a taken by the fishery, by recreationals and by poachers in fishing year y,
- $R(B^{sp})$ is the recruitment vs spawner biomass relationship assumed (see below),
- M is the natural mortality (assumed independent of age), and
- z is the largest age considered (i.e. corresponding to a "plus group").

The commercial abalone fishery season currently extends from October to June and a fishing year in the model is assumed to run from October to September. The approximation of the fishery as a pulse catch at the start of each calendar year is here considered of sufficient accuracy given that most of the catch is made over the October–March period (see Table 2), and because the annual catches from this long lived resource are not that large a fraction of the overall biomass. Equations (2) and (3) above have accordingly been modified to reflect the fact that catches are subtracted at the end of the first quarter of the fishing year. As the fisher-independent surveys are only conducted towards the end of the second quarter of the fishing year, comparisons with the observed FIAS data are made at time $y + \frac{1}{2}$ in terms of the model whereas comparisons with the remaining data are made at time $y + \frac{1}{4}$ in the model.

The subsistence sector of the fishery is ignored in the current analysis because it is a very recent participant and although no data on catches currently exist, the impact of this sector is presumed to be small. The subsistence sector could most easily be considered a subcomponent of the recreational sector, as although the subsistence sector is now permitted to sell its catch, they are essentially recreational fishers operating in shallow waters and with a fixed bag limit.

The total number of abalone of age a caught each year ($C_{y,a}$) is given by:

$$C_{y,a} = \sum_s C^s_{y,a} \tag{A4}$$

where s indicates the sector of the fishery (e.g. commercial, recreational, poaching).

The annual catch by mass (C^s_y) for sector s is given by:

$$C^s_y = \sum_{a=5}^{z} w_a C^s_{y,a} \tag{A5}$$

where w_a is the mass of an abalone of age a (to ignore clutter of subscripts, we ignore here that for the plus group mass $w_{y,z}$ is year dependent). The summation is taken from age $a = 5$ as no abalone of a size corresponding to ages below 5 are taken.

The mass-at-age is given by the combination of a von Bertalanffy growth equation and a mass-length relationship (where l refers to shell length in mm) (from Tarr 1995):

$$l(t) = l_\infty[1 - e^{-K(t-t_0)}] \tag{A6}$$

$$w_{y,a} = w(y, t = a) = c[0.913^{3\times}\, l(t) - 11.59]^d \tag{A7}$$

Note that mass-at-age is year-independent for abalone of age $a < z$ and that $w_{y,a+1/4} = w(y, t = a + 1/4)$ is computed for use in calculating the sector-specific exploitable biomasses after the first quarter (see below). However, the mass-at-age for the plus group varies over time, depending on the average age of the plus group in year y, $\bar{z}_y$, which is calculated as described below:

$$\bar{z}_y = \frac{(\bar{z}_{y-1} + 1)(N_{y,z} - C_{y,z})e^{-M} + z \cdot (N_{y,z-1} - C_{y,z-1})e^{-M}}{N_{y+1,z}} \tag{A8}$$

The above is an approximation only (as it ignores, e.g., the fact that catches are subtracted not at the start of the year but at the end of the first quarter of each year) but is considered sufficiently accurate for present purposes.

The sector-specific catch by mass in year y is given by:

$$C^s_y = \sum_{a=5}^{z} w_a N_{y,a} e^{-M \cdot \frac{1}{4}} S^s_a F^s_y \tag{A9}$$

where S^s_a is the fishing selectivity-at-age for sector s (this pattern is assumed not to change over time), and F^s_y is the fishing "mortality" (strictly here that proportion of the numbers present at the start of the calendar year which are caught) at a reference age, assumed for these computations to be $a = 11$ for all sectors. Based on data from A. Mackenzie (Marine & Coastal Management, pers comm), the minimum age of animals assumed caught by the poaching sector is 5 years, so that for this sector $S^s_a = 0$ for $a < 5$. The commercials and recreationals are both assumed not to catch animals below the legal size limit, so that for these sectors $S^s_a = 0$ for $a < 8$.

The sector-specific exploitable ("available") component of abundance is either in terms of exploitable biomass:

$$B^{exp,s}_y = \sum_{a=5}^{z} w_{y+1/4,a} S^s_a N_{y,a} e^{-M \cdot \frac{1}{4}} \tag{A10}$$

or "available" population numbers (in the case of FIAS, which for these purposes can be considered as another fishery sector s):

$$N^{exp,s}_y = \sum_{a=5}^{z} S^s_a N_{y,a} e^{-M \cdot \frac{1}{2}} \tag{A11}$$

The summation is from age $a = 5$ as only animals larger than 100 mm shell length are recorded so as to reduce uncertainty in the estimates due to the non-emergent/cryptic behaviour of juveniles. This corresponds to a minimum sampling age of approximately 5 years, so that for this sector $S^s_a = 0$ for $a < 5$.

The proportion of the resource harvested each year (F_y^s) by sector s is therefore given by:

$$F_y^s = C_y^s / B_y^{exp,s} \tag{A12}$$

where

$$C_{y,a}^s = S_a^s F_y^s N_{y,a} e^{-M \cdot 4} \tag{A13}$$

The annual zone C catch by the illegal sector C_y^{poach} is modelled by assuming that C_y^{poach} increases linearly from a value of zero in 1991 to a maximum value of $CP_{\max}$ tonnes in 1995, whereafter C_y^{poach} stays constant at this value. A separate (year-independent) model parameter p_{poach} defines the relative proportion of the poached catch that originates from the "nonpoached" subarea.

Spawning biomass—recruitment relationship

The spawning biomass of each subarea in year y is given by:

$$B_y^{sp} = \sum_{a=a_m}^{z} w_a N_{y,a} \tag{A14}$$

where a_m is the age corresponding to 100% sexual maturity, which is assumed here to be described by a knife-edge function with age.

The number of recruits in each of the two subareas at the start of fishing year y is related to the spawner stock size by a stock-recruitment relationship. A Beverton–Holt form is assumed, i.e.:

$$R(B_y^{sp}) = \frac{\alpha B_y^{sp}}{\beta + B_y^{sp}} \tag{A15}$$

In order to work with estimable parameters that are more meaningful biologically, the stock-recruit relationship is re-parameterised in terms of the pre-exploitation equilibrium spawning biomass, B_0^{sp}, and the "steepness" of the stock-recruit relationship, where "steepness" is the fraction of pristine recruitment that results when spawning biomass drops to 20% of its pristine level, ie.

$$hR_0 = R(0.2\ B_0^{sp}) \tag{A16}$$

from which it follows that:

$$h = 0.2[\beta + B_0^{sp}]/[\beta + 0.2\ B_0^{sp}] \tag{A17}$$

and hence:

$$\alpha = \frac{4hR_0}{5h - 1} \tag{A18}$$

and:

$$\beta = \frac{B_0^{sp}(1 - h)}{5h - 1} \tag{A19}$$

Biomass trajectories

Given a value for the pre-exploitation spawning biomass B_0^{sp} of abalone, together with the assumption of an initial equilibrium age structure, we have:

$$B_0^{sp} = R_0 e^{-Ma_m}\left[\sum_{a=a_m}^{z-1} w_a e^{-M(a-a_m)} + w_z e^{-M(z-a_m)}/(1 - e^{-M})\right] \tag{A20}$$

which can be solved for R_0. The initial numbers at age for the projections, corresponding to the deterministic equilibrium, are:

$$N_{0,a} = \begin{cases} R_0 e^{-Ma} & 0 \le a \le z-1 \\ R_0 e^{-Mz}/(1 - e^{-M}) & a = z \end{cases} \tag{A21}$$

Numbers-at-age for subsequent years are then computed by means of equations (1)–(20).

PARAMETER VALUES

Input parameters:

The following fixed parameter values used in the model are in the main based on estimates presented by Tarr (1993) and Tarr (1995):

$$\begin{aligned} l_\infty &= 173 \text{ mm} \\ \kappa &= 0.186 \text{ yr}^{-1} \\ t_0 &= 0 \text{ yr} \\ c &= 0.002 \text{ gm/cm}^{2.61} \\ d &= 2.61 \\ a_m &= 7 \end{aligned}$$

with the computations assuming a plus group at age $z = 15$ yrs.

Moreover, the base-case assumes that $p_{poach} = 0.1$ and that $h = 0.7$. The base-case value of the steepness parameter h corresponds roughly to the median ($h = 0.74$) of a distribution of h values for stock-recruit functions fitted to the fisheries stock recruitment database developed by R. A. Myers and colleagues (Myers *et al.* 1995), as advised by J. Ianelli (pers. comm).

Estimable parameters:

The sector-specific fishing selectivities S_a^s are assumed to follow the functional form:

$$S_a^s = \frac{P \cdot e^{-\mu a}}{1 + e^{-\delta(a - \tilde{a})}} \tag{A22}$$

where μ, δ and $\tilde{a}$ are three estimable parameters that control the shape of the function and P is simply a scalar fixed at a value such that $S_{11}^s = 1.00$. In essence, μ controls the slope of the right hand limb of the function, δ controls the steepness of the ascending left hand limb, and $\tilde{a}$ shifts the function to the left or right, all in relation to age a.

THE LIKELIHOOD FUNCTION

The likelihood function which is maximised in the parameter estimation process is based on equations developed by Geromont & Butterworth (1999). The model is fitted to abundance and catch-at-age data and the contributions by each of these to the negative of the log-likelihood ($-\ln L$) calculated as described below.

Abundance data:

The likelihood contribution is calculated assuming that the observed abundance index is log-normally distributed about its expected value:

$$I_y^s = \hat{I}_y^s e^{\varepsilon_y^s} \qquad \text{or} \qquad \varepsilon_y^s = \ln(I_y^s) - \ln(\hat{I}_y^s) \tag{A23}$$

where I_y^s is the abundance index for year y and sector s, $\hat{I}_y^s = q^s B_y^{exp,s}$ is the corresponding model estimated value, where $B_y^{exp,s}$ is the model value for exploitable resource biomass corresponding to sector s, given by equation (10) (if the index refers to numbers, $B_y^{exp,s}$ is replaced by $N_y^{exp,s}$–see equation (11)). q^s is the constant of proportionality for abundance series corresponding to sector s, and ε_y^s from $N(0,(\sigma^s)^2)$.

The contribution of the abundance data to the negative of the log-likelihood function (after removal of constants) is given then by:

$$-\ln L = \sum_{s}\left[\sum_{y} \ln \sigma_{s}^{y} + (\varepsilon_{s}^{y})^{2}/2(\sigma_{s}^{y})^{2}\right] \qquad \text{(A24)}$$

Variance unspecified: (CPUE abundance series)

In this case the standard deviation of the residuals for the logarithms of abundance series s is assumed to be independent of y, and is estimated in the fitting procedure by its maximum likelihood value:

$$\hat{\sigma}^{s} = \sqrt{\frac{1}{n_{s}}\sum_{y}(\ln I_{s}^{y} - \ln \hat{I}_{s}^{y})^{2}} \qquad \text{(A25)}$$

where n_s is the number of data points for the abundance series corresponding to sector s.

The catchability coefficient q^s for sector s's abundance index is estimated by its maximum likelihood value:

$$\ln \hat{q}^{s} = \frac{1}{n_{s}}\sum_{y}(\ln I_{s}^{y} - \ln \hat{B}_{s}^{\text{EXP}\,y}) \qquad \text{(A26)}$$

Variance specified: (FIAS data)

The catchability coefficient q^s for this sector's abundance index is estimated by its maximum likelihood value which, for the case of a log-normal error distribution is given by:

$$\ln \hat{q}^{s} = \frac{\sum_{y} 1/(\sigma_{s}^{y})^{2}(\ln I_{s}^{y} - \ln \hat{B}_{s}^{\text{EXP}\,y})}{\sum_{y} 1/(\sigma_{s}^{y})^{2}} \qquad \text{(A27)}$$

where $(\sigma_s^y)^2 = \ln(1 + (CV_s^y)^2)$ and the coefficient of variation (CV_s^y) of the resource abundance estimate for year y is input.

Catches-at-age:

The likelihood contribution is calculated assuming a log-normal error distribution and by making an adjustment (suggested by A. Punt, pers. comm.) to weight in inverse relation to sample size so that undue importance is not attached to data based upon a few samples only:

$$-\ln L = \sum_{y}\sum_{s}\sum_{a}\left[\ln\left(\sigma_{c}^{s}\sqrt{\hat{p}_{s,a}^{y}}\right) + \hat{p}_{s,a}^{y}\right.$$
$$\left.\left(\ln p_{s,a}^{y} - \ln \hat{p}_{s,a}^{y}\right)^{2}/2\left(\sigma_{c}^{s}\right)^{2}\right] \qquad \text{(A28)}$$

where $p_{s,a}^{y} = C_{s,a}^{y}/\sum_{a} C_{s,a}^{y}$ is the observed proportion of abalone caught/sampled by sector s in year y that are of age a, $\hat{p}_{s,a}^{y} = \hat{C}_{s,a}^{y}/\sum_{a} \hat{C}_{s,a}^{y}$ is the model-predicted proportion of abalone caught/sampled by sector s in year y that are of age a, where:

$$\hat{C}_{s,a}^{y} = N_{s,a}e^{-M/4}S_{a}^{s}F_{s}^{y} \qquad \text{A29}$$

and σ_c^s is the standard deviation associated with the catch-at-age data for sector s, estimated in the fitting procedure by:

$$\sigma_{c}^{s} = \sqrt{\sum_{y}\sum_{a}\hat{p}_{s,a}^{y}(\ln p_{s,a}^{y} - \ln \hat{p}_{s,a}^{y})^{2}/\sum_{y}\sum_{a}1} \qquad \text{(A30)}$$

Inspection of the various $-\ln L$ contributions revealed that the catch-at-age $-\ln L$ contributions were substantially larger than those for CPUE and the FIAS series, in part because they include many more data points because of summation over age as well as year. This is questionable as the $p_{s,a}^{y}$ values for a given y and s are not likely to be independent (as implicitly assumed by equation (28)), because the cohort-slicing method used to provide the catch-at-age information from length composition data likely introduces positive correlation. The catch-at-age $-\ln L$ contributions were thus downweighted by a multiplicative factor of 0.1, thereby downscaling these contributions to a similar order of magnitude as the CPUE and FIAS contributions.

Journal of Shellfish Research, Vol. 20, No. 2, 829–841, 2001.

SUSTAINABILITY DEMANDS VIGILANCE: EVIDENCE FOR SERIAL DECLINE OF THE GREENLIP ABALONE FISHERY AND A REVIEW OF MANAGEMENT

S. A. SHEPHERD* AND KATE R. RODDA
South Australian Research and Development Institute, P.O. Box 120, Henley Beach, South Australia, 5022

Who hears the fishes when they cry? It will not be forgotten by some memory that we were contemporaries.

Henry David Thoreau

ABSTRACT The greenlip (*Haliotis laevigata*) abalone fishery in the Western and Central Zones of South Australia comprises about 74 distinct metapopulations. Although the total catch has been maintained since 1979, analysis of catch and effort data for the two zones at a fine scale in 49 map code areas shows that 39 areas are in decline; of these, 28 areas, with declines exceeding 50%, are considered serious. In the Western Zone, the proportional catch from 23 inshore reefs has declined from ~69 to ~34% of the total catch over 20 y of fishing; whereas, that of 10 distant reefs has increased from ~26 to ~50% of the total over the same period. Fishing mortality is 0.4–0.6 on inshore reefs and 0.2–0.4 on distant ones, indicating serious maldistribution of effort. The frequency of declining populations reaching the 50% decline point peaked in the years 1989 to 1990; a subset of the same group of populations reaching the 80% decline point peaked in 1995 to 1996, indicating a continuing decline trajectory, despite quota imposition and reduction. Multiple regression analysis of the proportional rate of decline of 38 populations in the Western Zone showed that the rate of decline was inversely correlated with distance from port and with a closure index that measures the extent to which the population is bounded by land. The closure index is considered to estimate crudely the extent to which coastal topography retains larvae within the population. Comparison of the spatial extent of fishing areas in eight populations mapped in 1978 to 1979 and again in 1996 to 1999 showed strong spatial contraction matching the decline in catch. Spatial contraction occurred from deeper to shallow water leaving relict subpopulations around headlands and in bays, consistent with inferences on the effect of coastal topography on abalone larval retention. In the Central Zone, with six divers and 12 reefs fully fished over a shorter time period, the declines are less certain and less severe. The catches of five reefs have declined by >50% and increased substantially on one remaining productive reef. An overfishing hypothesis best explains the long-term decline in the catch of many reefs and the transfer of fishing to distant or remaining reefs.

The history of management is reviewed and shows that, over the lifetime of the fishery, management has moved from control by government with little consultation with industry in 1967 toward self-management with endorsement by government from about 1995. Since 1995, management has been unresponsive to declines in the fishery, and possible reasons are explored. We advocate application of the precautionary approach by management at the scale of the metapopulation to arrest the declines and the establishment of recovery plans for areas in serious decline.

KEY WORDS: abalone fishery, serial decline, *Haliotis laevigata*, metapopulation, larval retention, fishery indicator, precautionary approach, fishery management

INTRODUCTION

Focus on the causes and prevention of collapse of fisheries is a direct consequence of increasing emphasis on the conservation of exploited stocks and their sustainable management. The spectacular collapses of anchovetta, cod, and crustacean stocks in recent decades (Steele 1981, Hutchings & Myers 1994, Orensanz et al. 1998) have served to catalyze deep concern and critical analysis of the causes in the hope that appropriate lessons can be learned.

Many abalone fisheries have also collapsed worldwide (Shepherd & Baker 1998), except in Australia, where they have apparently been sustained (reviewed in Prince & Shepherd 1992), and where envious eyes have often turned to learn the touchstone of success. The collapse of abalone fisheries has many causes underlying the obvious proximate cause of overfishing. Basic problems of assessment are: ignorance of stock–recruitment relations and practical difficulties and high cost of obtaining fisher-independent data, such as abundance and recruitment estimates for many independent stocks. Problems confronting managers are: absence of proved fishery indicators and tendencies to maldistribution of effort. Yet, despite their reputation, all is not well with the Australian abalone fisheries. In particular, the fishery for greenlip abalone (*Haliotis laevigata* Donovan) has suffered declines of varying severity in several states (Shepherd et al. 2001), despite the fact that possibly more is known of the biology and population ecology of this species than any other abalone species. This paper seeks to discover an underlying pattern in the declines and why they are continuing in South Australia, despite the abundant knowledge and the recent warnings of decline. We focus our attention on the greenlip fishery, although blacklip abalone, *H. rubra* Leach, is taken on most reefs, although in different habitat.

First, we summarize the diverse evidence, both biologic and historic, showing a decline in the fishery, and undertake a preliminary analysis of factors associated with that decline. The recent (1995) availability of catch data at a fine (metapopulation) scale (Keesing & Baker 1998) has provided a catch history of some 49 independent greenlip stocks in the Western and Central Zones (see Shepherd & Brown 1993); our analysis is limited to these zones. We consider the evolution of management from government control toward self-management in the context of the changing legal and administrative structures. We then describe the history of key management decisions and explain the long-term declines in terms of failure to apply a precautionary approach. We conclude with recommendations for the improvement of management and the

restoration of the stocks. Our conclusions are relevant generally to management of exploited, sedentary invertebrates with multiple stocks.

METHODS AND MATERIALS

Historical Information and Catch and Effort Data

Historical data were extracted from the minutes of the Abalone Advisory Committee and later of the Abalone Management Committee (AMC) and the records of the first author, who has been involved in research and management of the fishery continuously since 1968. Catch and effort data, reported on monthly logbooks that recorded daily fishing excursions, have been collected since the inception of the fishery in 1967. Early data on catch and hours fishing were collected on a grid scale of ~37 × 37 km, and, from 1979, on a fine population scale with map code numbers (Fig. 1) allotted to individual reefs, islands, and sections of coast, reflecting the actual distribution of abalone populations. Thus, the Western and Central Zones have 153 map codes embracing about 164 distinct abalone metapopulations. Excluding the far west region north of Pt. Brown, which has ~34 greenlip populations, there are 138 reef codes embracing ~74 greenlip and a similar number of blacklip metapopulations. The number is approximate, because we have assumed that isolated reefs and islands have distinct metapopulations and that mainland populations separated by unsuitable habitat of >~20 km are distinct (see Shepherd & Brown 1993). The term population in this paper (names are followed by map code numbers in brackets for easy cross reference) means an inferred metapopulation, or in some cases, two or more juxtaposed metapopulations, following the detailed genetic work of Brown and Murray (1992). The populations considered and their corresponding map codes are listed in Tables 1, 2. Our study is confined to 49 map code areas, including Franklin I. but excluding the seldom visited, very small populations at Greenly I., west Spencer Gulf and Sir Joseph Banks Group in the Western Zone, and Cowell Grounds and Marion and Stansbury Reefs in the Central Zone with a total mean cumulative annual catch of ~1 t.

Catch and effort data at the scales described are given by Keesing et al. (2000), with partial analyses of specific features by Keesing and Baker (1998) and Shepherd and Baker (1998). Pending a full analysis of the data, we have here undertaken a preliminary analysis to identify important features deserving detailed study. We estimated rates of decline in the catch of individual populations by simple regression analysis, over the full time period (usually 19 or 20 y from the commencement of intense fishing) where the decline was monotonic, or with a broken stick model, where the catch fell sharply and then stabilized at a low level; in the latter case, we estimated the rate of decline by regression from the start of fishing to the year in which the catch had declined by 95%. For a few areas, mostly in the Central Zone, catches were initially low and peaked during the mid- to late-1980s; in these cases, the regressions to estimate rates of decline commenced at the point where catches first peaked, our object being to estimate decline rates from the time of peak catches rather than in relation

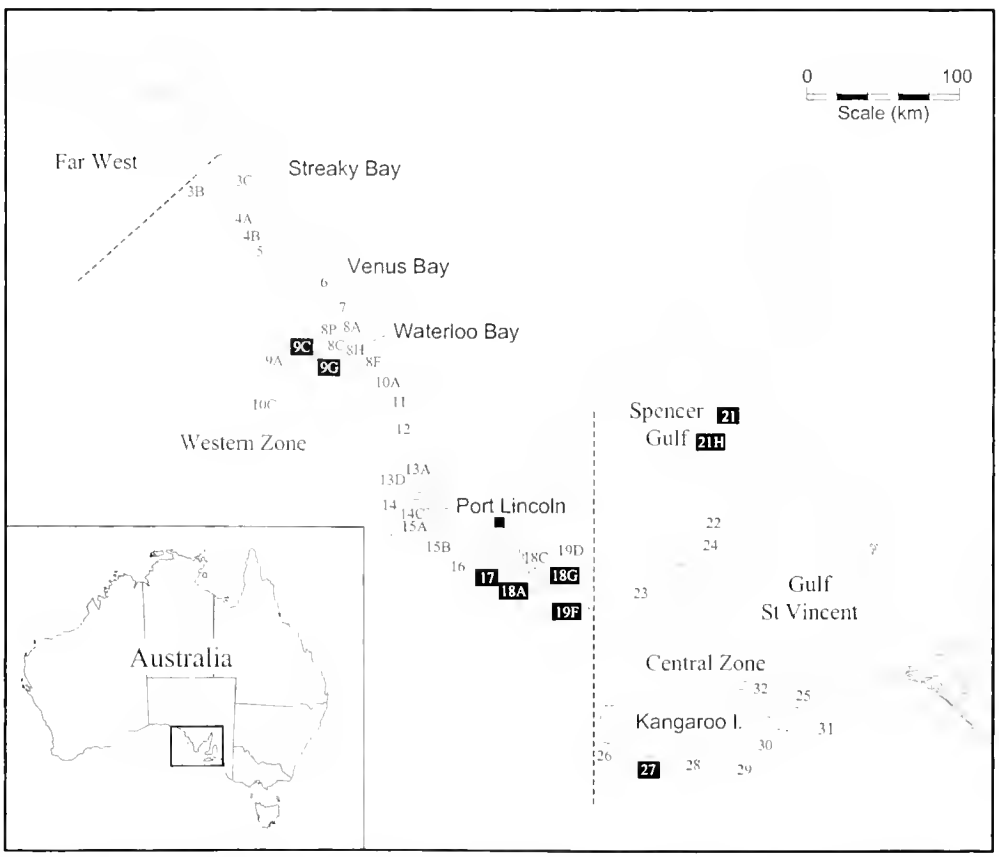

Figure 1. Map of South Australia showing distribution of greenlip abalone populations, individually indicated by map code numbers, in the Western and Central Zones. Numbers within black rectangles are the map codes of populations whose catches have been stable or have increased over time. See Tables 1 and 2 for names of numbered reefs.

Historic catch is the mean annual catch (t) for 1971 to 1978, early catch is the mean annual catch for 3 y commencing with the year shown in brackets, current catch is the mean annual catch (t) for 1996–1998, rate of decline (t/yr^{-1}) is for the period 1979 to 1998 or a lesser period where indicated, percentage decline is the present productivity as a percentage of original production (see text), Z is the instantaneous total mortality rate from catch curve analyses, and survey densities, D, are in numbers/m^2. A blank indicates absence of data. Statistical significance is shown thus: * = $P < 0.05$; ** = $P < 0.01$; *** = $P < 0.001$; NS = not significant. [a]closed to fishing 1982–1986 and 1995–1999. [b]reef discovered 1983. [c]reef discovered 1984.

to any specific fixed starting point. The 50 and 80% points of decline and total percentage declines were determined from the regressions. The mean annual catch for 1971 to 1978 (Table 1) is given to provide an estimate of productivity early in the fishery after removal of the virgin stock from 1967 to 1970. The "early catch" mean annual catch data in Table 1 are the mean annual catches over 3 y in the early 1980s after stabilization of the catches following granting of the right of divers to sell their licences in 1980. The mean annual catches were then only very slightly lower (<0.2%) than the mean annual catches for 1971 to 1978 and only 12.6% higher than the mean annual catch for the first 4 y after quota introduction in 1985. The current catch data given (mean annual catch for 1996 to 1998) are estimates of the present productivities of populations. In this paper, productivity is estimated by the annual catch of a stable population averaged over a number of years and assumed to be more or less fully exploited (Kesteven 1996).

All catch data are given in total (in-shell) weights (TW). Estimates of the total mortality coefficient, Z, are from: Shepherd and Baker (1998) for Waterloo Bay (8H–M), Sceale Bay (4D,E), Ward I. (9A,B), Thorny Passage (18C–F) and Tiparra (21); Shepherd et al. (2001), for Avoid Bay (15A) and Backstairs Passage (25A); and O'Loughlin and Shepherd (unpublished data) for the remaining sites. Mean density estimates are unpublished data.

See caption to Table 1 for explanation of headings.

Estimates of the spatial extent of fishing areas in 1978 to 1979 and in 1995 to 1999 were made during individual diver interviews by one of us (SAS) when divers marked on maps at a scale of 1 km = 1 cm (twice that scale for Watchers (8C,D) and Fishery Bay (16C)) the spatial extent of the places they fished. Hence, the data show only the gross extent of greenlip habitat, including interspersed sandy patches, rather than the precise extent of rocky substratum actually occupied by abalone. The areas shown here were drawn from the common area indicated by a minimum of four divers in 1978 to 1979 but only three divers in 1995 to 1999, because fewer divers fished areas that contracted spatially.

In the multiple regression analysis, the dependent variable, the proportional rate of decline of catches for individual reefs, was the absolute rate of decline calculated as described above divided by the initial production that was the y-intercept of the regression of catch versus time. The independent variables examined were: initial production (as defined above), distance from port, depth, and a "Closure Index" of the population. Distance from port was the distance from the mid-part of the reef in question to the nearest mainland boat ramp along the sea route used by divers; depth was the average depth of the population as then exploited as supplied by divers during the 1978 to 1979 diver interviews; and the "Closure Index" was the proportion of the perimeter of the areal extent of the fished reef bordered by land or emergent reef. For this purpose, reef maps prepared from the diver interviews described above were used to calculate the index, which took a value between 0 and 1.

History of Management

The history of the fishery has been reviewed by Prince and Shepherd (1992) with later detail added by Keesing and Baker (1998). Here, we summarize briefly the salient features of fishing controls and management. The fishery is controlled by input measures, size limits, and licence limitation, and by output measures, and individual quotas.

After the virgin stocks were fished down by 1970 (Shepherd & Baker 1998, Keesing et al. 2000) and the number of divers reduced to 21 in the Western Zone and 5 in the Central Zone by 1971, the fishery was stable for the next 9 y. In 1973 to 1975 there was slight evidence of stagnation in the fishery as divers aged until three more divers were admitted in 1976. In 1980, licences became saleable, and catches increased somewhat until 1984, when growth overfishing became marked in the Western Zone and various controls were introduced to reduce the level of fishing (see below). In 1985, individual quotas were introduced in the Western Zone (12 t for greenlip) and in 1989 in the Central Zone (23.7 t for greenlip). Greenlip quotas were reduced by 3 t (25%) in the Western Zone in 1989. During the 1990s, as inshore catches progressively declined in the Western Zone, competitive behavior between divers became evident as divers at the beginning of the fishing year competed to be the first to fish the fishing grounds and maximize their catch rates.

Management has evolved progressively since 1967. From 1967 to 1978 the Director of Fisheries managed the fishery, under delegation from the Minister of Fisheries. In practice, decisions were made on scientific advice and/or in response to representations by the divers' association. Such key decisions as licence limitation and their early reduction in number, and the imposition of zones in the fishery were made in accordance with ministerial policy and sometimes in conflict with the wishes of divers. This may be called the "instructive" period of government management (Fig. 2) after the terminology of Sen and Raakjaer Nielsen (1996). In 1978, following a prolonged dispute in which divers resisted the addition of more licences to the fishery (Chatterton & Chatterton 1981), an advisory committee was established, comprising divers and government representatives in about equal numbers. The committee had no authority, but made recommendations on research and management. Matters, some of them contentious, considered by the committee in the first 7 y included: the issue of rewards by indus-

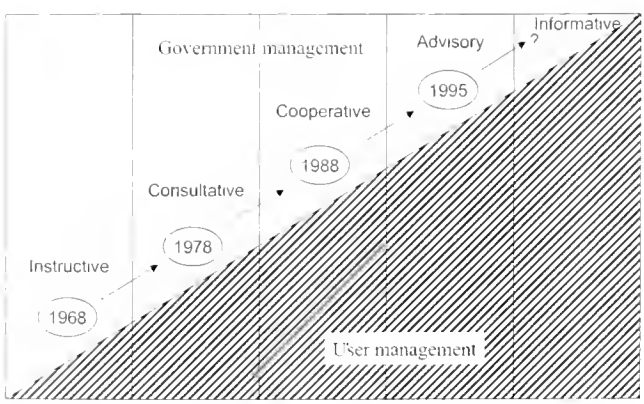

Figure 2. Shift in comanagement arrangements over time in the South Australian abalone fishery. The years in brackets indicate approximately the suggested point of transition along the spectrum of change.

try for evidence of poaching; relief diver days (awarded during sickness of licensee); landing abalone in the shell; permit sharing; research closures; increase in size limits; and a buy-back scheme. On major issues, such as the admission of more divers and the right to sell licences, divers dealt directly with the government and bypassed the committee, but on other issues, divers' views were taken into account in the final decision. During this period, the arrangement could be termed *consultative* in terms of mode of influence (Hersoug & Ranes 1996) for major issues and *cooperative* for minor issues (Fig. 2). Thus, major issues were resolved by the Director or Minister and minor ones in a cooperative manner within the committee.

By 1985, divers were showing increased responsibility in terms of resource conservation and management following evidence of overfishing in 1981–1983 (Lewis et al. 1984). Divers urged a 4-mo closure of the Western zone during 1984 to reduce the catch from the overfished region, and agreed to an increase in size limit from 130 to 145 mm SL for that zone (advocated by researchers since 1979). They also proposed closures during the spawning season, increased the reward to $5,000 for information about poaching, investigated the feasibility of quotas, and then voluntarily assumed quota restrictions before promulgation of the amending regulations, assented to the abolition of relief diver days, and offered assistance with research.

In 1988, an abalone management committee (AMC) was formally established to "advise on management, harvesting strategies, and on policy and legislation." Divers instigated the landing of abalone in the shell in the Central and southern Zones (later modified), and the introduction of quotas in those zones in 1988 and 1989.

In 1989, the greenlip quota in the Western Zone (see Fig. 6) was reduced by 3 t TW (25%) upon evidence of declines in inshore populations and in partial recompense for the loss, an increase in the blacklip quota of 0.75 t TW was negotiated by the divers from 1990. A decline in the catch in Backstairs Passage was reported by research in 1989, and an increase in size limit for greenlip on Kangaroo Island was proposed, but not accepted. Thus, during the 1980s, divers took the initiative and were pro-active on many, but not all, measures directed toward the conservation of the stocks.

In 1989, the president of the Abalone Divers Association was appointed chairperson of the management committee in tacit acknowledgment of the industry's constructive participation in management. From this time, it might be claimed that management was joint with government, although formal acknowledgment of the *de facto* joint management arrangements did not occur until 1995, when the requisite regulations establishing the AMC became law. By 1992, the right of permit holders to employ divers to take their catch was recognized, and the practice began and soon became widespread, for licences to pass into the control of companies, in which one or more divers, under contractual or share fishing arrangements, were nominated to take abalone. The implication of this was that, as time went on, divers' representatives on the management committee became increasingly likely to be business persons with little first-hand knowledge of abalone abundances in the field.

The 1995 regulations essentially passed control of the fishery to divers, because only industry members had voting rights. Four government observers on the committee represented administration, management, research, and enforcement sections of government; subsequently other observers representing the umbrella association of all professional fishers, recreational, and conservation interests were added. The Director of Fisheries retained the power to set quotas, but in practice, quotas were recommended by the government manager, endorsed by the AMC, and approved by the director. Under the regulations, the Minister reserved the power to override decisions of the AMC, but this has not happened. By 1995, government policy was explicitly one of cost-recovery; i.e., the industry was required to pay all costs of administration, management, enforcement, and research in the fishery. In consequence, the AMC increasingly involved itself in the scrutiny of government expenditure on research and management and "demanded the types and levels of service that offered the greatest value for money" (Geen & Nayar 1988).

In 1997, an independent chairman of the management committee was appointed, in accordance with government policy to have chairpersons with no financial interest in the fishery. Thus, from 1995, responsibility and power have increasingly passed to industry, and government observers have increasingly been limited to an advisory role. Overall, as shown in Figure 2, a transition from government management with little consultation, toward self-management with endorsement by government has occurred from 1967 to the present. At the same time, we may observe an increasing acceptance of responsibility by divers who, during the 1980s up till 1995, proposed many of the measures actually adopted to conserve stocks.

In 1995, the AMC was first advised of declines in eight greenlip stocks (a subset of those in Table 1) and a few blacklip ones in the Western Zone, and workshops were held in 1995, 1996, and 1999 with industry to consider them. Researchers advocated closures and an increase in size limits, but these were resisted, and no action resulted. Annual stock assessments and other reports to the AMC from 1995 to 1999 reiterated the serious character of the declines and assessed the impact of a size increase. In 1999, industry accepted that there were problems in the fishery, and a stock recovery plan was initiated for four sites: Avoid Bay (15A), Frenchman (13B,C), Anxious Bay (6E,7A,B), and Sceale Bay (4D,E). Unfished, stunted abalone subpopulations occurred near these sites, and researchers and industry cooperated in the translocation of adults into the fishing grounds to increase larval settlement.

RESULTS

Catch Declines

The Western Zone is subdivided into two subzones, A and B. Subzone B (the far west) has low productivity, and the annual quota is correspondingly low (1.8 t per diver unallocated between blacklip and greenlip); greenlip catches have fluctuated cyclically but have shown no long-term downward trend. We do not consider them further in this study.

The total catch for the two zones (Fig. 3) has remained stable save for a slight reduction in catch in the Western Zone with the 1989 quota reduction. The zones comprise many spatially separated greenlip populations of different productivities geographically distributed on exposed coasts and near the gulf entrances, except for Tiparra (21) and Hardwicke (22,24) within Spencer Gulf (Fig. 1). The size distribution of these populations, in terms of their 1971 to 1978 mean annual productivity values (see Table 1) for each zone (Fig. 4) shows that the majority of reefs had productivities of <10 t and that the majority in each productivity size class in each zone have suffered declining catches since 1979. Examples of the declines in catch in individual populations are

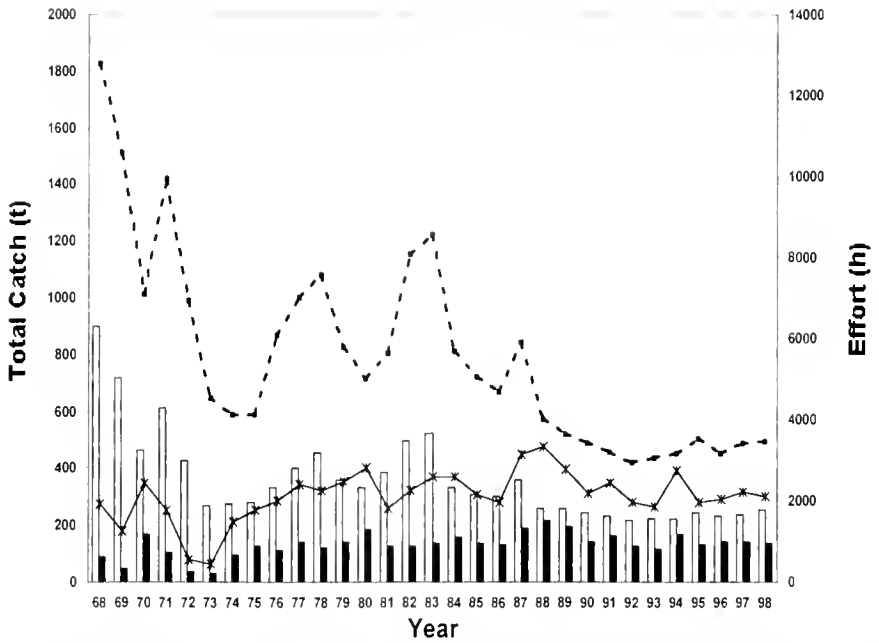

Figure 3. Global greenlip catch (TW) and effort in the Western and Central Zones from 1968 to 1998. Data are for financial years, July to June; i.e., 68 = 1968 to 1969. Hollow bars (total catch) and dotted line (total effort) are for the Western Zone and black bars and continuous line are for the Central Zone.

given in the companion paper (Shepherd et al. 2001) and in Shepherd and Baker (1998).

Historic and present catches of declining populations, rates of decline, and the percentage decline (derived from regression analyses), and estimates of the total mortality coefficient, Z, and recent density estimates are summarized in Table 1. Historic and early annual catch data (Table 1) are taken to indicate the approximate productivity of reefs over a decade or more during the 1970s and early 1980s, and current annual catch data are taken to indicate the present productivities of those reefs. In all, 39 reefs show declines in catch of 12 to >99% (mean % decline 71%) in the two zones (Table 1) and six reefs show no decline or increasing catches (Table 2). These percentage decline values represent the declines from maximum catches in 1980 to 1982, equivalent to the mean annual catches during the 1970s after removal of the virgin stocks.

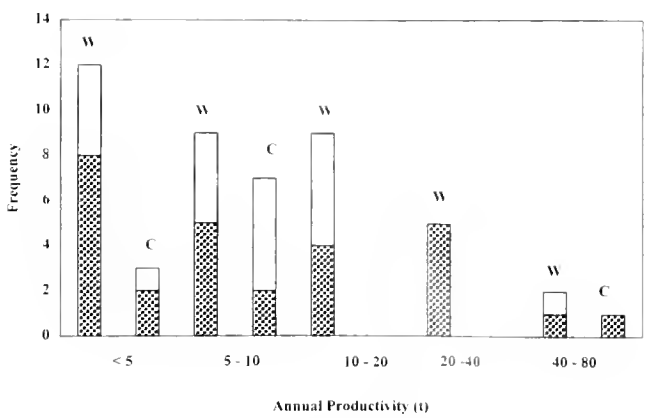

Figure 4. Frequency distribution of the annual productivity (t) estimated from the mean catch of greenlip-bearing reefs in 1971 to 1978 in the Western (W) and Central (C) Zones. Reefs whose catches have declined by >50% are shown by crosshatching.

Next, we examined the temporal pattern of the decline in catch in the Western Zone by plotting the frequency distribution over time of populations reaching their respective 50 and 80% decline points after 1980. The results (Fig. 5) show that the number of declining reefs (extracted from the data in Table 1) at the 50% decline point peaked in 1989 to 1990, and the number at the 80% decline point (a subset of the same reefs) peaked from 1995 to 1996.

Changes in Fishing Pattern

The pattern of fishing gradually shifted from 1979 to 1998 in both zones. In the Western Zone, as near-shore catches declined, fishers increasingly sought their catch from more distant reefs. This long-term shift in the source of the catch is shown by the gradual proportional decline of the catch in 23 near-shore populations from ~65 to 70% in 1979 to ~34% in 1998, and the corresponding proportional increase in catch at 10 distant reefs from ~26% to ~50% over the same period (Fig. 6). Distant reefs are 30–50 km from the nearest port, except Venus (6A–D), Baird Bay (5B–F), (which are close to port but distant from Port Lincoln where most fishers live) and Sleaford (17A,B). The remaining reefs cumulatively contributed about the same proportion to the total catch over time. In the Central Zone, the picture is simpler. As catches declined on nine reefs around Kangaroo I. and Hardwicke Bay (22,24) (Table 1) they progressively increased at one reef, Tiparra (21), by a massive 77%.

To determine whether the spatial shift in fishing in the Western Zone was related to more intense fishing on near reefs than on distant ones, we examined Z for 11 reefs (see Tables 1,2). A plot of Z versus distance (D) from port (Fig. 7), shows a decline in Z with increasing distance. We fitted the linear regression equation:

$$Z = 0.71 - 0.008D \qquad (R^2 = 0.56;\ P < 0.01)$$

For this regression, we used the earliest Z estimates available for Avoid Bay (1987) and Backstairs Passage (1980); whereas, the

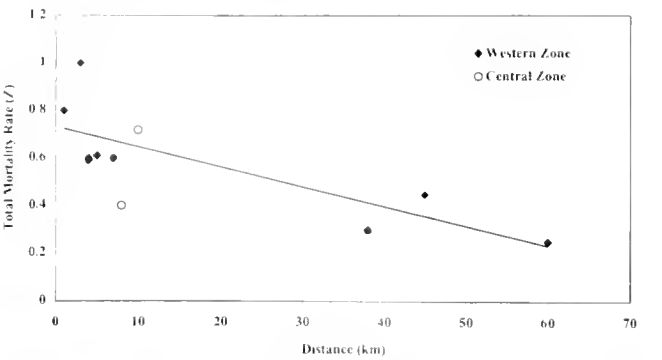

Figure 7. Plot of total mortality coefficient, Z, for greenlip populations in the Western and Central Zones versus distance from port in km.

remaining estimates were obtained since 1995 (Shepherd & Baker 1998, O'Loughlin & Shepherd, unpublished data).

Rate of Decline in Catch

The relation between the proportional *rate* of decline of the catch in declining populations, and the variables: initial production (IP), distance (D), depth (De), and the "Closure index" (C) for populations in the Western Zone was examined by multiple regression analysis. The constant and the two variables, D ($P = 0.002$) and C ($P = 0.01$) were significant, but the variables IP and De were not significant and were removed from the regression. The regression equation (with standard errors in brackets) is:

$$R = 9.4(1.6) - 0.07(0.02)D - 9.2(3.5)C$$
$$(R^2 = 0.31;\ P = 0.0006)$$

Plots of the proportional rate of decline of reefs versus the variables IP, D, and C, but not De (which shows little of interest), are shown in Figure 8.

Spatial Contraction of Fishing Areas

Plots of the recorded spatial contraction of fished reefs in six greenlip populations are shown in Figure 9. The respective spatial extent of areas originally and presently fished are given in Table 3, with the calculated percentage contraction of fishing areas. Table 3 also includes the relevant data for the two populations, Avoid Bay (15A) and Backstairs Passage (25A), whose declines are described in greater detail by Shepherd et al. (2001). The spatial declines have been groundtruthed for four of the eight populations (see Table 1 and Shepherd et al. 2001), and they show very low densities in the areas of decline. Such low abundances are not surprising, because divers fish the areas in motorized scooters (Prince & Shepherd 1992) and cover the bottom systematically and over distances of >10 km per dive. The low relief, calcrete (limestone) substratum, sometimes interspersed with sandy patches (see

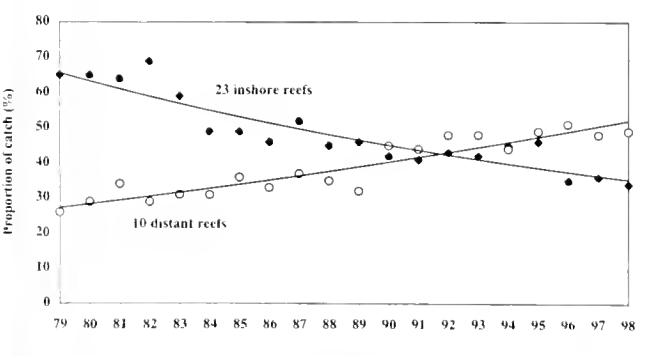

Figure 6. Proportional change in of the greenlip catch for twenty-three near-shore and ten distant reefs in the Western Zone from 1979 to 1998. The distant reefs are Venus Bay, Ward I., Hotspot, Flinders I. (both sides), Baird Bay, Sleaford, Thistle I., Wedge I., and southern Thorny Passage, and the near-shore reefs are the remainder of those listed in Table 1, other than Central Zone reefs.

Spatial contraction of six greenlip populations in the Western Zone. a: Sceale Bay (4D,E); b: Watchers (8C,D); c: Anxious Bay (6E, 7A,B); d: Point Drummond (12A,C); e: Frenchman (13A,C); f: Fishery Bay (16C). Dotted shading and cross hatching together show the areas fished in 1978 to 1979, and cross hatching the areas fished in 1995 to 1999. Depth contours in meters.

TABLE 3.

Spatial extent of fished areas in eight populations of *H. laevigata* in 1978 to 1979 and 1995 to 1999 with % decline of area fished.

Map Code	Population	Area (1978 to 1979) (km^2)	Area (1995 to 1999) (km^2)	% Decline
4D,E	Sceale Bay	7.3	2.0	68
6E,7A,B	Anxious Bay	87.5	19.1	78
8C,D	Watchers	4.9	1.4	71
12A,C	Pt. Drummond	11.5	4.1	64
13A,C	Frenchman	7.8	1.7	78
15A	Avoid Bay	14.7	0.7	95
16C	Fishery Bay	1.5	0.2	87
25A	Backstairs Pt.	2.0	0.7	65

Keesing et al. 2000), and the exposed habitat of abalone on the bottom at most of the sites ensure high efficiency of capture and the capacity to reduce abundances to very low levels. We also have inconclusive evidence of spatial contraction for other populations: e.g., Highcliff (4A–C), Reef Head (13D–F), and Whidby Is (14E). For many other populations, which occur along a narrow coastal strip, spatial contraction, if it occurred, was at too fine a scale to be detectable by our mapping.

The mapped populations show a striking common pattern in spatial contraction. Fishing areas contracted in every case from deeper, offshore waters toward the coast where they were clustered around headlands, in bays or, in the case of the Watchers, in shallower waters on the lee side of, or between, the islands.

DISCUSSION

Evidence of Overfishing

The assumption is pervasive that the tragedy of the commons (Hardin 1968), in which fisheries collapse under open access policies, will be avoided by the use of extensive input and output restrictions. However, Scott (1993) points out that even with restrictive quotas competitive behavior among fishers can still operate and cause collapses. Although the global catches in each zone give no hint of instability (Fig. 3), the fine-scale analysis tells a different tale. The devil lies in the detail.

The basic problem in this greenlip fishery, maldistribution of effort, in which divers have increasingly competed to overfish the most productive grounds close to port and underfish others was first noted by Prince and Shepherd (1992), but they lacked supporting data on differences in fishing mortality rates, F. However, more recent data on the total mortality coefficient, Z, with distance from port now enable a better quantification of the gradient in F. Estimates of the natural mortality coefficient, M, for greenlip range from 0.22 at Tiparra, 0.38 at West I., and 0.2–0.4 at Waterloo Bay, all inshore sites, to 0.1 at a deep offshore site outside Ward I., which was considered unusually low (reviewed by Shepherd & Breen 1992; Shepherd & Baker 1998). Hence, in the absence of evidence of a gradient in M with increasing distance offshore, we may conclude that F declines from ~0.4–0.6 on near-shore reefs in the Western Zone to ~0.2–0.3 on reefs 40 km from port. The almost universal decline in the catch from near-shore reefs with these high levels of F and the increasing catches at more distant reefs strongly implicate overfishing as the likely cause. But when did overfishing commence?

Increased catches and levels of fishing from 1981 to 1983 were first noted by Lewis et al. (1984), and presumably led to the decline in abundance on inshore reefs in 1984 when divers urgently pressed for a closure of the Western Zone. However, the decline in abundance continued unabated and precipitated the 1989 reduction in quota. The age composition of greenlip in the catch is mainly 6–10 y (O'Loughlin & Shepherd unpublished data), so the consequences of any recruitment overfishing event must be sought some 6 to 8 y later. In retrospect, the most likely explanation for the declines in the late 1980s, evidenced by the peak in the number of populations whose catches had declined by 50% in 1988 to 1989 (Fig. 5), is that recruitment overfishing had occurred from 1981 to 1983. The continuing decline of the same populations that constituted the 80% decline peak in 1995 to 1996 suggests that the quota reduction in 1989 had little or no ameliorative effect.

In the Central Zone with only six divers, the picture is less certain. Reefs were visited by few divers, and in a few populations, catches increased in 1987 to 1988 in anticipation of quotas introduced in 1989 (Keesing & Baker 1998). Hence, changes in abundance must be inferred from time series of catch data varying from 10 to 20 y. Implications of decline inferred from short time series of only 10 y must be tentative until supported by other evidence. Subject to this caveat, the data suggest the widespread decline of Kangaroo I. populations (Map codes 26–32) and increased compensatory fishing pressure at Tiparra (21). Because the Kangaroo I. coast is much more difficult for divers to access than Tiparra, the reverse effect to that seen in the Western Zone occurs; i.e., a movement of fishing away from distant reefs to a near-shore one, where fishing intensity is now high. The reason for the reverse effect is that divers visit Kangaroo I. annually about mid-year when the weather is favorable to take their blacklip quota, and they have historically exploited greenlip stocks during these visits. In recent years, divers have increasingly returned to Tiparra (21) later in the year to complete their greenlip quota, presumably because catches have progressively declined on Kangaroo I. The reasons why declines in the Central Zone seem less serious than in the Western Zone are twofold. First, with many fewer divers in the Central Zone, competition between divers has likely been less, particularly during prequota years, so that overfishing has been less severe. Second, presumed overfishing developed some 6–8 y later in the Central Zone and so has had less time within which to become apparent.

Factors Associated with the Declines

The multiple regression analyses of proportional decline rates are illuminating and suggest major factors affecting the decline of populations. First, we consider the nonsignificant factors. The nonsignificance of IP (initial production) as a factor influencing the rate of decline is consistent with our earlier finding (Fig. 4) that the proportion of populations in serious decline did not change with increasing size of population. This may surprise, as Shepherd and Baker (1998) predicted that small populations would be more vulnerable to overfishing than large ones, because of their higher recruitment variability as found for Backstairs Passage (25A) (Shepherd et al. 2001). One of the assumptions of this analysis is that populations similar distances from port are subject to roughly the same fishing mortality, F. It is possible that smaller populations are visited less often and fished less intensively than larger ones, so that the decline rates of smaller ones would be less than under the assumption of equal exploitation rate. We are currently examining exploitation rates in populations of different sizes to test this possibility.

The other nonsignificant factor in the analysis was depth. However, depth may be relevant at the extremes of shallowness and deep water. At some near-shore shallow sites; e.g., Waterloo Bay, divers have customarily accepted low catch rates while following safety decompression schedules after fishing in deep water, and precipitated a decline (Shepherd & Partington 1995). On the other hand, populations that extend into deep water (>30 m), such as Hotspot (9C,D), Thorny Passage (18C–F), Ward I. (9A,B), and Pearson I. (10C), of which only the last has declined, may find a partial refuge in depth and be more resilient to fishing (Karpov et al. 1998). However, some divers do occasionally fish to 30-m depths and say that deep-water populations have poor recruitment and recover more slowly than shallower populations after fishing. The question remains open until methods are found to survey deeper water.

The significance of D (distance from port) is not surprising, given the gradient in Z with increasing distance from port, and is confirmatory evidence of the maldistribution of effort in the fishery (see above). However, the variable of special interest is the closure index C. This estimates the boundedness of a population by land (or emergent reef) and, by implication, the extent of larval retention within the population. Apart from a very low value of 0.15 for Whidby Isles (14E), where the population collapsed after 6 y fishing, values ranged from 0.30–0.74. We hypothesize that coastal topographic features restrict dispersal of larvae and tend to maintain recruitment or decrease its variability. The hypothesis has substantial support. Wolanski and Hamner (1988) reviewed the effect of coastal topography, such as headlands and islands, on larval transport and noted that topographically generated fronts aggregated eggs and larvae. In empirical studies on this abalone, Shepherd et al. (1992) found that larvae were retained in near-shore eddies and bays, and Shepherd et al. (2001) found that in Avoid Bay (15A) and Backstairs Passage (25C) recruitment was stronger close to shore and weaker off-shore in open habitats, where currents were stronger. Furthermore, the pattern of spatial contraction toward shore around headlands and in bays, found for these populations as well as for six additional populations (Fig. 9), reinforces the evidence in favor of a strong effect of coastal topography on the resilience of greenlip populations. This hypothesis could be tested experimentally by measuring density of larval settlers in collectors in populations with different values of C (see McShane 1995, Rodda et al. 1997). The hypothesis also explains the hitherto puzzling absence of greenlip populations from the many very small islets and sea-mounts that abound within the geographic range of greenlip abalone. Their C values may simply be too low for larval retention.

Spatial contraction of stocks is known for declining fish stocks (e.g., Rose & Kulka 1999), but has not previously been documented for exploited molluscan stocks. The phenomenon may be an example of a much more general principle. Metapopulation models predict that larger metapopulations have higher local abundances than smaller ones, because recruitment rates are higher and extinction rates lower (Hanski & Gyllenberg 1997). The converse; namely, that reductions in density in local populations will reduce the metapopulation range but to a less extent, is expected to follow if recruitment rates declined. In the eight populations in Table 3 the mean percentage decline in catch (90%) is significantly more than the mean percentage spatial decline (76%) ($t = 2.4$; $P < 0.05$), suggesting that, on average, density declined more than the spatial area occupied, as predicted by theory. However, other models not based on metapopulation theory and with other assumptions may predict the same result (Rosenweig 1991, Holt et al. 1997, & see Lawton 2000).

Alternative Explanations for the Declines

The major underlying assumption of the above analysis is that the total catch reflects abundance. Jamieson (1993) noted the tendency in capture fisheries for divers to move to new reefs only when exploited ones are exhausted, and McShane (1998) observed the preference of divers to fish reefs closer to home. Keesing and Baker (1998) relied on these arguments in their earlier analysis of this dataset to interpret trends in abundance of local stocks. Shepherd et al. (2001) reviewed diver behavior in the context of abalone fisheries and concluded that the diversity of diver exploratory behaviors and the single dominant motivation of all divers; namely, maximization of catch rates, ensured complete coverage of every reef and efficient removal of abalone aggregations. Hence, the total catch should crudely reflect stock abundance in fully or near fully exploited stocks, although the relation may not be linear where spatial contraction of the stock occurs. Empirical evidence from Avoid Bay (15A) and Backstairs Passage (25A) show a curvilinear relation between survey densities and catch (Shepherd et al. 2001). However, in stable populations, there is no such correlation between catch and density (e.g. Tiparra Reef (21): $r = -0.10$, $n = 18$; Thorny Passage (18C–F): $r = -0.39$, $n = 11$; Ward Island (9A,B): $r = -0.07$, $n = 18$; Hotspot (9C,D): $r = 0.28$, $n = 17$—see Shepherd et al. 1999). This result is not surprising, because surveys are not coordinated with fishing that may occur before or after an annual survey (Shepherd & Baker 1998). Thus, there is an asymmetric relation between catch and abundance in which the catch reflects abundance but only in declining populations. Nevertheless, it cannot be concluded that a declining catch is, of itself, proof of declining abundance. This is the well-known fallacy of *affirming the consequent*. In formal terms, declining catch is a necessary, but not a sufficient, indicator of declining abundance. The alternative, testable hypothesis—that a population is stable but the catch declines for reasons unrelated to abundance—must now be considered.

Two versions of this hypothesis have been proposed by industry and managers to account for the observed trends in the catch. First, it is suggested that changes in management since 1979 could have caused the patterns seen. The notable changes were: saleability of licences, size limit increase, and short-term closure (Western Zone only), quota imposition, and quota reduction (Western Zone only), (see above). The argument ignores history and fails to distinguish cause and consequence. The declines in catch from 1984 to 1988 in the Western Zone were real and pervasive and led to strong pressure from divers to introduce quotas and increase size limits and also led to increased government concern in 1988, which was followed by the quota reductions in 1989. Size limit increases could not have caused catch declines, because they were largely neutral in respect to yield (Shepherd & Baker 1998). Furthermore, if management measures up until 1989 caused the catch declines, they would not have continued unabated into the 1990s (see Fig. 5), but would have stabilized or oscillated within stable limit cycles as observed in the Far West (Keesing et al. 2000).

The second version of the hypothesis is that the pattern of fishing has gradually changed over time, not as a response to declining abundance, but for reasons as diverse as: occasional presence of sharks, higher catch rates at offshore islands and its variant, the use of Global Positioning Systems, and preference for clear rather than dirty water.

We term both versions the underfishing hypothesis, because a necessary implication of each is that *underfishing* of populations with declining catches is occurring. If a population is stable with a surplus available for capture, then the capture of less than the surplus will lead to an increase in population size. Moreover, the greater the decline in catch and the longer it has been declining, the greater would be the increase in numbers and biomass, until eventually, the population would approach virgin densities, and Z would approach the natural mortality rate M. This hypothesis can be variously tested by research diver surveys, evidence of spatial contraction, and estimation of Z, from catch-curve analysis. The combined cumulative evidence in this paper of low densities from survey data, spatial contraction of populations and/or high Z values for twelve problematic reefs with declining catches (see Table 1) together point to widespread overfishing, inconsistent with the underfishing hypothesis.

A satisfactory explanatory hypothesis must be able to withstand tests of internal coherence, external consistency, and predictive accuracy (Giere 1999). Since 1995 when major declines were first detected, overfishing of specific reefs has been conceded as data have accumulated, but only as exceptions to an otherwise stable fishery. A hypothesis is incoherent if every contradiction constitutes an *ad hoc* exception to it.

Is the underfishing hypothesis externally consistent with other statements? Historically, surveys of divers, increasingly accepted as a valuable source of information at a local scale (see Neis et al. 1999), have provided valuable evidence on divers' perceptions of the status of reefs. Surveys of divers of the Western Zone during 1995 to 1999 (see Shepherd 1996 for a progress report) showed that divers' perceptions were cumulatively in unanimous agreement with inferences of decline drawn from catch data for every reef from Fishery Bay (16C) north to Sceale Bay (4D.E), except for Sceale Bay itself where opinions were divided. (Each diver was familiar with only a small subset of the reefs.) Divers judged the productivity of reefs by the frequency of their visits, a fact that has long been known. In an early perceptive submission to government the divers' association wrote: "When abalone start to get hard to find in an area or a diver knows of somewhere he may do better, he moves on, and in this way rotates the areas and allows them to rest. The divers find that they are rotating their areas faster each year. . . . Even though they are able to maintain their catch rate the areas are not supporting the previous year's effort." (Letter from Abalone Divers Association to Minister for Agriculture and Fisheries dated 18 October 1976.) Thus, from the relatively early days of fishing, divers recognized that decision thresholds for ceasing to fish were a response to low abundance (see Shepherd et al. 2001 for further discussion). Last, if low abundance is not the basis of the decision to cease fishing a reef, no other credible cause has been proposed that coordinates the behavior of 29 idiosyncratic divers to underfish or cease fishing reefs in entire geographic regions for a decade or more. Thus, the underfishing hypothesis is counterbalanced or refuted by many other statements of divers and lacks credibility.

Last, does the underfishing hypothesis have predictive accuracy? As shown above, the hypothesis has been tested at twelve reefs and failed. Although testing the hypothesis at other reefs is an ongoing program, the underfishing hypothesis, so far, has failed every test of coherence, consistency, and predictive accuracy. It is, moreover, value laden, because it is proposed on behalf of those with a strong economic interest to maintain quota levels.

A third hypothesis is that long-term environmental changes have affected population persistence in this abalone. Coastal waters of South Australia are influenced by seasonal upwellings from January–March each year, but this occurs well after the spawning season in October–November (Shepherd & Laws 1974) so is an unlikely agent directly affecting recruitment. Even if it affected adults, the upwellings extend up to 60 km from the coast (Griffin et al. 1997) so the selective decline of populations in two zones and very few in the far west are difficult to explain. Moreover, the evidence of long-term temperature changes in the region is slight. Hence, this hypothesis seems untenable.

In contrast, the overfishing hypothesis provides a common explanatory mechanism for the decline of catch on many disparate reefs and also suggests new areas for further research. One is that coastal topography influences population persistence via mechanisms of larval retention. This will be a useful criterion in the search for, and protection of, larval source habitats and in determining sustainable exploitation rates of reefs.

Management in Review

The historical trend in management from government to fisher control, as exemplified in this fishery, is, in the view of Scott (1993), part of a broad endogenous movement, not unique to fisheries, whose endpoint, at least for territorial stocks, is local self-management by fisher groups and cooperatives. Within fisheries, a general theory of government–community comanagement is emerging from the reviews of Jentoft (1989), Scott (1993), Pinkerton (1994), Wilson et al. (1994), Jentoft and McCay (1995), Sen and Raakjaer Nielsen (1996) and Hutton and Pitcher (1998). Almost all of these reviewers argue that it is the role of government to set quotas and of the management committee to "decide the how, when, and where of fishing" (Kesteven 1995). The present self-management system for the abalone fishery displays many of the positive features, such as flexibility, responsiveness, equity, and homogeneity of interest reducing internal conflict, considered by these authors and also lacks many negative features, such as deficits of information and excessive numbers of fishers. Fixing quotas is properly reserved to government. However, are there deficiencies in the present system as it has moved toward self-government?

The influence of government in the AMC seems to have declined relative to the power of the major interest groups since 1995, especially in matters relating to the conservation of stocks. Management has not applied the precautionary approach (PA) as mandated in the management plan (Zacharin 1997) nor addressed the maldistribution of effort by closures and other means. It might be argued that management has been unwilling to make hard decisions or that too much power has passed to an industry increasingly dominated by economic interests. It might be claimed, in defence of inaction, that the inherent uncertainty of assessment, the absence of satisfactory reference points (Shepherd et al. 2001), or the insufficiency of the evidence have not required action even under the PA. These issues are complex and controversial and will be considered elsewhere. Our purpose, here, is to highlight the basic problem and suggest a way forward. The problem of possible conflict of interest in the AMC could be met structurally by more effectively divorcing day-to-day management from the fixing of quotas. Referral of the quota-setting function to an independent quota committee of experts, as operates in New South Wales, would facilitate independent and objective appraisal of the evidence. The problem of uncertainty of assessment must be ad-

dressed by accumulating more and stronger evidence, developing an agreed set of indicators for the fishery (Richards & Maguire 1998, Shepherd et al. 2001) and applying it to stocks at risk. In the meantime, application of the PA, incorporating understanding achieved from monitoring known, collapsed stocks, could minimize the risk of further overfishing.

Precautionary Approach (PA)

Although this study does not establish conclusively the serial decline of the greenlip fishery as a whole, is the evidence sufficient to invoke the PA? The PA (reviewed by Foster et al. 2000) reverses the onus of proof and states (Principle 15 of Rio Declaration as applied to fisheries) that where there are threats of serious damage, lack of full scientific certainty shall not be used as a reason for postponing measures to prevent overfishing. For data-poor fisheries (such as this one in which nothing is known of >90% of the stocks), respective FAO and U.S. national guidelines for application of the PA (Garcia 1994, Garcia 1996, Restrepo & Powers 1999) advocate conservative measures, including:

1. setting catch limits based on qualitative judgements about stock status and stock rebuilding strategies for stocks *believed to be* overfished, within time frames of 10 y (our italics); and
2. establishing provisional reference points by analogy to similar and better known stocks.

They also recommend that in situations of doubt, scientists analyzing management options should systematically analyze and highlight the most pessimistic scenarios. Dayton (1998) argues that reversal of the onus of proof is the only mechanism by which action can be achieved, given the penchant for regulators to procrastinate by "creating imaginative, alternative explanations" or simply by asserting "that the data are incomplete" (Dayton 1998). Given the coherent, cumulative evidence for a pervasive overfishing scenario there seems a proper case for application of the PA to this fishery. In the terms of Orensanz et al. (1998), overfishing "has to be considered as the default working scenario, even before being tested as a scientific hypothesis."

Signs of serial decline of this greenlip fishery were first noted in 1995 (Shepherd 1996, Keesing and Baker 1998), and a mechanism for decline proposed by Shepherd and Baker (1998). The apparent continuing decline toward commercial extinction of many stocks finds a parallel in the decline of about a third of the Canadian salmon stocks (Riddell 1993). As emphasised by Pinkerton (1994), dependence of a fishery on fewer stocks is risky, because effort is increasingly focused on the remaining stocks and will increase the risk of their decline. On the other hand, conserving more stocks is a buffer against future recruitment failure, which could simultaneously affect many stocks.

For the conservation of sedentary invertebrate stocks, Jamieson (1993) advocated:

1. very high minimum size limits;
2. unexploited refuges;
3. maintenance of high densities in many areas; and
4. specific management of metapopulation units.

In this fishery, high size limits have been advocated by Shepherd and Baker (1998), creation of refuges and management of metapopulations by Keesing and Baker (1998), who also suggested multiple size limits and temporal closures to control yields. The establishment of small fishery reserves (Baker et al. 1996, Nowlis & Roberts 1999) in areas where relict subpopulations persist, supplemented by adult transplants, would allow aggregations of adults to accumulate and provide a source of larval recruits. A multiplicity of measures applied at a fine scale over large areas will be necessary to restore the former productivity of the fishery.

The desired outcomes of comanagement are that sustainability, efficiency, and equity in managing the resource will be improved (Sen & Raakjaer Nielsen 1996). However, if the first of these fails, the rest no longer matter. Although management of this fishery may have enjoyed some success on the last two outcomes, the first is now at risk.

ACKNOWLEDGMENTS

We thank the many divers who patiently provided information during diver interviews from 1978 to 1999. Annette Doonan helped with the recalcitrant abalone data management database. Greg Howe, Dr. P. A. Breen, Dr. M. J. Tegner, and an anonymous referee kindly criticized early versions of the manuscript. The Fisheries Research and Development Corporation provided funds for the abalone database management system.

A CHRONICLE OF COLLAPSE IN TWO ABALONE STOCKS WITH PROPOSALS FOR PRECAUTIONARY MANAGEMENT

S.A. SHEPHERD,[1]* KATE R. RODDA,[1] AND KELLY M. VARGAS[1,a]

[1]*South Australian Research and Development Institute, PO Box 120, Henley Beach, South Australia*

ABSTRACT Two populations of greenlip abalone, *Haliotis laevigata*, in Backstairs Passage and Avoid Bay, collapsed during 30 years of fishing. The former population was monitored from 1980 to 1999, and the latter from 1987 to 1999. Both populations showed strong spatial contraction as their respective subpopulations in open habitat failed first compared with those in inlets, bays and around islands, where recruitment was higher. Stock-recruitment curves are gently sloping or indeterminate, indicating weak density-dependence in the one case and high variability in the other case. From data gathered during the decline of these populations we review various fishery indicators which may be useful for monitoring greenlip abalone populations and for predicting collapse. Total catch was correlated with relative spawner abundance from survey data, and thus appears to be a useful indicator of abundance in this fishery. Other useful indicators are densities and size compositions, from which annual recruitment strength and total mortality can be derived, and survey evidence of spatial contraction of fished areas. Egg-per-recruit analyses are also useful to estimate the extent of departure from predetermined safe levels of egg production. Given the fuzzy knowledge of the status of populations, several indicators are best used in concert to determine management strategies. We propose a "troublespot thermostat" approach in which a suite of indicators, sequentially triggered off, call for increasingly severe management responses. In this way declines can be detected and arrested, and timely steps taken to avoid collapse.

KEY WORDS: population ecology, stock-recruitment, spatial contraction, fishery collapse, fishery indicator, biological reference point, abalone fishery, *Haliotis laevigata* egg-per-recruit

INTRODUCTION

While a legislative framework to achieve the ecological sustainability of fisheries has been in place for some years in Australia, management has either been weak or has lagged seriously (Nicholls & Young 2000). The principle risks degenerating to empty rhetoric unless rigorous criteria are developed to detect and arrest fishery declines at an early stage. In particular robust biological reference points to indicate declines have been developed for very few fisheries.

The fishery for greenlip abalone (*Haliotis laevigata* Donovan) started in about 1966 in southern Australia and was controlled in the different States initially by input measures and then by quotas progressively introduced in the 1980s (Prince & Shepherd 1992). Greenlip populations have been slowly declining in the last two decades, first in Victoria and progressively in Tasmania and South Australia (Officer 1999, Shepherd & Rodda 2001). Management response to the declines has been tardy for many reasons. The absence of clear fishery indicators has promoted uncertainty, continued high catch rates have engendered skepticism about overfishing concerns, and the propagation of the notion that a stock-recruitment relation in abalone "is largely uncorroborated dogma" (McShane 1995) has favored complacency.

Catch data from the South Australian abalone fishery were collected from 1968 at a coarse scale of 37 × 37 km, and from 1979 at a finer (metapopulation) scale (Sluczanowski 1986, Keesing & Baker 1998, Shepherd & Rodda 2001). Data collection at the fine scale enabled researchers from about 1995 to follow long-term trends in individual populations. Annual monitoring of commercially exploited populations started in 1980 (Shepherd & Baker 1998) at a few sites and was gradually extended to many others. Two of these populations, monitored during part of their fishing history, collapsed during the 1990s and this article describes their decline. We document the spatial contraction of the stocks, provide length compositional data and estimates of the total mortality coefficient, Z, obtained during the decline phase, and the decline in density of spawners and recruits. We present spawner-recruit curves and evaluate various fishery indicators of possible use in abalone fisheries. In the absence of unambiguous indicators of overfishing, we suggest a protocol, which we term a trouble spot thermostat approach, by which population declines can be detected early, data assembled, and declines arrested by appropriate management measures before final stock collapse when recovery becomes problematic. In this article we use the terms population and stock to mean an inferred metapopulation (Shepherd & Brown 1993, Shepherd & Rodda 2001), following the detailed genetic studies of Brown and Murray (1992) on greenlip abalone.

MATERIALS AND METHODS

Site Descriptions

Backstairs Passage

Backstairs Passage lies at the entrance to Gulf St Vincent (see map in Shepherd & Rodda 2001). Greenlip abalone populations occur discontinuously on boulder or reef bottom over an area of ~2 km^2 from several km east of Blowhole Creek to a little north of Cape Jervis on the Fleurieu Peninsula, South Australia (Fig. 1a). Rocky substratum is Cambrian greywackes and schists, tilted at a sharp angle providing microhabitat for juvenile abalone. Further offshore, boulders lie scattered on sandy or rocky bottom (Keesing et al. 2000). Abalone habitat is narrow at the southern end but broadens toward Fishery Bay and Cape Jervis where rocky bottom extends continuously or interspersed by seagrass patches to nearly 1 km from shore to a depth of 12–13 m. Highest densities occur near the entrances to the numerous inlets along the coast, in Fishery Bay and north of Lands End.

The Passage is swept by tidal currents, which reverse twice daily due to diurnal and semi-diurnal components (Bye 1976,

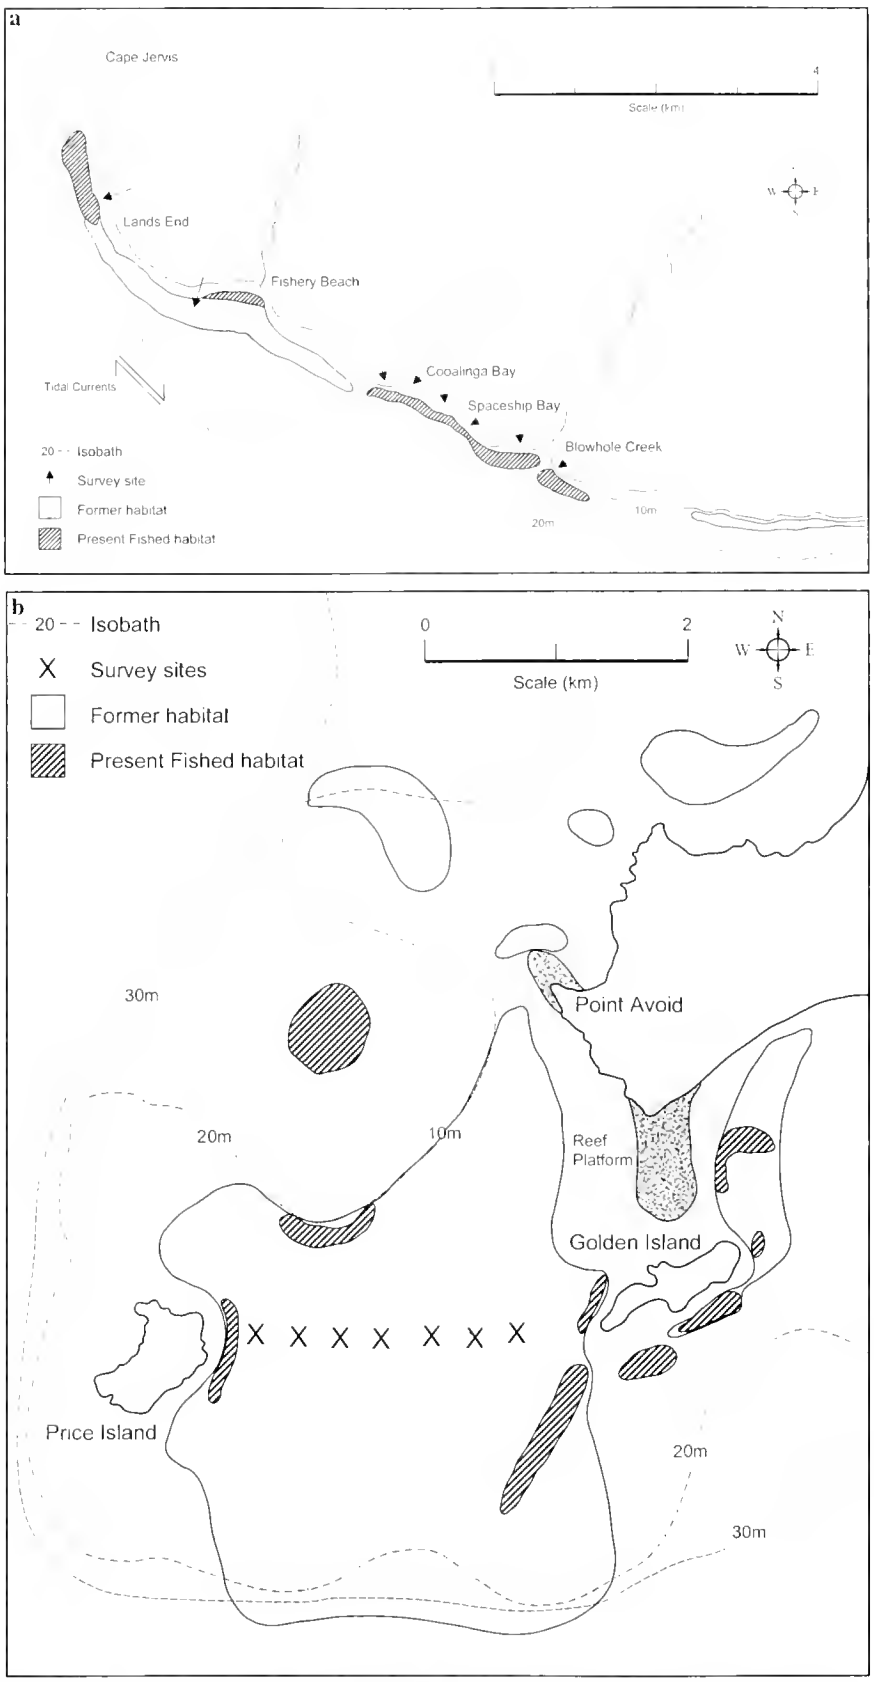

Figure 1. (a) map of greenlip abalone habitat in Backstairs Passage showing fished areas in 1978 (light shading), and in 1999 (dark shading). Survey sites are marked with arrows. (b) map of greenlip abalone habitat off Point Avoid showing fished areas in 1978 (light shading) and in 1999 (dark shading). Very dark areas are intertidal reef platforms. Survey sites 1–7 are shown by crosses, and numbered 1 to 7 from left to right.

Bowers & Lennon 1990). During neap tides, which occur every 14 days, when tidal movement is minimal, water velocities are 35 cm sec^{-1}, increasing to 1.4 m sec^{-1} seven days later during the spring tide (Carvalho & Bye 1996). The maximum tidal excursion is > 6 km during a neap tide and > 20 km during a spring tide. Close inshore on the coast of Fleurieu Peninsula currents are slower, and in the inlets from Blowhole Creek to Fishery Bay and north of Lands End (Fig.1a) there are reverse currents or eddies. There is a mean annual residual flow out through Backstairs passage of ~10 cm sec^{-1}, suggesting a net transport of larvae southeasterly, unless the net flow is reversed by southerly winds.

Fixed sampling sites were established in 1980 at the southern, central and northern sections of the population, namely at Blowhole Creek in the south, Spaceship and Cooalinga Bays in the center, and in Fishery Bay and Lands End in the north. Rocky bottom was continuous at the sampling sites and divers either followed a constant direction or in the case of the southern sites followed the sand-rock interface.

Avoid Bay

Abalone habitat of gneissic or calcrete substratum extends over an area of about 14.7 km^2 from the 30 m isobath south of Pt Avoid between Price and Golden Islands mainly at depths of 15–25 m northwards toward Pt Avoid, with smaller local populations northwest to northeast of Pt Avoid and northeast of Golden I. (Fig. 1b) (Keesing et al. 2000).

From drogue studies at similar coastal sites we estimated that maximum tidal currents which reverse twice daily with a north/south flow are ~20 cm sec^{-1}, and that the maximal tidal excursion is ~4 km. These estimates may be extreme due to the dampening effect of swell on water currents (McShane et al. 1988). Seven survey sites were established at 250-m intervals between Price and Golden Islands at 17–21 m depth (Fig. 1b).

Monitoring Procedures

Monitoring of greenlip populations started in Backstairs Passage in 1980 and in Avoid Bay in 1987. For each population we chose representative sites according to the known distribution of the populations and subject to time and depth constraints. The sampling was systematic to minimize spatial variability, and sampling sites were fixed by reference to land marks in Backstairs Passage and by radar or Geographic Positioning System (GPS) in Avoid Bay. We used the free-swimming, timed swim technique (Kenchington 1978, Shepherd 1985) to measure the relative abundance and size distribution of greenlip *in situ*. Divers measured all abalone encountered with an underwater measuring gauge, in which data points of shell length (SL) are imprinted onto plastic (Shepherd 1985), within a swathe of 1m for 10 min. Surveys were done in the summer and fall from November to May.

The number of replicate 10-min swims per site varied according to the conditions and number of divers available. In Backstairs Passage the mean replication was 5.3 (range 3–9) in the southern section, 8.1 (range 3–16) in the central section and 6.7 (range 2–12) in the northern section. In Avoid Bay there were four replicate 10-minute swims per site. For Fishery Bay we lacked data for the years 1982, 1985 and 1988. For the purpose of calculating mean values for Fig. 6 we estimated recruitment (i.e. the density, D_3, of the 3+ age class) in those years from the density, D_4, of the 4+ age-class in the following year at the site from the equation $D_3 = 0.44\ D_4^{2.77}$ (range of D_4 values 0–1.9/100 m^2) derived empirically over 10 y from all sites combined in the central section where we had the most data. For the same years we interpolated the density of the spawning stock as the mean of the values for the preceding and succeeding year. The above equation has no implications about survival of the D_3 age-class due to the effect of changing sighting probabilities of recruits over time (Shepherd 1990).

Data Sources and Analysis

Catch data, presented in total (in-shell) weights, (TW) are derived from the catch and effort monitoring system in place since 1968. Backstairs Passage is in the Central Zone where there are six licensed divers and Avoid Bay is in the Western Zone with 23 divers. Some poaching in Backstairs Passage was reported occasionally during the 1980s but not since. Backstairs Passage has been predominantly fished by only one or two divers since the mid 1980s. About half the catch from Avoid Bay was graded by size during processing. The three grades, in terms of number of meats per unit weight, are approximately (after metric conversion): 1: <4/kg; 2: 4–6/kg; 3: >6/kg. The data are given in full in Keesing et al. (2000).

Juvenile *H. laevigata* are cryptic to an age of two and a half years then gradually emerge with size (Shepherd 1990, Shepherd & Partington 1995), so we used the 3+ age-class as an index of

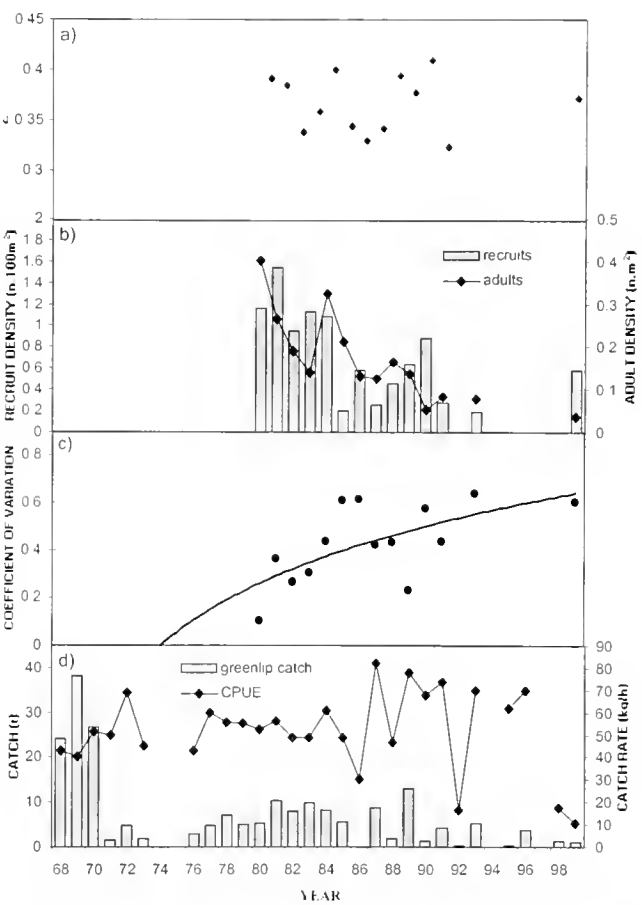

Figure 2. Catch/effort and survey history of the Backstairs Passage greenlip fishery showing: (a) change in total mortality coefficient, Z, over time; (b) mean adult and recruit (3+ age-class) densities for survey sites from 1979–1998; (c) change in coefficient of variation of mean recruitment at survey sites over time, with a trend line fitted to the data; (d) total catch (t TW) and catch rate in kg/hr from 1968–1999.

recruitment strength, and estimated its size range at the date of sampling from the known growth rate. The growth rate of *H. laevigata* is linear during the first 4 y of life in Backstairs Passage (21.3 mm/y) and at Avoid Bay (22.2 mm/yr) (unpublished data, Shepherd & Triantafillos 1997) and we assumed a uniform birthdate on 1 December each year. We used knife-edge separation from the 2+ and 4+ year classes to estimate their abundance in length-frequency samples.

In order to estimate density from the timed swim data we used the equation relating area covered, A, to swimming time, T, number of abalone measured, N, measuring time, m, and diver power, r, given by Shepherd (1985):

$$A = Tr - mrN$$

Swell and algal cover were low at all our sampling sites so we modified the original equation given by Shepherd (1985) to exclude effects of swell and algal cover on diver power.

As the individual power and measuring time of some of the divers used in the surveys were not calibrated (although all were experienced in abalone survey work) we used mean values of r = 20 m^2 min^{-1}, and m = 4 sec (see Shepherd 1985) to calculate the area covered per 10 minute swim. Mean recruitment density (D_3) and adult densities were estimated for each site and the mean for all sites gave the mean annual population values.

Recruitment variability was measured as the coefficient of variation (the standard deviation of the mean annual recruitment values for all sites divided by the mean) and expressed as percentage values (Pimm 1991).

Estimates of the original reef area fished for abalone were obtained from information supplied by commercial divers in 1977 to 1979 to one of us (SAS). We drew maps during interviews with three divers for Backstairs Passage and four for Avoid Bay, and the resultant map was the common area described by the divers for Avoid Bay, but a composite map for Backstairs Passage, which included our own survey data.

Total mortality rates, Z, were obtained from catch-curve analysis. Commercial samples of shells (>450 shells per site), taken throughout the fishing area, were aged (O'Loughlin & Shepherd unpublished data) with the shell-aging technique of Shepherd and Triantafillos (1997) and an age-length key prepared for each site. Length-frequency distributions were then converted to age-frequency distributions and Z estimated from the Chapman and Robson (CR) (1960) estimator, preferred by Dunn et al. (1999) to regression methods. The equation used is:

$$CR = \mathrm{Ln}\,(1 + a - 1/n)/a$$

where a is the mean age (above the recruitment age) and n is the sample size. The analysis assumes a stable age-length structure. This seems reasonable for this abalone, given the absence of evidence for inter annual variability in growth rates (Shepherd & Hearn 1983).

To estimate the density of the spawning stock in Backstairs Passage for the missing year, 1996, we used the empirically derived curvilinear relation between total catch and adult density given in Results. Similarly we estimated the density of the spawning stock in Avoid Bay for 1988 from the respective equation for Avoid Bay (see Results).

In this paper the spawning (or adult) stock is the number of

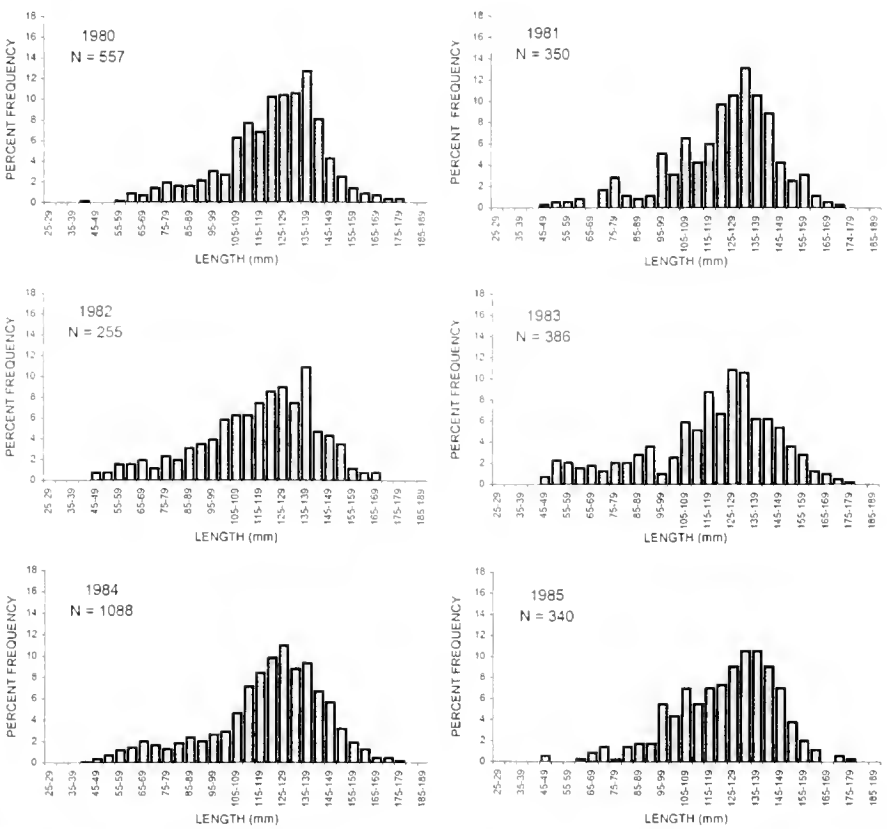

Figure 3. Backstairs Passage. Length frequency data from annual research surveys for all sites combined. The 1993 survey was interrupted by bad weather.

individuals ≥4 years of age i.e. ≥85 mm for Backstairs Passage and ≥90 mm for Avoid Bay.

RESULTS

Backstairs Passage

The catch history of the Passage shows high initial catches in the first three years, typical of a virgin stock, followed by a sharp decline in the catch, and then irregular pulse fishing until the population collapsed after about 1990 (Fig. 2). The catch rates remained high, with occasional falls until 1998 when it fell sharply to a low rate. The fall was due, according to the main diver then working there, to his replacement by an inexperienced diver.

Survey data from 1980 to 1999 provide more detail about the mechanism of decline. Length-frequency data pooled for all sites within years (Fig. 3) showed little change during the period of monitoring, and estimates of Z derived from them also varied little around a mean of 0.37 (s.e. 0.01, range 0.32–0.41), with no downward trend as density declined (Fig. 2a). Mean adult density declined more or less continuously until 1993, and then leveled out, but by 1999 had fallen even lower (Fig. 2). Recruit density varied in an apparently cyclic manner but showed a long-term downward trend, and recruitment variability increased, as shown by the significant ($r = 0.65$; $P < 0.05$), long-term, upward trend in the coefficient of variation (CV).

Local populations at survey sites did not decline uniformly (Fig. 4). The Fishery Bay subpopulation failed first following a steep decline in 1985 to 1987, and by 1993 greenlip abalone were virtually extinct there, except on inshore reefs where small numbers still persisted even in 1999. The spatial contraction of the subpopulation in Fishery Bay and that east of Blowhole Creek (Fig. 1a) was ~115 ha. The remaining populations declined more or less linearly, at a mean annual rate of 3.8% for the southern sites and 5.8% for Lands End. The difference in decline rates was significant ($t = 3.4$; $P < 0.05$). Spatial contraction also occurred in these subpopulations as they retreated toward the coast, but we have not attempted to estimate the areas involved.

The total catch, C in tonnes TW, smoothed with a 3-y running average, shows a curvilinear relation with adult density, D in numbers/m^2 (Fig. 5). The equation of best fit is:

$$C = 10.03 + 2.46 \ln D \qquad (R^2 = 0.36;\ P < 0.05)$$

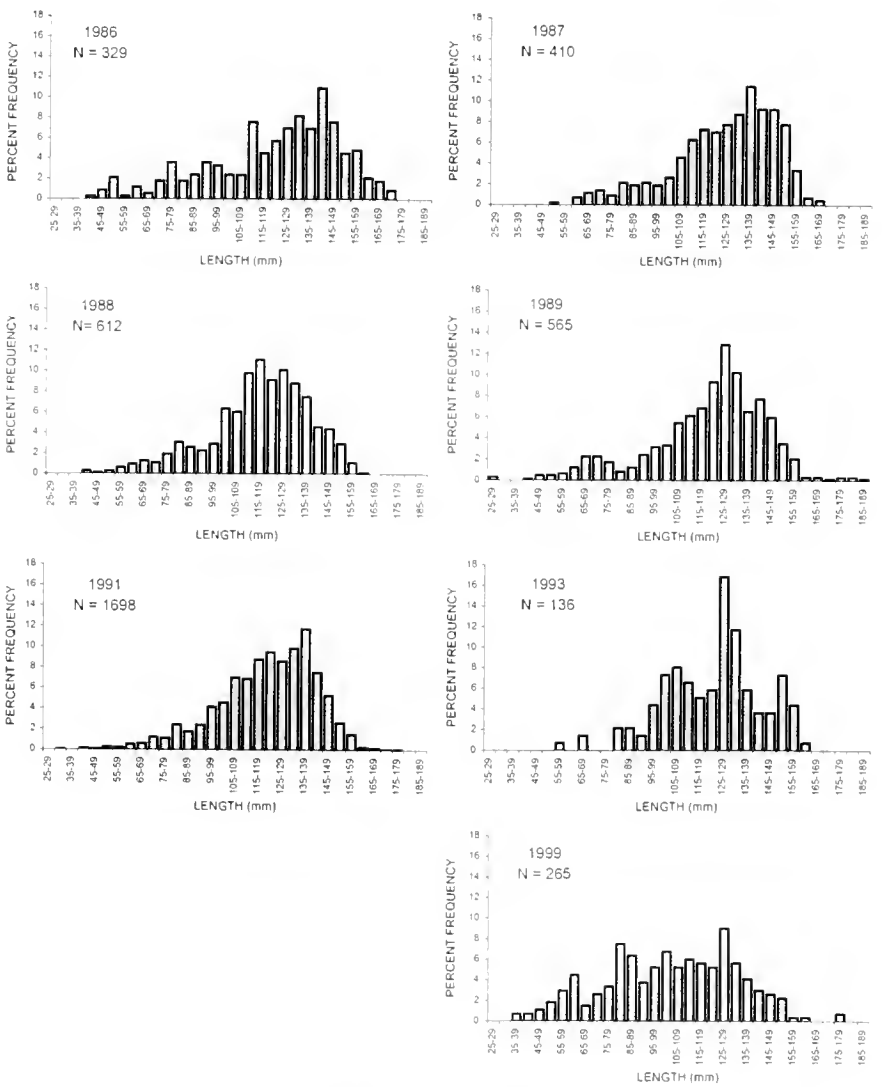

Figure 3. Continued.

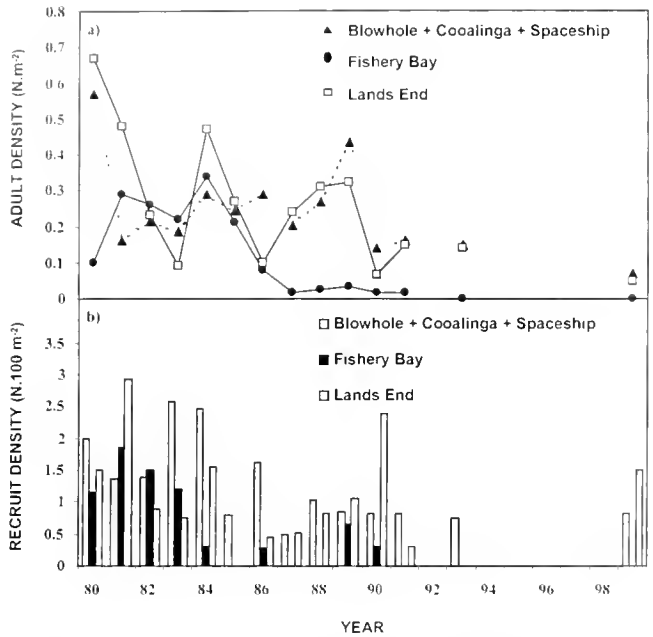

Figure 4. Backstairs Passage. Survey densities of (a) adults in numbers/m^2, and (b) recruits in numbers/100m^2, from 1980–1999 in three sections of the population: Blowhole Creek to Spaceship Bay, Fishery Bay, and Lands End.

Assuming that the Backstairs Passage population is isolated from other populations i.e. without external larval sources, and that larvae from component subpopulations enter a common larval pool (see Discussion), we can examine recruitment in relation to spawner abundance. Stock-recruitment (SR) curves for (a) data from all sites combined and (b) for the Fishery Bay population alone (Fig. 6) show lower curves for Fishery Bay compared with that for all sites, consistent with the more frequent recruitment failures at Fishery Bay. We used the same annual densities of spawning stock for both curves on the assumption that the Fishery Bay subpopulation was linked by larval dispersal to other subpopulations in Backstairs Passage. The equations of best fit are:

$$R_{all} = 1.07 + 0.28 \ln D \qquad (R^2 = 0.19)$$

for all sites combined and:

$$R_f = 0.77 + 0.28 \text{ Ln } D \qquad (R^2 = 0.16)$$

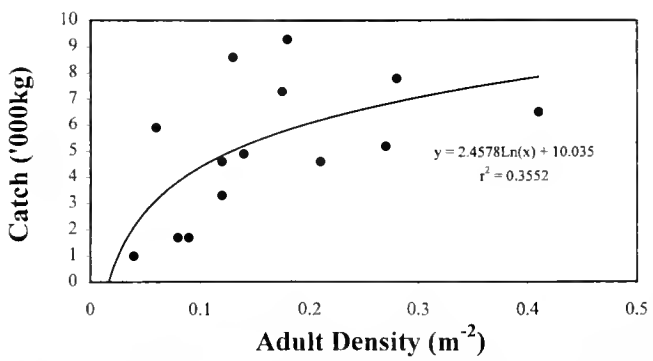

Figure 5. Backstairs Passage. Plot of total greenlip catch in tonnes TW vs adult density in numbers/m^2 with curve of best fit.

for the Fishery Bay subpopulation. In these equations R_{all} and R_f are the mean density of the 3+ age-class for all sites, and for Fishery Bay, respectively, in numbers/m^2 and D is the mean adult density for all sites in numbers/m^2. The data points for 1977 to 1999, for which density was estimated from the catch, are shown in Figure 6 as hollow symbols. These estimated points were excluded from the regression analyses, but are included to show that strong recruitment from the earlier years of the fishery may have produced more elevated or even dome-shaped curves. Note that no strong recruitment occurred at mean densities of <0.15 /m^2.

Avoid Bay

We do not have data at a reef scale for the catch from 1968–1970 when virgin stocks were removed, but the subsequent mean annual catch in Avoid Bay for years 1971 to 1978 was 49.1 t (Keesing et al. 2000). From 1979 to 1983 the annual catch was on average 14% higher than the previous eight years and then declined sharply from 1984 until 1998 when the catch was ~1 t (Fig. 7), giving a mean annual rate of decline of 5.8% since 1979. Catch rates in Avoid Bay remained more or less constant, save for a slight decline in 1996.

Surveys of the Bay started in 1987 when the catch was already well in decline. Length-frequency data (Fig. 8) show little change over the period, and estimates of Z similarly are within a narrow range of 0.50 to 0.67 with a slight but non-significant downward trend (see Fig. 9a). Adult densities, initially two to three times higher at the inshore Sites (1–4) than at the offshore sites (5–7), declined more or less continuously at both, so that from 1996 offshore densities were only ~0.05.m^{-2} and too low to be worth fishing. Density of recruits showed only a weak downward trend over time at Sites 1–4, while at Sites 5–7 recruitment was low, variable, and not detectable after 1995. The coefficient of variation of recruitment (Fig. 7b) increased until 1993 and thereafter fluctuated widely. Although survey data are lacking for the most productive period of the fishery (1971–1983) it is clear that adult populations failed at the offshore sites earlier than they did at the inshore ones. Spatial contraction of the stock was very marked (Fig. 1b), with a total loss of fishable habitat of ~14 km^2. The only places now fished are those close to Price and Golden Islands and near Pt Avoid.

Plots of changes in proportional abundance of three size grades

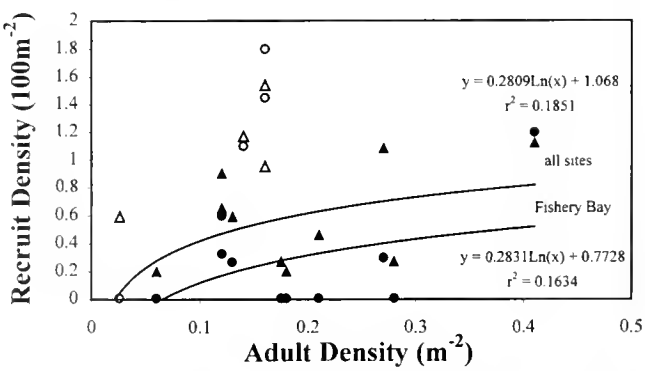

Figure 6. Backstairs Passage. Stock-recruitment curves for all sites combined and for Fishery Bay alone with curves of best fit. The mean annual density of recruits (3+ age-class) is plotted against the mean density of adults 3 y earlier. Recruit densities are: solid triangles (all sites), solid circles (Fishery Bay) and hollow symbols for the years 1977–9.

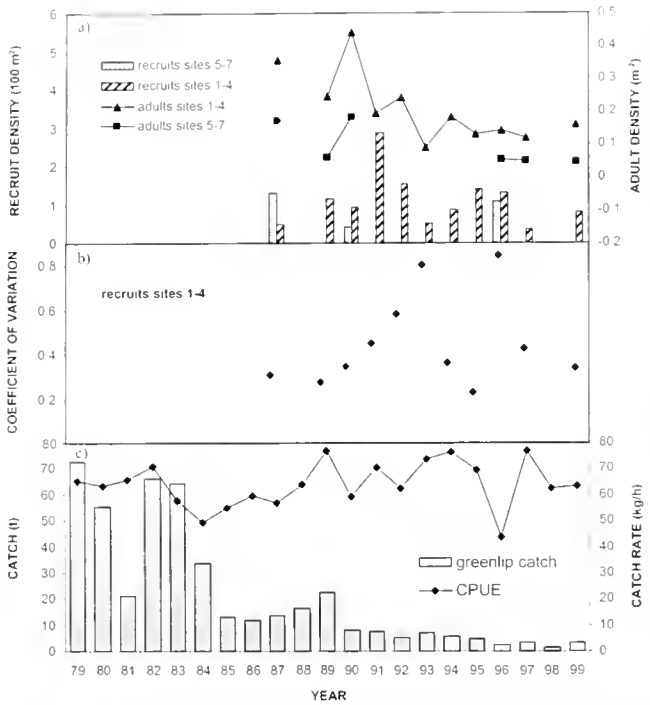

Figure 7. Catch history of greenlip abalone in Avoid Bay showing: (a) mean adult (numbers/m^2) and recruit (numbers/100 m^2) densities for 1979–1999; (b) change in coefficient of variation of mean recruitment for sites 1–4; (c) total catch (t TW) and catch rate in kg/hr for 1979–1999.

over time (Fig. 9b) show that the largest grade (Grade 1) increased significantly ($P < 0.001$), and the smallest (Grade 3) decreased significantly ($P < 0.05$) over the 21 y, but this may have been contributed to by the size limit increase in 1984. If we exclude data prior to 1984 then the same trends in grades are apparent but they are not significant ($P > 0.05$).

The total catch, C, smoothed with a 3-y running mean, shows a curvilinear relation with adult density, D (Fig. 10). The equation of best fit is:

$$C = 20.57 + 6.76 \ln D \qquad (R^2 = 0.63;\ P < 0.05)$$

Plots of mean recruitment density for nearshore and offshore sites vs mean adult density (Fig. 11) show very variable recruitment in relation to adult density at nearshore sites and generally poor recruitment for the few offshore data points. The shape of any SR relationship appears indeterminate so we simply show the line of best fit for each group of sites forced through the origin. The curves imply weak density-dependence.

DISCUSSION

The two studies provide vital information on the process of decline of these abalone populations. Two effects are conspicuous: the increase in recruitment variability and the spatial contraction of the populations. Increasing recruitment variability implies that a population will be more susceptible to overfishing during years of poor recruitment (Myers & Pepin 1994, Shepherd & Baker 1998). Hence this effect may itself contribute to the spatial contraction of a population because subpopulations with poor recruitment will run a higher risk of increasing depletion, fragmentation and extinction. However, independently of any effect of recruitment variability, spatial contraction may occur through differential recruitment or juvenile mortality throughout the habitat of the original population. We have no data on juvenile mortality but the topographic features defining population boundaries suggest a mechanism for differential recruitment acting at the pre-settlement stage.

Shepherd et al. (1992) noted that topographic coastal or benthic features, such as inlets and rock pinnacles, increased local recruitment strength of greenlip abalone. McShane (1995) reviewed the effects of hydrodynamics on larval transport and concluded that in open waters abalone larvae may be transported large distances but near reef of high relief can be retained near the natal site. Shepherd and Rodda (2001) reviewed other studies showing that islands and bays generate sheer zones and eddies that concentrate larvae. The studies of Shepherd et al. (1992) and Rodda et al. (1997) both suggested transport distances for greenlip larvae of several km from their natal site in places of tidal currents. Studies of the behavior of greenlip larvae (Madigan et al. 1997, Madigan 2000) show that during the trochophore and early veliger stage, together lasting about four days, larvae tend to swim upward. Hence they are likely to be distributed throughout the water column and transported passively in wind-driven and tidal currents for several days before settlement (Sasaki & Shepherd 1995).

Larval behavior at settlement is also important. McShane (1992), McShane (1995), Nash (1992) and Shepherd and Partington (1995) all showed a significant inverse relation between recruitment strength and water movement. McShane (1992) considered that water turbulence could keep larvae away from suitable sites, thus preventing them from making contact with the substratum and responding to settlement cues. Thus several hydrodynamic factors and larval behavior can interact to cause spatial differences in recruitment in abalone habitat.

In greenlip abalone spawning is believed to occur mainly during October to November at around the neap tide (Rodda et al. 1997, Shepherd & Daume 1996, and K. Rodda pers. comm.), so that larvae would remain pelagic to within two days of the beginning of the spring tide when currents are maximal. Thus tidal currents would transport larvae for much of the tidal cycle from neap to flood tide. Hence we may conclude that both in Backstairs Passage and in Avoid Bay, where tidal excursions are at about the same spatial scale as the abalone populations, larvae originating from any subpopulation could settle in any other subpopulation, and are likely to be concentrated by hydrodynamic forces near inlets, headlands and islands. Wind-driven currents and swell could bias up or down any estimated distances of larval transport by tidal currents.

Our recruitment data are consistent with the above predictions. In Backstairs Passage (Fig. 1a), the sites of strongest recruitment, at Lands End, Blowhole Creek, Cooalinga Creek and Spaceship Bay were all in near-shore eddies out of the strong current flowing through the Passage. In Fishery Bay, where recruitment failed earliest, the habitat was of low relief and water currents were very strong. In Avoid Bay (Fig. 1b) populations persisted near the headland of Point Avoid and around Price and Golden Islands, but largely disappeared from the low-relief habitat with stronger tidal currents between the islands. In summary, the three effects, increasing recruitment variability, concentration of larvae by topographic features and an inverse relation between settlement strength and water velocity, can together explain the differential declines observed.

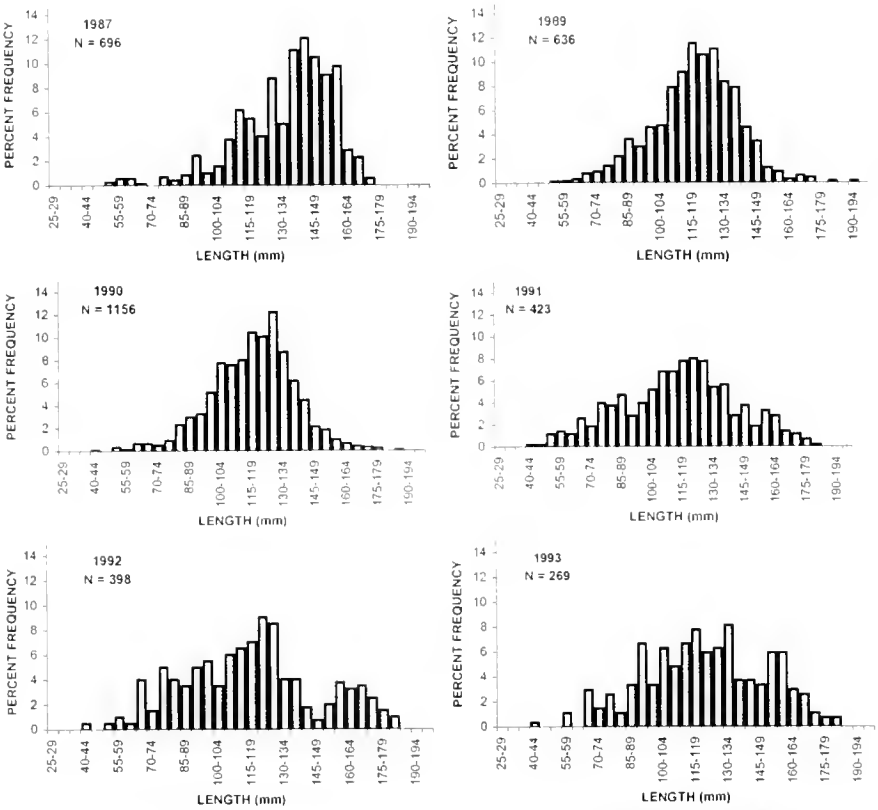

Figure 8. Avoid Bay. Length-frequency data from annual research surveys for all sites combined.

Catch-Abundance Relations

The relation between total catch and abundance is complex and can be confounded by sampling contingencies, spatial contraction of a stock, and diver behavior. We consider them in turn.

Survey densities will vary according to the time of survey in relation to fishing and according to the representativeness of the survey sites in relation to the population response to fishing. Researchers tend to choose sampling sites at shallower, more accessible places close to shore, where subpopulations may be more resilient to fishing and hence may not be representative of the whole population.

Spatial contraction will also confound a direct catch-abundance relation. As abundance is a function of density × area, if the area occupied by the population decreases, overall abundance will decline faster than a decline in density alone at fixed sites, unless the sites are systematically located throughout the spatial extent of the population.

Lastly, divers operate in a visual fishery and a range of human responses may influence their catch. The dominant motivation of commercial divers is to maximize their catch rates (Keesing & Baker 1998, Prince & Hilborn 1998). Divers use their knowledge to fish the largest aggregations, and then progressively smaller ones, and finally cease fishing when densities are low. The decision threshold prompting departure from a reef is principally determined by the catch rate, but other factors such as distance from homeport and depth also play a role (Shepherd & Rodda 2001). Divers accept lower catch rates close to homeport and in shallower water (Keesing & Baker 1998; McShane 1998). Divers also have different spatial strategies, and include: *risk-takers*, divers who fish more reefs and take risks looking for new concentrations of abalone; *followers*, who are content to revisit familiar grounds; and those with intermediate strategies (Prince & Hilborn 1998, McShane 1998). Surveys of South Australian divers by one of us (SAS) have shown that most (~70%) divers tend to fish a group of 5–10 populations with which they are most familiar. But a few, ~20% in the sample, (the risk-takers) show more exploratory behavior and fish up to 20 populations. The remainder has intermediate strategies. The different diver strategies ensure that all exploitable stocks are periodically visited and fished. The implication from these behaviors is that, in the long term, a stable or fluctuating total catch implies stability and a declining total catch, as also declining effort, a declining abundance. While other factors, such as price, weather, and diving conditions, may also affect the behavior of divers there is no evidence that they do other than increase the noise, without changing the underlying relation.

The catch-density curves for the two sites support the hypothesis that the total catch crudely reflects abundance. The relation is noisy and curvilinear as predicted, and suggests that total catch is likely to show hyperstability during the early decline of a population, but when abundance has substantially declined the total catch will decline more steeply.

Stock-Recruitment (SR) Relations

Caddy (1999) noted that in spatially structured populations of sedentary species stock recruitment relations depended on local densities not stock size. Hence SR relations can strictly only be fully described by a family of curves covering every local area with a different recruitment pattern (see Wing et al. 1998, Oren-

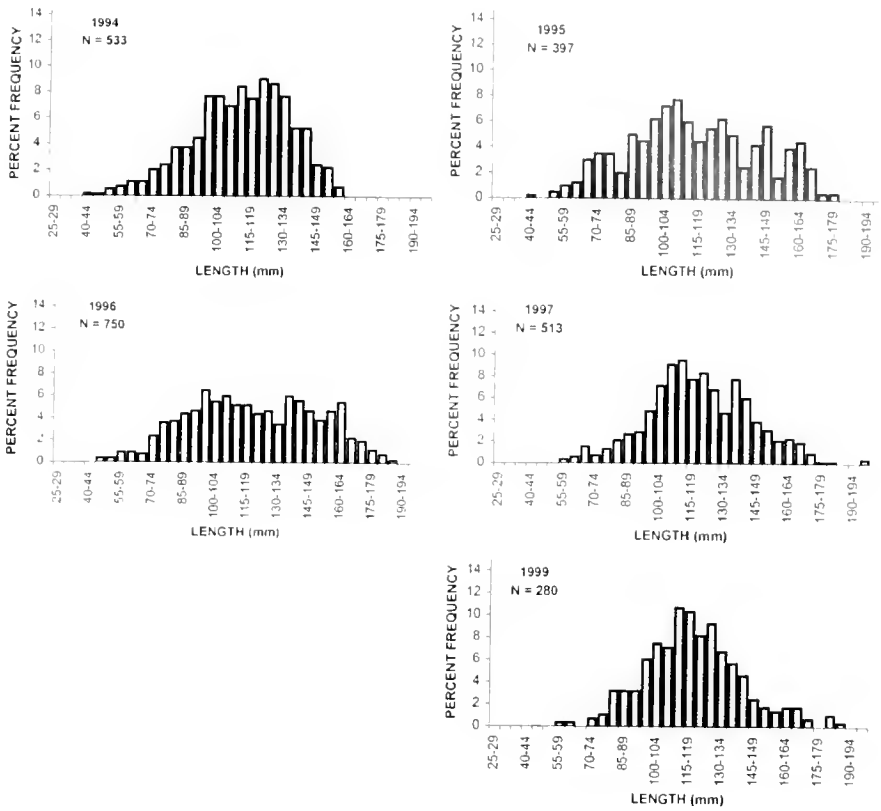

Figure 8. Continued.

sanz & Jamieson 1998 for a discussion of SR patterns in spatially structured stocks). Given the spatial limitations of our data set and the small time series for Avoid Bay, the pair of SR curves presented for each of the two sites can at best be taken as vaguely representing (a) resilient abalone habitats where larvae are retained by hydrodynamic effects, and (b) vulnerable habitats where larval settlement and/or survival are less successful. As discussed previously the models assume a common larval pool.

Whether habitats are vulnerable because of intrinsic factors such as their hydrodynamics or predation, or because of attractant biotic factors, such as the presence of conspecifics, is speculative. On the latter possibility there are four field studies in addition to some laboratory experiments on abalone which suggest that the presence of conspecifics plays an important role in attracting settling larvae. Tutschulte (1976) removed adult abalone from experimental areas of 25 m^2 and found that recruitment in those areas failed. Prince et al. (1987) and Prince et al. (1988) did similar experiments with the same results. Recently Andrew et al. (1998) did the reverse and placed adult abalone in crevices previously without them. They found a 10-fold increase in recruitment. In

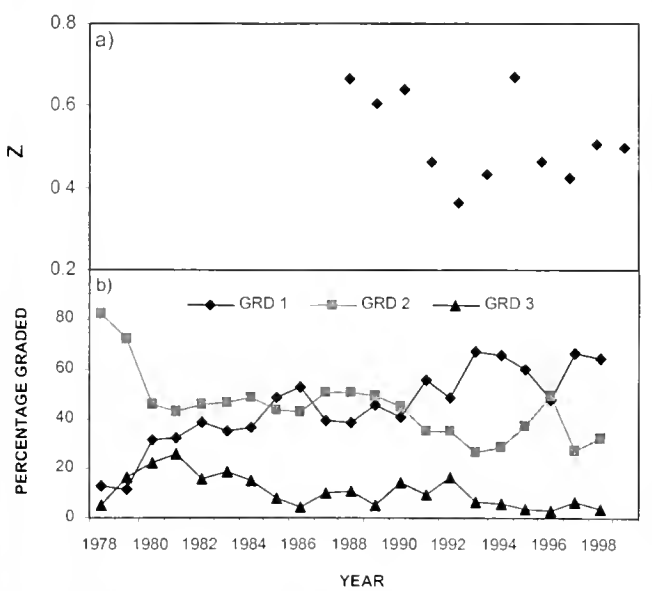

Figure 9. Avoid Bay. (a) change in total mortality coefficient, Z, from 1987–1999; (b) change in proportions of three grades of meat weight in the total catch, expressed as a percentage, from 1978–1998. Grade 1 is < 4 meats/kg; grade 2 is 4–6 meats/kg; grade 3 is >6 meats/kg.

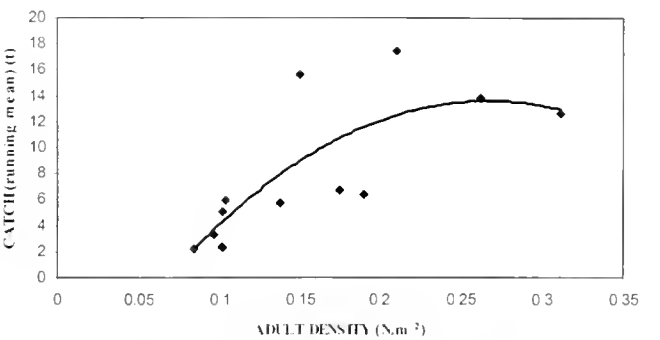

Figure 10. Avoid Bay. Plot of total catch (running mean) vs mean adult density with curve of best fit.

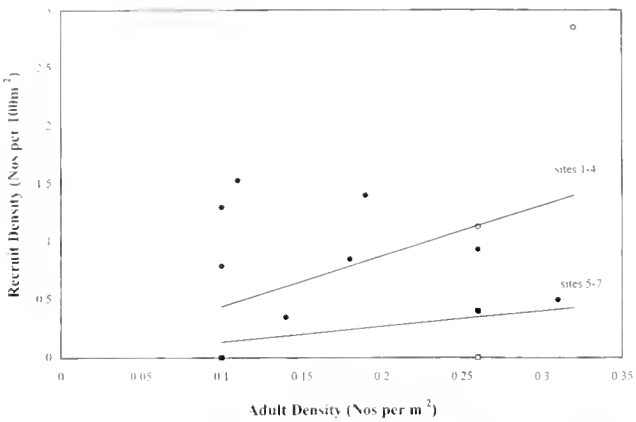

Figure 11. Plots of mean annual recruit density vs adult density for Avoid Bay. Recruit densities are: solid circles for Sites 1–4 and solid squares for sites 5–7 and hollow symbols for years in which adult densities were estimated from the catch. Trend lines for Sites 1–4 and 5–7 are shown. See caption to Figure 6 for 3-y lag time procedure used in the plots.

Western Australia T. Adams (pers. comm.) did a similar experiment with greenlip abalone at a site from which abalone had disappeared some years before and later recorded good recruitment there. Conversely Shepherd et al. (1992) did both additions and removals of adult greenlip at experimental sites with moderate to strong tidal currents but found no effect of local adults (but a strong effect of topography) on recruitment. More recently Daume et al. (1999) showed experimentally that *H. laevigata* settled gregariously in the presence of older conspecifics consistent with the slime trail hypothesis suggested by earlier workers (McShane 1992).

Whatever the mechanism for the failure of recruitment, the SR curves demonstrate the complexities of spatially structured stocks. Unlike the single isolated population in Waterloo Bay with its restricted larval dispersal (Shepherd & Partington 1995), these populations are not internally homogeneous in terms of recruitment strength. Hence SR relations will vary according to habitat and any analysis based on a few survey sites must be a gross over-simplification.

We do not pretend that the SR curves presented here represent the true shape of any underlying SR relation. As argued by Hilborn (1986), Underwood and Fairweather (1989) and Koslow (1992), the concept of a deterministic relation between stock size and recruitment is not easily applicable to invertebrate stocks with high fecundity and correspondingly high, strongly density-dependent mortality during the early life history. Nevertheless, the lower and likely flatter, SR curves for vulnerable habitats at each site suggest the Achilles heel of these populations and the mechanism of their spatial contraction. Flat SR curves imply weak density dependence such that even small increases in exploitation reduces the recruitment rate below the replacement rate and thus leads eventually to population collapse within that habitat (Shepherd & Cushing 1980). Prince and Guzmán del Próo (1993) modeled populations of declining Mexican abalone stocks and found that a similar flat SR relationship best explained the decline of those stocks. Perusal of the SR curves suggest that recruitment overfishing in Backstairs Passage must have occurred about 1980, because no strong recruitments occurred after that year. In Avoid Bay overfishing probably occurred before 1987 when surveys began, but, in the absence of information about the rate of spatial contraction, conclusions about the timing of overfishing events are speculative. Maintenance of productivity of these greenlip populations at the catch levels existing up till about 1985 will thus depend on maintaining abalone densities in vulnerable habitats at much higher levels than those required for resilient habitats.

Fishery Indicators (FI)

The concept of FI and the related one of biological reference points (B.R.P.) have emerged in recent years to enable managers to continuously evaluate the state of fished stocks and employ strategies to prevent their collapse (Myers et al. 1994). The approach is precautionary and accepted both in this fishery (Zacharin 1997) as in international instruments (Caddy 1998, Caddy 1999). Recent developments in this approach include improved decision-making under uncertainty, and consensual adoption of decision rules once limits are approached or exceeded. Nowhere is this more urgent than in abalone fisheries which have depressingly collapsed in nearly all major fisheries in the world (Shepherd & Baker 1998), and now partially in southern Australia (Shepherd & Rodda 2001).

Empirical data from these two stocks provide a testing ground of potential indicators for this fishery. With modification we believe it may be widely applicable to other abalone fisheries. First we note that abalone must be classified as data-poor fisheries, because they comprise many independent stocks for which good fisher-independent data even in the best conditions are seldom available. So what is needed are very simple indices that can be derived 'with only fuzzy knowledge about stock levels and recruitment curves' (May et al. 1978). Such indices are to be sought from (1) historical catch and effort data provided by fishers to government agencies, (2) survey data, and (3) parameters such as the total mortality coefficient, Z, and dependent analyses such as egg-per-recruit (EPR).

Historical Catch and Effort Data

It is almost trite that catch rates (CPUE) offer little or no help as an FI (Breen 1992, McShane 1998, Orensanz et al. 1998). This is because abalones have a clumped distribution, and after fishing they tend to re-aggregate in favored habitats (Shepherd & Partington 1995). Because divers search for aggregations and give up searching at low densities, searching time is not proportional to overall density and catch-rates show hyperstability (Sluczanowski 1986). CPUE thus depends very largely on diver behavior as described previously. Shepherd & Partington (1995) noted that as the fishery in Waterloo Bay collapsed CPUE increased, because divers ceased searching the whole area of the bay and concentrated their effort in the few remnant places where abalone aggregated. A similar behavior may explain the constancy of CPUE in Backstairs Passage (except 1998–1999) and Avoid Bay despite the long-term decline in abundance.

Although CPUE is of dubious value, we propose that a time series of total catch data is a crude but useful indicator of abundance in declining populations, providing it is collected at a fine scale (Shepherd & Brown 1993, Keesing & Baker 1998). The proviso is important because, if the catch data are collected at too coarse a scale, serial depletion occurring at a finer scale is masked. The use of total catch itself is the concept of maximum constant yield (MCY) currently used in New Zealand (Annala 1993, Francis 1993). It is "the maximum constant catch that is estimated to be sustainable, with an acceptable level of risk, at all probable future

levels of biomass". Shepherd and Baker (1998) used the constancy of historic catches for specific metapopulations as empirical evidence on which to base estimates of safe fishing mortality rates (see later in text). Shepherd and Rodda (2001) examined declines in the catch of many other greenlip populations in this fishery and showed that alternative explanations for their decline were so implausible that in this fully exploited fishery, a declining catch should be accepted as evidence of declining productivity.

Changes in the size grading of catches, like other measures based on the size structure, probably reflect changes in the exploitation rate (Andrew et al. 1997, Worthington et al.1998) and may therefore be useful to monitor. However, Keesing et al.(2000) noted great ambiguity in the signal, due to changes in diver behavior and spatial contraction of a stock. The exploitation rate, Z, may remain constant or even fall during the decline of a stock, (Shepherd & Baker 1998), so that neither it nor measures related to size structure are definitive indicators. As in the two examples in this article, populations may collapse with little or no change in CPUE, size grading, length-frequency distributions or Z.

Survey Data

If changes in the spatial extent of declining abalone populations are common, as our data for other declining populations suggest (Shepherd & Rodda 2001), then surveys need to be designed explicitly to cover the spatial extent of the populations to be monitored. If the coverage is partial (as at both sites described here) or biased, then the results are, to that extent, diminished. In research surveys other valuable information such as data on density, the size composition of the emergent population, and the aggregational structure (Shepherd & Partington 1995, McShane 1998) can also be obtained. While spatial information and density estimates together clearly provide the best FI of a stock, cost, especially in deeper water, prevents their widespread or optimal use. Data from Backstairs Passage and Waterloo Bay show a high risk of recruitment failure below mean densities of 0.2 (±0.05)/m^2. The Avoid Bay data suggest even higher densities of ~0.3/m^2 should be maintained, given that the population was already in decline when surveys started. However, a collapse threshold density was only evident for the Waterloo Bay SR curve, possibly due to high larval retention and the more constant recruitment there. The existence of vulnerable habitats, with more variable recruitment, complicates the picture and indicates the need for even higher densities as a buffer against recruitment failure.

Size compositional data are valuable because they can be used to estimate recruitment either in length-based models (Worthington et al. 1998) or in age-based analyses. According to Shepherd et al. (1984) a time series of recruitment is the most unambiguous indicator of abundance in a population. Lastly, there are measures based on the frequency and size of aggregations in surveys. Such measures certainly change as a stock collapses, and they may prove to be valuable, as implied by McShane (1995), and shown by Shepherd and Partington (1995) for the Waterloo Bay population.

Egg-Per-Recruit Analyses and Mortality Coefficients

The problem for precautionary management is to ensure that sufficient spawning biomass is conserved to minimize the risk of recruitment failure. One approach, termed a constant relative escapement strategy, is to set a safe maximum fishing mortality, F (Mace & Sissenwine 1993, Garcia 1996). This leaves a variable spawning biomass from year to year depending on annual recruitment strength. Shepherd and Baker (1998) proposed this for greenlip abalone and suggested $F_{50\%}$ for small stocks and $F_{40\%}$ for large stocks, the difference being due to the observed greater vulnerability of small stocks to overfishing. Here the notation $F_{50\%}$, for example, means that level of F which reduces egg production in an EPR analysis to 50% of the unfished value. This suggestion was based on the analysis of a number of exploited greenlip stocks combined with a global review of nine other abalone fisheries. During the major period of fishing the egg production conserved was 32% in Backstairs passage and 37% in Avoid Bay (O'Loughlin & Shepherd unpublished data). Both were clearly inadequate, and demonstrate the need to reduce F substantially. The recovery of a stock is very unlikely to occur if fishing is permitted to continue in depleted stocks, because divers will continue to fish down the shrinking remnant subpopulation until near extinction. The failure of other collapsed greenlip stocks to recover after 15–20 y (Shepherd & Brown 1993, unpublished data) suggests that depensation at low stock densities may occur.

An alternative strategy is to have a constant absolute escapement, as advocated by Caputi (1992) for a prawn fishery, a strategy that would require routine estimation of annual recruitment strength. This would enable better exploitation of strong year-classes, and may be well suited to short-lived species like prawns with highly variable recruitment. For longer-lived species like abalone in which the catch typically comprises individuals aged six to ten years (Shepherd & Avalos-Borja 1997, Officer 1999), and recruitment strength is very costly to measure, this strategy would confer little advantage and in any event would be practically impossible to implement.

Mace (1994) suggested a threshold biomass based on the shape of the SR relationship i.e., that biomass at which recruitment is one half of the maximum possible. While this is readily determined from the Ricker SR curve for Waterloo Bay (Shepherd & Partington 1995), it is indeterminate for populations like Backstairs Passage and Avoid Bay where SR curves vary spatially and may show a continually ascending curve as in vulnerable habitats. Any chosen threshold from such a curve is dubious because gains in recruitment can always be expected from every increase in spawning stock. Besides, an SR curve will be unknown for all but the very few stocks that have been monitored to collapse.

Other BRPs and FIs are reviewed by Caddy (1998) but either require better data sets than are usually available for abalone or are not appropriate for sedentary stocks.

Use of Multiple Indicators in a Fuzzy System

The above analysis suggests that three kinds of measures, catch data, density, and possibly patch size, data, and $F_{40-50\%}$ values, are the best candidates for use as FIs in the greenlip fishery. They need to be evaluated by simulation and, if shown robust, should then be incorporated into the management protocols described below. Given the lack of information available for individual populations, except for catch data, but the capacity to quickly gain more as required in specific trouble spots, we propose a 'trouble spot thermostat' approach (Caddy 1998, Caddy 1999). First, populations with declining catch (trouble spots) are identified from historic catch data and targeted for assembly of archival information and field survey. Because total catch data tend to be hyperstable early

TABLE 1.

Trouble spot thermostat protocol for decision making after detection of early declines in individual greenlip abalone populations. Read table from bottom to top by analogy to a rise in temperature. The table uses a suite of fishery indicators (left), ordered from levels 1 to 4 according to increasingly severe criteria in a troubled population. Each level leads by an arrow in column 2 to an agreed management response in column 3, and triggers either a demand for more detailed research information or a sterner management response. The ultimate measure is a closure of the troubled population if the criteria are not met.

	Metapopulation Fishery Indicator		Agreed Management Response
4	Total catch decline >60%[3]	→	Close fishery. Establish recovery plan.
	OR		
	Recruitment decline >20% over last 4 years		
3	$F > F_{40\%}$-$F_{60\%}$ according to site[2]	→	Take corrective measures to reduce F (reduced season, closure or increased size limit)
2	Estimated spatial decline >50%	→	
	OR		
	Mean survey density <0.25 m^{-2}		Do EPR analysis. Commence annual recruitment survey.
	OR		
	Z > 0.4		
1	Total catch decline >30%[1]	→	Survey spatial extent of population and compare with historical records. Do catch curve analysis.

[1] Catch decline per map code area since 1985 (Western Zone), 1988 (Central Zone) and 1989 (Southern Zone), being the years in which quotas were introduced.

[2] $F_{40\%}$ for populations of initial productivity >10 t/y^{-1}, $F_{60\%}$ for populations with initial productivity <10 t/y^{-1} (from Shepherd & Baker 1998). Even higher % values of F should be conserved in populations already in serious decline.

[3] Adopt this alternative if corrective measures at level 3 have not been taken; otherwise adopt the second alternative.

in a population decline we propose a small decline (30%) as a trigger for initial action. As the indicators are generated and triggered at level 2 (Table 1), management action is required to commission more data on the trouble spot in question. Then, if the indicator, $F_{40\%}$, for example, is triggered, a more severe management response is dictated. The alternative indicators at several steps reflect the uncertainty inherent in any single indicator. The ultimate response is to close the troubled population to fishing and initiate a stock recovery program.

The consequences of overexploitation of a poorly managed stock are decline and ultimately collapse, so the risks in procrastination are great and will generate large economic losses. A thermostat approach would stimulate timely corrective action, and restore the fishery at a small present cost but with great long-term benefit.

ACKNOWLEDGMENTS

This paper is dedicated to the memory of Kevin L. Branden who competently and enthusiastically led the dive team for 12 years during these surveys. We also thank other participant divers: A. Burnell, P. Clarkson, M. Clark, S. Clarke, B. Davies, A. Dalgetty, C.H. Deane, B. Foureur, N. Holmes, J.K. Keesing, D. Lowe, I. McGraith, M. Miller, A. Mower, P. Preece, S. Rodda, J.A. Turner, J. R. Turrubiates, J. Van der Broek, G.W. Wright. Commercial divers helpfully provided information on their fishing areas. The RV Ngerin crew assisted divers and manned the diving dinghies in Avoid Bay. G. Wright prepared Figure 1 and Dr P.A. Breen made many constructive comments. Dr S.A. Guzmán del Próo and an anonymous referee criticized the manuscript. The Fisheries Research and Development Corporation provided funds during the early surveys.

QUANTIFYING THE PHYSICAL AND BIOLOGICAL ATTRIBUTES OF SUCCESSFUL OCEAN SEEDING SITES FOR FARM-REARED JUVENILE ABALONE (*HALIOTIS MIDAE*)

S. DE WAAL* AND P. COOK

Zoology Department, University of Cape Town, Private Bag, Rondebosch 7701, Cape Town, South Africa

ABSTRACT In short term experiments of under 3 mo, carried out in McDougall's Bay, on the northwest coast of South Africa, survival of seeded juvenile abalone (*Haliotis midae*) has been shown to be directly linked to both the size of the abalone at seeding and to the physical attributes of the seeding site. The presence of the sea urchin (*Parechinus angulosus*) has been shown to be insignificant in terms of short-term survival of juvenile *H. midae*. Within the context of selecting the right seeding site attributes, short-term survival was shown to be up to a minimum average of 59% for animals with an average size of 26.61 mm (SD ± 1.33mm), compared to a minimum average of 24% for animals with an average size of 13.87 mm (SD ± 1.73 mm). The fact that the presence of urchins played no significant role in the survival of juvenile abalone, ranging in size from 13 to 27 mm, changes the idea of what the characteristics of successful seeding sites might be. A positive correlation has been established between habitat consisting of stacked boulders, of diameter less than 30 cm, and abalone survival.

KEY WORDS: seeding size, urchin exclusion, site characteristics, habitat, abalone

INTRODUCTION

Seeding experiments using juvenile abalone, *Haliotis midae*, carried out by Sweijd et al. (1998) on the Northwest coast of South Africa showed that some potential existed for the successful introduction (seeding) of this species along this stretch of coastline. To optimize success, it is necessary to understand both the recruitment and ecological dynamics of the species and to determine the life cycle stages that would be most successful in terms of both survival and growth (Tegner & Butler 1989, Davis 1995). One of the most fundamental aspects of the successful recruitment of *H. Midae* is the association between the juveniles of the species and the urchin, *Parechinus angulosus*. This association is considered so strong that the presence of the urchin is considered a driving factor in the population dynamics of this abalone species (Day 1998, Tarr 1995, Tarr et al. 1996). The association between urchin species and abalone species is reported worldwide, and is not restricted to the South African species (Inoue 1987, Kojima 1981, Rogers-Bennet & Pearse 1998, Tegner 2000). Indications are that naturally occurring *H. midae*, up to the average size of 35 mm, are found almost exclusively under urchins (Day 1998, Tarr et al. 1996). While there are also indications that long-term survival of juvenile abalone is linked to the utilization of urchins as refuge, the relationship between artificially seeded *H. midae* and their assumed habitat has not been investigated or quantified. A range of long-term experiments was designed to begin addressing these issues. Initial results, collected over a period of 6 mo, using abalone ranging in size between 8 and 18 mm, showed very low survival rates, ranging from 0 to 12%. This was in contrast to the results of the previous experiment (Sweijd et al. 1998), in which animals ranging in size between 8 and 14 mm showed an average 6-mo survival rate of 30%, seeded in what was regarded as similar seeding environments. While survivors did show a very high association with sea urchins, it became clear that the precise physical attributes of the seeding site, in terms of shelter and protection against both possible predation and against adverse ocean conditions, appeared to be an important factor in survival (Emmett & Jamieson 1988, Schiel 1993). The initial results were confusing; the effects of rough sea conditions could not be differentiated from the effect of abalone seeding size or the influence of the physical or biological attributes of the seeding site. To address these issues, a series of short-term experiments were carried out in McDougall's Bay, Port Nolloth, seventy kilometers south of the Orange River at 29°17′S and 16°52′E. The experimental area is in a bay which, while protected from direct wave action by a reef, is exposed to strong currents and surges. An important advantage of this site was that it allowed constant access by divers to the seeded abalone. The average depth of the experimental area was between 2 and 4 m, with the physical substratum on which the animals were seeded, being predominantly loose, overlapping boulders, of differing sizes. The experiments were designed to address three basic questions:

1. the importance of sea urchins to the survival of seeded juvenile abalone.
2. the influence of abalone size on short-term survival.
3. the type of habitat which offers juveniles short-term protection and shelter.

METHODS

The seeding procedure used for all experiments was the same. The traps used for seeding were those described by Sweijd et al. (1998), consisting of lengths of PVC piping of decreasing diameter, cut in half and placed inside each other. A gap of approximately 1.5 cm was left between pipe sections, and the pipes were then mounted on a flat plastic base. This base was then mounted on a steel plate, which acted as a weight that kept the trap stable on the ocean floor, allowing the animals to leave and return to stable refuge (Schiel 1993). The juvenile abalone were gently brushed into the semi-cylindrical tubes making up the trap. The traps were then closed at both ends with perforated plastic covers that allowed a through-flow of water, and placed into well-aerated, seawater holding tanks. After approximately 30 min, the traps were placed in plastic bags, sealed and placed in Styrofoam containers with sponge-wrapped freezer blocks. The containers were closed and transported to the seeding sites. The trip normally took approximately 20 min. On arrival at the seeding sites, the traps were immediately taken out of the containers and placed into rock

TABLE 1.

Urchin densities and juvenile abalone survival.

Site	Period (days)	% Survival	Urchins Density Per M^2	% Found Under Urchins	% Found Under Boulders
1	17	5.67	6.79	35.29	64.71
2	17	5.67	0	0	100
3	17	15.67	8.91	27.66	72.34
4	17	3.33	0	0	100
5	23	28.67	0	0	100
6	23	25.33	4.51	39.47	60.53
7	23	28.33	0	0	100
8	23	38	8.59	29.82	70.18

Total number of urchins were counted in a 3 m radius around each trap. Period in days indicates time between seeding and sampling.

pools or in shallow water. The traps were then moved underwater to the seeding sites.

The traps used in the experiment were kept closed until they were in position, and then opened. All the traps were monitored for approximately 20 min after they were opened. Other than a few animals, which were sitting on the plastic covers, no animals exited from the traps and no predators were attracted to the traps in the time immediately following opening. Traps were also observed on a daily basis, and this revealed that by far the greatest majority of animals did not begin to leave the traps until well into the night of the first day, and in many cases not until the second or third day.

Diver efficiency and sighting probabilities were considered. However, due to the fact that only one person was responsible for the searches, the very small numbers of experimental animals used, and the restricted experimental areas, they were disregarded. The sighting probabilities mentioned by Shepherd (1998) were used to weigh the survival figures for the different sized abalone used in the size experiments.

Urchin Exclusion Experiment

To test the short-term effects of the presence of sea urchins on juvenile abalone the following experiment was carried out. Eight experimental sites were selected in typical west coast kelp beds in which there was an abundance of loose boulders, with a biota including local species of crustose corraline algae and sea urchins. The sites were chosen to resemble each other as closely as possible, both in terms of physical appearance and in depth (2–4 m). In a 3-m radius around each trap, an estimate was made of the relative percentage cover of different size boulders and the amount of exposed area between boulders. Percentage cover by encrusting corraline algae was estimated for the experimental area. From four of these sites, all the sea urchins, in a radius of three meters from the trap, were removed. At the other four sites, all those urchins collected from the first four sites were placed directly surrounding the traps. The average density of urchins around each of these traps was 7.20 m^2 (SD ± 2.02). Each trap contained 300 animals with an average size of 12.24 mm (SD ± 1.62 mm) The traps were monitored every few days to make sure that those from which the urchins had been removed remained clear of urchins. The sites were sampled in two groups, after 17 days and 23 days respectively, with each group having two sites with urchins and two sites without urchins (Table 1). On sampling, the number of urchins in a 3 m radius around each trap was counted and the percentage utilization of urchins and boulders by abalone juveniles was calculated for each site, together with abalone survival.

The Effect of Abalone Size at Seeding

The same procedure as above was followed, except that no urchins were removed from any area. Along with percentage cover by encrusting corraline algae (estimated per square meter for the experimental area), urchin densities were calculated around each site. Eight experimental sites were again selected to resemble each other as closely as possible. 200 animals were placed in each trap, 100 larger ones, with an average size of 26.61 mm (SD ± 1.33 mm), and 100 smaller ones, with an average size of 13.87 mm (SD ± 1.73 mm). Placing both the large and small animals together in the traps meant that all the animals were exposed to exactly the same conditions on release. The traps were sampled in two groups of four, the first group after one month, and the second group after two months (Table 2).

Quantifying the Physical Attributes of the Seeding Sites

In an attempt to quantify the physical attributes of each site, a very basic approach was taken. All the experiments mentioned above were treated in the following way. In a 3-m radius around the trap the percentage cover of the surface was estimated according to the following categories:

1. boulders with a diameter of greater than 50 cm.
2. boulders with a diameter of between 30 and 50 cm.
3. boulders with a diameter of less than 30 cm.
4. exposed area, i.e. flat rocky or sandy area that provides little or no protection for juvenile abalone in terms of cracks or crevices that can be used as a microhabitat.

TABLE 2.

Seeding size and juvenile abalone survival.

Site	Period (days)	Size (mm)	Std. Dev (mm)	Survival %	Size (mm)	Std. Dev (mm)	Survival %
1	30	28.07	3.56	62	12.25	1.63	26
2	30	24.64	3.2	55	12.25	1.63	29
3	30	24.64	3.2	68	12.25	1.63	33
4	30	25.53	2.9	54	12.25	1.63	5
5	60	27.5	3.47	66	15.49	2.14	36
6	60	27.5	3.47	59	15.49	2.14	23
7	60	27.5	3.47	50	15.49	2.14	19
8	60	27.5	3.47	33	15.49	2.14	24

One problem with the categories listed above is that boulders are obviously not completely round and while the estimate is carried out on two-dimensional basis, the site is three-dimensional. In an attempt to compensate for this potential problem, the same person did all the estimates and, as a result, there is a degree of consistency throughout the series of experiments. Survival was correlated with the different classifications of site description at the end of each experiment, along with percentage cover of crustose corraline algae species, urchin density, percentage utilization of urchins by abalone per site, abalone seeding size and the ratio between percentage boulder cover to percentage exposed area.

RESULTS

Urchin Exclusion Experiment

At all the sites, sampling was performed around the traps until no more animals were found. During destructive sampling, all boulders were picked up, all the urchins were removed and all crevices and cracks were inspected. The majority of the animals were found within a radius of 2 m of the trap and very rarely were any animals found further than 3 m from the trap. Survival rates give an indication of minimum survival, because some of the surviving animals may not have been found. Destructive sampling can, however, be regarded as effective enough to compare experimental results between sites.

The first four traps were placed on a day in which sea conditions were becoming progressively worse, and the last four traps were seeded during a sustained period of calm sea conditions. This is reflected in the survival rates, with the second batch of animals all surviving in much greater numbers than the first batch. The first four sites were sampled after 17 days and the second four after 23 days. Using the Mann-Whitney U Test, no significant difference was found in the survival of abalone between those sites from which all the urchins had been removed and those sites from which they were still present, $p = 0.67$ (Fig. 1).

The Effect of Abalone Size at Seeding

The first group of four sites was sampled after one month and the second group after two months. Again destructive sampling was used (Table 2). Using the Mann-Whitney U Test, it was found that there was a significant difference in survival between animals that were below 18 mm in length and those that were greater than 24 mm in length ($p = 0.00136$, Fig. 2). This difference in survival

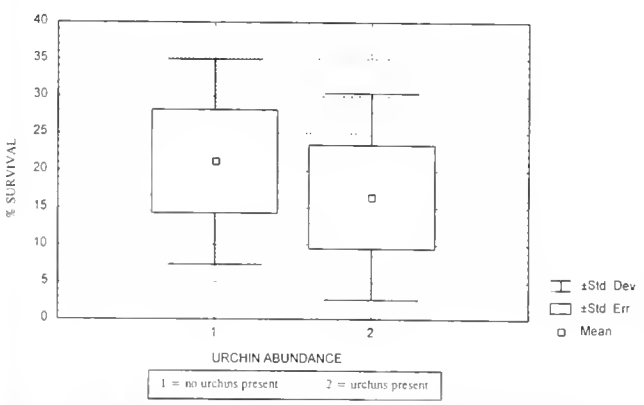

Figure 1. Results from a Mann-Whitney U Test, showing that there is no significant difference in abalone survival between sites with and without urchins.

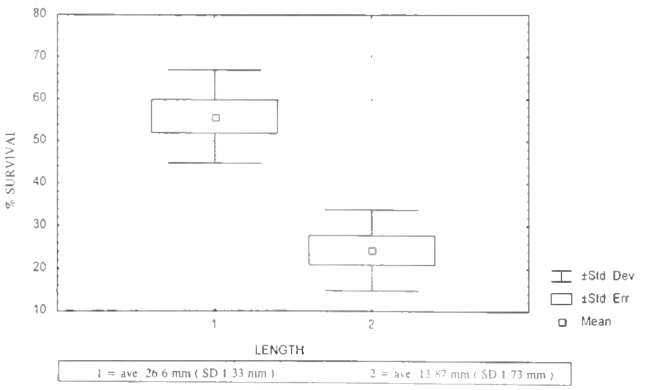

Figure 2. Results from a Mann-Whitney U Test, showing that seeding size makes a significant difference in the survival of juvenile abalone.

was calculated within the context of the similar seeding site characteristics for the different sized animals used in each experiment. While there was a very strong positive correlation between size of seeded abalone and an increase in short-term survival (significant at a 99% confidence level), there was no significant difference between survival after one month and survival after two months, for either size class.

Seeding Site Attribute Classification

Within the context that the substrate is a three dimensional environment, made up of layered boulders and open spaces, the strongest positive correlation (significant at a 95% confidence level) between survival and boulder size is that between survival and boulders with a diameter of smaller than 30 cm. A negative correlation exists between survival and exposed area.

DISCUSSION

The fact that the abalone used in the urchin exclusion experiment were shown to gain no significant benefit in terms of survival, from the presence of urchins, was in direct contrast to expectations (Day 1998, Tarr et al. 1996, Kojima 1981, Scott et al. in prep, Rogers-Bennet & Pearse 1998). These are, however, short term results (Fig. 1). While the advantage, in terms of access to drift kelp, is abundantly clear when observing the masses of drift kelp trapped by urchins, the advantage of the shelter provided by urchins becomes negligible, indicated both by the numbers of unutilized urchins and the extent to which the abalone are hidden in the cracks and crevices provided by rock piles and boulders. Survival rates of juvenile abalone may have been influenced by the fact that abalone not living under urchins would have had to seek other sources of nutrition, thus exposing themselves to predation. Abalone living in close association with urchins have been shown to expose themselves less than animals living in cracks and crevices (Day 1998). Table 3 shows the marginally significant positive correlation between survival and the presence of urchins. The experiments mentioned above, suggest that the juvenile abalone were not relying on urchins for survival. These results are not contradictory to those from the urchin exclusion experiment. This is also reinforced by the insignificant correlation between the percentage of successful abalone that did utilize urchins as refuge. The correlation between the presence of urchins and abalone survival could be interpreted as indicating an area in which there was good habitat for both urchins and abalone (Day 1998). In other words, what is a good habitat for urchins may also be a good habitat for

abalone. If this is so, the relationship between abalone and urchins may be coincidental.

One of the common features found among the sites discussed above was that the abalone were found clumped in very close proximity to the traps, by far the majority being within a radius of two meters, with as many as 30 or more found under single boulders (Saito 1984, Tegner & Butler 1985). There was very little evidence that the juveniles had moved out of the experimental areas. This is in contrast to results on juveniles of the species *Haliotis rufescens*, which seemed to move very quickly (Rogers-Bennet & Pearse 1998). Observations at seeding sites, specifically chosen to be unsuitable at the preliminary stage of experimentation, did show some abalone staying in the trap for up to 4 mo. In those cases, however, it was obvious that the trap provided the only suitable local shelter. Movement from the trap would obviously expose the juveniles to predation. Not finding the abalone in subsequent sampling would not clarify the question of whether they had moved or whether they had been eaten by predators (Tegner & Butler 1985). The choice of seeding site obviously influences behavior extensively, determining whether an abalone will move and how far it will move (Saito 1984). From the results of the current experiments, it was clear that, if the habitat was suitable, movement was very restricted. Results also showed that the smaller the abalone, the higher the mortality rates resulting from moving into an exposed area. The link between long-term survival of artificially reared juvenile abalone and urchins still needs to be quantified. Whether a habitat of layered boulders could replace any long-term benefit that abalone might derive from the presence of urchins, still needs to be established. This will influence the selection of commercial seeding sites.

In defining the attributes of a successful seeding site, the complexity of a three dimensional habitat made up of layered rocks, and the potential refuge that these may provide, must be kept in mind. The smaller the rocks, the higher the surface area and the more cracks and crevices available per unit area. This may explain the positive correlation between survival and boulders with a diameter less than 30cm, compared to the bigger boulders. While not statistically significant, there did appear to be some type of negative correlation between survival and exposed space. This is to be expected because, in these areas, no shelter was provided for the juvenile abalone. The ratio of area under boulders to area exposed (Table 3), showed a positive correlation with survival (Schiel 1992, Schiel 1993, Shepherd 1998). While this has not proven to be significant, the relationship between sheltered and exposed area was a good, simple measure of habitat suitability. Although the relationship between the amount of crustose corraline algae and survival is shown as not significant in these experiments, naturally occurring juvenile abalone and urchins are found predominantly on encrusting corralines. The movement of sand and general substratum as a result of strong currents is a major and obvious cause of mortality in natural and seeded abalone (Tegner 1992, Tegner 2000). The presence of corraline algae could be an indicator of reef or rock surfaces that are relatively clean of sand, providing abalone with secure footing and space to move, as well as a source of nutrition.

Observations in Mc Dougalls Bay showed the ease with which smaller animals were washed into the water column when boulders were disturbed. Many of the juvenile abalone released themselves without being touched by divers. Many of the sites showed up to 60% losses within one week. Initial mortalities were very high and probably accounted, to a large extent, for much of total mortality. It seems that mortalities in smaller seeded animals may be caused by a lack in the ability to handle strong water currents and disturbances. Farm-reared animals are not exposed to the same extremes of water movement as natural abalone, and animals may need time to adjust to these conditions. It is not clear whether this is a behavioral process or whether it is a muscular strengthening process. Based on this, the size-test experiments were designed (Fig. 2, Table 2). The larger animals used in the experiments showed a completely different response when being sampled. They were much more resilient to being disturbed and, in some cases, removing them caused shell damaged because they were lodged so securely. Increasing seeding size, and thus both the muscle and shell strength of the juveniles, may take pressure off the behavior adaptation phase that the juvenile has to go through after seeding, (Olla et al. 1998, Munro & Bell 1997, Tarr et al. 1996). While there are some differences between the effects of size on survival of seeded *Haliotis rufescens* and *H. fulgens* from the USA (Tegner 2000), the current results on *H. midae*, are similar to those of both Japanese and Australian researchers. While Japanese research has suggested seeding a minimum size of 30 mm, combined with the correct choice of refuge or seeding site for *Haliotis discus* (Masuda & Tsukamoto 1998, Munro & Bell 1997), Australian research has shown that both size and the abundance of predators play an important role in the survival of seeded *Haliotis sp.* (Shepherd 1998). There was also an indication of size playing a role in the experiments of Sweijd et al. (1998). Two different size batches of animals were placed in the same site at two different times. The larger 14-mm animals showed a 39.2% survival compared to a 27.8% survival figure for 8-mm animals, over a six-month period. While the traps were deployed at two different times, resulting in two entirely different sets of environmental conditions acting on the animals, some site attributes would have been the same.

The relationship between seeding size and survival is not a simple one. The effects of size on survival have many facets. Not only does shell thickness increase, but so also does muscle strength. The ability to assimilate survival techniques and experience may also be affected. Seeding is a traumatic event, with high initial mortality. In the case of *H. midae*, it may be possible to address this through correct site selection and seeding size selection. The transition from short-term survival to long-term survival, growth, movement and the environmental factors influencing this need to be investigated. These experiments suggest that differences

exist in the behavior of natural and seeded populations of juvenile abalone. Understanding these differences may lead to a better understanding of the factors that affect survival of seeded juvenile abalone.

USE OF A SPREADSHEET MODEL TO INVESTIGATE THE DYNAMICS AND THE ECONOMICS OF A SEEDED ABALONE POPULATION

S. DE WAAL* AND P. A. COOK

Zoology Department, University of Cape Town, Private Bag, Rondebosch 7701, Cape Town, South Africa

ABSTRACT Using a simple spreadsheet model it was possible to investigate both the dynamics of a seeded abalone population and the economic implications of seeding such a population. The two variables used to drive the population model were the initial survival after seeding-induced mortality, and age-specific differential mortality. In the model, initial survival or initial population size was the variable that played the dominant role in determining the potential yield of any seeded population. In reality, seeding size plays a significant role in initial survival. Within the same experimental context, 14-mm animals showed a minimum survival of 24% while 26-mm animals showed a minimum of 56%, an exponential increase in potential yield. To address the issue of potential yield on a commercial scale, differential mortality amongst seeded populations of abalone needs to be researched. A cost-benefit analysis has shown that high production costs will only allow ranching to be economically viable in areas where the potential differential mortality regime is very favorable, where survival per age class increases as the population ages.

KEY WORDS: *Haliotis midae*, cost-benefit analysis, commercial seeding, abalone

INTRODUCTION

The possibility of introducing the abalone species *Haliotis midae* to the Northwest coast of South Africa has resulted in the development of an experimental commercial seeding program along a 60 km stretch of coast between Kleinzee and Koingnaas, 120 km south of the Orange River. There are no existing stocks of abalone in this area, though there are fossil records of an extinct abalone species *H. saldanhae*, dating back to more than 1 million years ago (Sweijd et al. 1998). The success of such a commercial venture will be based on a number of criteria, including the following:

1. a very specific understanding of the ecology of the species, especially of the juvenile stage of its lifecycle,
2. the quantification of the mortality of the seeded populations,
3. the long-term economic viability of such a venture.

To do a cost-benefit analysis of the potential project, based on realistic experimental data, (Heppel & Crowder 1998, Hilborn 1998, Schiel 1993), a simple spreadsheet model was used as a means to consolidate biological data collected from seeding experiments. The model was developed after reference to current literature, expert opinion from abalone research scientists and data collected from the present experimental seeding program. As abalone age, the probability of survival to the next age class changes; this is age-specific differential mortality or survival. Experimental data has shown that seeding induced mortality, be it due to handling stress or behavioral adaptation problems, is size related (de Waal & Cook 2001, Schiel 1993, Shepherd et al. 2000). One of the underlying themes of the model was that a trade-off existed between initial mortality and survival of seeded juveniles and the cost of producing juvenile abalone of different size classes. One of the goals in developing the model was to attempt to quantify this relationship. While differential mortality figures do exist for some species (Masuda & Tsukamoto 1998), differential mortality figures do not exist for *Haliotis midae*.

Although these figures are not known, commercial ventures are taking place in South Africa. Being able to explore the ecological limitations in terms of population survival may assist the decision making process and minimize unnecessary risk.
